Wiley Eastern University Edition

MINING ENGINEERS' HANDBOOK

WILEY ENGINEERING HANDBOOK SERIES

HANDBOOK OF ENGINEERING MATERIALS. Edited by DOUGLAS F. MINER and JOHN B. SEASTONE.

HANDBOOK OF ENGINEERING FUNDAMENTALS. Second Edition. Edited by OVID W. ESHBACH

KENT'S MECHANICAL ENGINEERS' HANDBOOK. Twelfth Edition.

- DESIGN AND PRODUCTION. Edited by COLIN CARMICHAEL.
- POWER. Edited by J. K. SALISBURY.

ELECTRICAL ENGINEERS' HANDBOOK. Fourth Edition.

- ELECTRIC POWER. Edited by HAROLD PENDER and WILLIAM A. DEL MAR.
- ELECTRIC COMMUNICATION AND ELECTRONICS. Edited by HAROLD PENDER and KNOX MCILWAIN.

MINING ENGINEERS' HANDBOOK. Third Edition. Edited by the late ROBERT PEELE.

HANDBOOK OF MINERAL DRESSING.

- ORES AND INDUSTRIAL MINERALS. Edited by ARTHUR F. TAGGART.

MINING ENGINEERS HANDBOOK

WRITTEN BY A STAFF OF FORTY-SIX SPECIALISTS
UNDER THE EDITORSHIP OF

ROBERT PEELE
LATE PROFESSOR EMERITUS OF MINING ENGINEERING IN
THE SCHOOL OF MINES, COLUMBIA UNIVERSITY

WITH THE COLLABORATION OF

JOHN A. CHURCH
MINING AND METALLURGICAL ENGINEER

THIRD EDITION
TENTH PRINTING

IN TWO VOLUMES
VOL. I

AMERICAN UNIVERSITY CENTER
U S I S - Calcutta

WILEY EASTERN PRIVATE LIMITED
NEW DELHI

PRESENTED BY USIS

Third Edition 1941
Eleventh Printing, February 1960

This book is not to be sold outside
the country to which it is consigned
by Wiley Eastern Private Limited
Sales Area India, Pakistan, Ceylon and Burma

This book has been published with the assistance of the Joint
Indian—American Standard Works Programme

Price Rs 11 00 per volume

Published by Anand R Kundaji for Wiley Eastern Private Limited,
J 31, South Extension 1, New Delhi 3 and Printed by Sudhir Balsaver
at Usha Printers, 6 Tulloch Road, Bombay 1 Printed in India

PUBLISHER'S PREFACE

In making plans for new editions of our handbooks in mechanical engineering and in electrical engineering, it soon became clear that engineering science and practice had developed to such an extent that handbooks were growing beyond all practical bounds. They had become both bulky and inconvenient and contained much duplicated material. In order to solve the problems presented by these conditions, the editors of our various handbooks were asked to serve as an advisory editorial board.

This board recommended, first, that the fundamental material underlying all engineering be published in a separate volume, and, second, that the existing handbooks as they are revised be issued in several volumes containing material closely related to the specialized branches of engineering. As a result of these recommendations, the Wiley Engineering Handbook Series has been initiated, which in the beginning will comprise the following: Eshbach's "Handbook of Engineering Fundamentals"; Kent's "Mechanical Engineers' Handbook" in two volumes, viz., "Power" and "Design and Shop Practice"; Pender's "Electrical Engineers' Handbook" in two volumes, viz., "Electric Power" and "Communication and Electronics"; Peele's "Mining Engineers' Handbook."

This division has also made it possible to devote more space to the various topics so that the entire new series of handbooks contains more complete information on all topics than heretofore has been possible. It is our hope that this new plan will give engineers information that is more useful, more complete, and in more convenient form.

JOHN WILEY & SONS, INC.

PREFACE TO THIRD EDITION

The first edition of this book was published early in 1918. In preparing the second edition, issued in 1927, many changes in subject matter were found necessary, as set forth in the preface to that edition, and references to them need not be repeated here. Most of these alterations were called for by the progressive modifications of mining methods and appliances, and the development of new methods. Much new matter was added, some of the older text omitted, and some sections of the book were almost entirely rewritten.

Rewriting the present edition made necessary the radical revision of text and illustrations of Sections 3, 4, 5, 8, 10, 10A, 12, 14, 15, 16, 22, 24, 26, 27, 32, 33, 35 and 40, together with minor changes in many other parts of the book.

Especial attention is called to the following: (*a*) important new matter throughout Section 10, on further changes in practice in "Methods of Mining," by James F. McClelland, Vice President of Phelps Dodge Corp; (*b*) new articles 24 to 28 of renumbered Section 45; (*c*) a valuable new Section 44, on "Petroleum Production," by S. F. Shaw, has been added; (*d*) the marked advance of "Geophysical Prospecting" during the past decade has made advisable the addition of an entirely new Section 10A, on that subject, by Frederick W. Lee, of the U. S. Geological Survey. This Section replaces, in greatly expanded form, the data formerly contained in Articles 3 and 4 of Section 10; (*e*) Section 14, on "Mine Ventilation," has been almost wholly rewritten by George E. McElroy, of the U. S. Bureau of Mines; (*f*) radical revisions have also been made in Section 12, "Hoisting Plant, Shaft Pockets and Ore Bins," by Professor Philip B. Bucky, of the Columbia School of Mines, and of Section 15, "Compressed Air Practice," by A. W. Loomis, of the Ingersoll-Rand Co; (*g*) the wide development of methods and devices for underground handling and conveying of mineral has led to the transfer of most of the data, formerly in Article 92 of Section 10, to Section 27, the first part of which has been rewritten and expanded by Walter M. Dake, Research Manager of the McGraw-Hill Publishing Co.

The preparation of this edition has further required resetting the entire book. A larger format was necessary, since the two volumes of the Third Edition are Nos VI and VII of the new Wiley Engineering Handbook Series. This change, together with the extensive revisions of text already referred to, has consumed much more time and labor than were required for the second edition.

To the list of deaths of the original Associate Editors, noted in the preface to the second edition, the following names must now be added: Edwin S. Jarrett (Sec. 8), F. Ernest Brackett (Sec. 14), Richard T. Dana (Sec. 15) T. R. Woodbridge (Sec. 29), E. J. Hall (Sec. 30), and Charles H. Burnside (Sec. 36).

For various reasons, a number of associate editors of the second edition were unable to serve again. Their places have been taken by: Clinton L. Bogert (Sec. 3), Samuel R. Russell (Sec. 5), Charles F. Jackson (Sec. 6), Ralph H. Chambers (Sec. 8), Philip B. Bucky (Sec. 12), George E. McElroy (Sec. 14), A. W. Loomis (Sec. 15), Walter M. Dake (Sec. 27), J. B. Morrow and staff (part I of Sec. 35), and Theodore Baumeister, Jr. (Sec. 40). For further information as to these accessions to the list of Associate Editors, see the Table of Contents.

It is a pleasure to acknowledge the efficient collaboration of my friend John A. Church, in connection with this new edition. Besides being the Associate Editor of Section 7, on "Shaft Sinking in Rock," he has done a large amount of work in revising manuscripts, as received from the contributors to the book, and in the preparation of illustrations for the engraver.

ROBERT PEELE

NEW YORK,
March, 1941

PREFACE TO FIRST EDITION

There is a considerable literature of mining, comprising treatises, textbooks, monographs, papers published in the transactions of engineering societies, and the contents of the mining periodicals. The treatises and textbooks are largely descriptive, and are intended chiefly for students. Among the best known are those of Foster, Hughes, Haton de la Goupillière, Köhler, Cambessédès, Callon, Ponson, Bulman and Redmayne, Bailes, Boulton, and Pamely. Though many of these books are antiquated in their engineering features, some of the older ones (as those of Callon and Haton) contain much that is still of value, and mining engineers would do well to have acquaintance with them. Besides the general treatises there are the more recent monographs of Truscot, Hatch and Chalmers, and Denny, on the Witwatersrand goldfields, Charleton's "Tin Mines of the World," Hoover's "Principles of Mining," Finlay's "Cost of Mining," and a number of useful books on specific subjects relating to mining, or to the mechanical engineering of mines.

A valid reason for bringing out a new Mining Engineers' Handbook may be found in the fact that the two already in existence either omit, or treat too briefly, many subjects which constitute important parts of the professional equipment of the present day mining engineer. It will be apparent, even on a cursory examination of the following pages, that a handbook of mining must include a greater variety of subject matter than books on other branches of engineering, and that the field to be covered is too wide to be dealt with satisfactorily by a single writer within any reasonable period of time.

In February and March, 1913, the Editor of this book outlined the table of contents, and invited a number of Associate Editors to contribute sections on their respective specialties. Besides those sections dealing with mineralogy, ore deposits, methods of prospecting, exploration and mining, and mining plant of all kinds, there are others on certain branches of civil, electrical and mechanical engineering. It may be thought by some that this collateral material occupies too much space in a book on mining. But, in view of the important part played by the allied branches of engineering in equipping and operating modern mines, the Editor believes the allotment of space is reasonable. He has endeavored to meet the demands not only of engineers concerned with the development and management of mines, but also of the large number of those who have more to do with, and greater interest in, the construction details involved in the installation of plant. Therefore, the aim has been to supply such data on machinery, power plant, electric transmission and structural design, as the mining engineer may need when in the field and out of reach of his personal notes and technical library. For office use, there is at the end of each section a bibliography of the more important books and papers on the subjects dealt with.

In practice, no well-defined boundary exists between the fields of work of the mining engineer and the metallurgist. While, under some conditions and in some regions, the mining engineer's functions end with the winning of the ore and its delivery to a custom reduction works (mill or smelter), in other cases the mining company's plant includes a concentrating mill, amalgamating or cyaniding works (as at many gold and silver mines), or even a smelting establishment. In planning the book, the question arose as to how much space should properly be given to the processes of ore treatment. To cover any considerable part of the great field of modern metallurgy would be impracticable, without extending the work beyond the limits of a single volume. Realizing that the urgent need of a companion Handbook of Metallurgy must soon be supplied, it was decided, as a compromise, to furnish condensed summaries of those processes of treatment which are frequently carried on by mining companies themselves. The book, therefore, contains sections on ore-dressing, ore-testing, gold amalgamation, an outline of the cyanide process, the preparation of anthracite, bituminous coal and coke, and a brief résumé of certain facts respecting the selling, purchasing, and metallurgical treatment of ores, that are of immediate interest to the engineer in control of mining operations.

The relatively small space allotted to coal mining is due chiefly to three considerations: first, a Coal-mining Pocketbook is already in existence; second, metal-mining methods are more varied than those for coal, due to the greater diversity in form and occurrence of metalliferous deposits; third, having discussed in Section 10, under Metal-mining Methods, the operations common to nearly all mining, the articles on coal mining are properly confined to the methods and data peculiar to that branch of the industry.

The question of supplying cost data is difficult. A large number of itemized tables are included in the sections on Cost of Mining, Exploitation of Mineral Deposits, Boring, and other subjects, but costs of machines and apparatus are given sparingly throughout the book. This has been judged best, because of frequent price changes, and the great diversity of types of mechanical plant. In any case, to make close estimates, the engineer must apply to the makers for current prices. In some parts of the book, the names of machinery builders have been used freely, but without intention to indicate a preference for the product of any particular maker.

While the Editor has aimed to make the style and arrangement uniform, he has had good reason to realize the difficulty of securing consistency in these matters, considering the heterogeneous nature of the subject matter, and the fact that it has been written or compiled by so large a corps of Associate Editors. In these circumstances, unity and evenness of treatment can hardly be expected, but an endeavor has been made to observe a reasonable proportion between the length of each section and its relative importance. To save space, abbreviations are employed for a few words in common use by engineers, and chemical elements and compounds are generally represented by their symbols.

The thanks of the Editor are due to members of the staff for their painstaking work, in many cases carried on in the intervals between pressing professional engagements in the field, and to the Publishers for their liberal spirit of coöperation in facilitating the preparation of the book. The Editor desires to express his especial appreciation of the valuable suggestions and assistance in revising manuscript and correcting proof, of Professor Edward K. Judd, of the Columbia School of Mines. It was planned to publish this book in 1916. The breaking out of the Great War, about one year after the work was begun, is responsible in large measure for the delay.

ROBERT PEELE

COLUMBIA SCHOOL OF MINES,
NEW YORK, *December*, 1917

LIST OF CONTRIBUTORS

Arthur P. Ackerman.—*Rock Excavation.*

Theodore Baumeister, Jr, Associate Professor of Mechanical Engineering, Columbia University; Consulting Engineer.—*Power and Power Machinery.*

Clinton L. Bogert, Consulting Engineer.—*Earth Excavation.*

Charles B. Breed, Professor of Railway and Highway Engineering, Massachusetts Institute of Technology.—*Surveying.*

Philip B. Bucky, E.M., Associate Professor of Mining, School of Mines, Columbia University.—*Hoisting Plant, Shaft Pockets, and Ore Bins.*

C. H. Burnside, Late Associate Professor of Mechanics, Columbia University.—*Engineers' Tables* and *Mathematics and Mechanics.*

F. Ernest Brackett, Late Mining Engineer.—*Mine Ventilation.*

Ralph H. Chambers, D.Eng., Consulting Civil Engineer.—*Shaft Sinking in Unstable and Waterbearing Ground.*

Homer L. Carr, Mining Engineer.—*Shaft Sinking in Rock.*

John A. Church, Jr., Mining Engineer.—*Shaft Sinking in Rock.*

Walter M. Dake, Research Manager, Mining Publications, McGraw-Hill Publishing Company.—*Underground Mechanical Loading, Conveying. and Handling.*

Richard T. Dana, C.E., Late Consulting Engineer.—*Compressed Air Practice, Earth Excavation* and *Rock Excavation.*

D. H. Davis, Chief Chemist, Pittsburgh Coal Co.—*Preparation and Coking of Bituminous Coal.*

John V. N. Dorr, Metallurgical Engineer, New York City.—*Gold Amalgamation and Cyanidation.*

Archibald Douglas of Douglas & Armitage, Counsellors at Law, New York City.—*Mining Laws.*

Edward L. Dufourcq, Late Consulting Engineer.—*Gold Amalgamation and Cyanidation.*

Edward B. Durham, Mining Engineer.—*Aerial Tramways and Cableways.*

Howard N. Eavenson, Mining Engineer.—*Coke.*

J. K. Finch, Renwick Professor of Civil Engineering, Columbia University.—*Elements of Hydraulics* and *Elements of Structural Design.*

J. R. Finlay, Consulting Mining Engineer.—*Cost of Mining* and *Mine Organization and Accounts.*

Halbert P. Gillette, C.E.—*Earth Excavation* and *Rock Excavation.*

E. J. Hall, Late Professor of Assaying, School of Mines, Columbia University.—*Assaying.*

V. D. Hanson, Preparation Engineer, Pittsburgh Coal Co.—*Preparation and Coking of Bituminous Coal.*

H. G. Haskell, E.M.—*Explosives.*

Robert E. Hobart, Mechanical Superintendent, Lehigh Navigation Coal Co.—*Drainage of Mines.*

Edwin C. Holden, Consulting Mining Engineer.—*Underground Transport.*

Fletcher B. Holmes, A.B.—*Explosives.*

Charles F. Jackson, Mining Engineer.—*Tunneling.*

Edwin S. Jarrett, C.E. (The Late).—*Shaft Sinking in Unstable and Waterbearing Ground.*

Edward K. Judd, E.M., Formerly Assistant Professor of Mining, School of Mines, Columbia University.—*Chemical and Physical Notes and Tables; Prospecting, Develop-*

ment and Exploitation of Mineral Deposits; Underground Surveying; and *Wages and Welfare.*

James Furman Kemp, Late Professor of Geology, Columbia University.—*Geology and Mineral Deposits.*

Edward F. Kern, Formerly Professor of Metallurgy, School of Mines, Columbia University.—*Assaying.*

Paul F. Kerr, Professor of Mineralogy, Columbia University.—*Geology and Mineral Deposits* and *Mineralogy.*

Arthur LaMotte, Ph.G., B.Sc.—*Explosives.*

Frederick W. Lee, Chief, Section of Geophysics, U S Geological Survey.—*Geophysical Prospecting,*

F. J. LeMaistre, Ph.G., B.Sc.—*Explosives.*

Robert S. Lewis, Professor of Mining, University of Utah.—*Boring.*

A. W. Loomis, Mechanical Engineer, Ingersoll-Rand Co.—*Compressed Air Practice.*

W. W. Lynch, E.M.—*Prospecting, Development, and Exploitation of Mineral Deposits.*

James F. McClelland, E.M., Vice President, Phelps Dodge Corporation.—*Prospecting, Development, and Exploitation of Mineral Deposits* and *Engineers' Tables.*

George E. McElroy, Senior Mining Engineer, U S Bureau of Mines.—*Mine Ventilation.*

Charles M. Means, Consulting Engineer, Pittsburgh.—*Electric Power for Mine Service.*

Alfred J. Moses, Late Professor of Mineralogy, Columbia University.—*Mineralogy.*

Arthur Notman, Consulting Engineer.—*Cost of Mining* and *Mine Organization and Accounts.*

Robert Van Arsdale Norris, Late Consulting Mining Engineer.—*Drainage of Mines.*

S. M. Parmley, Preparation Engineer, Pittsburgh Coal Co.—*Preparation and Coking of Bituminous Coal.*

H. L. Parr, Professor of Mechanical Engineering, Columbia University.—*Mechanical Engineering Miscellany.*

Robert Peele, Professor Emeritus of Mining Engineering, School of Mines, Columbia University.—*Chemical and Physical Notes and Tables* and *Engineers' Tables.*

George S. Rice, Formerly Chief Mining Engineer, U S Bureau of Mines.—*Mine Air, Gases, Dusts, Hygiene, Explosions, and Accidents.*

Samuel R. Russell, Explosives Dept, E. I. DuPont de Nemours & Co.—*Rock Excavation.*

Reno H. Sales, Geologist to the Anaconda Copper Mining Co, Butte, Mont.—*Mine Geologic Maps and Models.*

Walter I. Slichter, Professor of Electrical Engineering, Columbia University.—*Electrical Engineering.*

S. F. Shaw, E.M., Consulting Engineer, Westgate Oil Co, Anglo-Canadian Oil Co, Ltd, etc.—*Petroleum Production Methods.*

Paul Sterling, Mechanical Engineer, Lehigh Valley Coal Co.—*Preparation and Storage of Anthracite Coal.*

Arthur F. Taggart, Professor of Mineral Dressing, School of Mines, Columbia University.—*Boring; Breaking, Crushing, and Sorting of Ores;* and *Testing of Ores.*

Edward D. Thurston, Jr, Formerly Associate Professor of Mechanical Engineering, Columbia University.—*Engineering Thermodynamics.*

Arthur L. Walker, Formerly Professor of Metallurgy, School of Mines, Columbia University.—*Selling, Purchasing, and Treatment of Ores.*

William M. Weigel, E.M.—*Hoisting Plant, Shaft Pockets, and Ore Bins.*

William Young Westervelt, Consulting Mining Engineer.—*Mine Examinations, Valuations, and Reports.*

Horace V. Winchell, Late of the California Bar.—*Mining Laws.*

George R. Wood, Electrical Engineer.—*Electric Power for Mine Service.*

T. R. Woodbridge, Late Consulting Metallurgical Chemist, U S Bureau of Mines.—*Ore Sampling.*

TABLE OF CONTENTS FOR VOLUME I

Detailed tables of contents are given at the beginning of each section. An alphabetical index appears following Section 14.

SECTION 1. MINERALOGY

PAGE
Identification of Minerals........... 02– 10
Occurrence and Association of Minerals........... 10– 11
Uses and Products of Minerals........ 12– 14
Descriptive and Determinative Tables. 16– 52

SECTION 2. GEOLOGY AND MINERAL DEPOSITS

Geology: Rocks, Composition and Occurrence........... 02– 17
Mineral Deposits, Metalliferous...... 18– 27
Mineral Deposits, Non-metallic...... 28– 32

SECTION 3. EARTH EXCAVATION

Economics, Physics, Mechanics...... 02– 04
Excavating Equipment and Methods. 05– 17
Embankments and Dams........... 18

SECTION 4. EXPLOSIVES

Chemistry and Composition......... 02– 09
Transport, Storage, Handling........ 10– 18
Charging and Firing; Blasting Supplies........... 19– 31

SECTION 5. ROCK EXCAVATION

Rock Characteristics............... 02– 03
Drill Bits; Hand and Machine Drilling. 03– 11
Blasting; Charging and Firing....... 11– 21
Loading by Hand and Machine...... 21– 23
Quarrying; Open-cutting; Trenching.. 23– 28

SECTION 6. TUNNELING

Examples and Organization......... 02– 06
Plant and Equipment.............. 06– 08
Drilling, Blasting, Mucking, Tramming........... 08– 20
Ventilating, Timbering; Work in Loose Ground........... 20– 26
Costs........... 26– 28

SECTION 7. SHAFT SINKING IN ROCK

Shape and Size of Shafts............ 02– 03
Plant and Organization............. 03– 06
Drilling, Blasting, Mucking, Ventilating........... 06– 11
Working Shafts; Raising of Shafts.... 11– 12
Wall Support: Timber, Steel, Concrete, Etc........... 12– 22
Kind–Chaudron Method............ 22– 23
Speed and Costs.................. 23– 32

SECTION 8. SHAFT SINKING IN UNSTABLE AND WATERBEARING GROUND

Expedients; Piling................. 02– 06
Drop-shafts; Pneumatic; Honigmann. 06– 20
Freezing; Cementation and Grouting. 20– 24

SECTION 9. BORING

PAGE
Shallow Work: Augers, Spring-pole, Empire Drill, Etc........... 02– 09
Oil-well Drilling, Casing, Sampling; Directional Drilling; Costs........ 09– 40
Churn Drilling for Prospecting; for Blasting........... 41– 44
Diamond-drilling Equipment, Methods, Costs........... 44– 61
Shot or Calyx Drilling............. 61– 63
Surveying of Boreholes; Choice of Boring Method................ 63– 69

SECTION 10. PROSPECTING, DEVELOPMENT, AND EXPLOITATION OF MINERAL DEPOSITS

Definitions; Surface Prospecting..... 02– 33
Exploration by Boring; Sampling and Estimating........... 34– 75
Exploration by Shafts, Tunnels, Etc; Equipment........... 76– 80
Development: Entry, Drifts and Crosscuts, Raises, Winzes.............. 81–123
Exploitation: Classification of Methods; Breaking Ground........... 123–132
Open Stopes: Gophering, Breasting, Room-and-pillar, Under- and Overhand, Sub-level Methods.......... 132–197
Square-set Stoping; Mitchell and other Systems; Timber Preservation 197–236
Filled Stopes, Horizontal, Inclined; Resuing; Crosscut Method........ 237–274
Shrinkage Stopes.................. 274–297
Caving Methods: Top-slicing; Sub-level Caving; Block-caving........ 297–371
Combined Methods: Boston Con, Ray, Miami, DeBeers, Etc........ 371–398
Mining through Boreholes; Leaching Ore in Place; Chutes and Gates; Mechanical Handling; Sand Filling; Choice of Mining Method......... 398–430
Open-cut Mining, Hand- and Machine loading; Glory-holing; Coal Stripping........... 430–472
Coal Mining: Room-and-pillar; Robbing Pillars; Longwall............ 472–519
Ground Movement and Subsidence... 519–533
Placer and Hydraulic Mining; Sluices and Riffles; Elevators; Dredges and Dredging; Drift Mining; Thawing.. 533–619
Mining Alluvial Tin in Malaya...... 619–629

SECTION 10-A. GEOPHYSICAL PROSPECTING

Gravimetric, Magnetic, and Electrical Methods........... 02– 21
Seismic Prospecting............... 21– 26
Temperature, Radioactivity, and Micro-gas Surveys; Choice of Method........... 26– 29

PAGE
Physical Properties of Rocks and Minerals 30– 41

SECTION 11. UNDERGROUND TRANSPORT

General Considerations; Primitive Methods 02– 03
Mine Cars, Track, Dumps 03– 32
Hand Tramming; Animal Haulage 32– 35
Locomotive Haulage 35– 41
Rope and Miscellaneous Haulage; Costs; Accidents 41– 46

SECTION 12. HOISTING PLANT, SHAFT POCKETS, AND ORE BINS

Hoisting Systems; Drums, Brakes and Clutches; Sheaves 02– 18
Hoisting Ropes: Vegetable-fiber; Wire 19– 29
Hoisting Cycles: Cylindrical, Conical, Cylindro-conical Drums 29– 40
Hoists, Types and Calculations: Electric, Steam, Comp-air, Etc 42– 56
Windlass and Whim 57– 58
Hoisting in Deep Shafts; Examples and Costs 58– 60
Headframes: Designs in Wood, Steel, and Concrete 61– 82
PAGE
Guides and Tracks; Signal Systems... 82– 91
Buckets, Cages, Skips: Design and Construction; Overwinding 91–119
Shaft Pockets 119–125
Ore Bins: Design and Construction... 126–135

SECTION 13. DRAINAGE OF MINES

Sources and Control of Mine Water; Prevention 02– 04
Sumps, Dams, Tunnels, Siphons; Hoisting of Water 04– 11
Mine Pumps: Steam, Comp-air, Air-lift, Electric 11– 21

SECTION 14. MINE VENTILATION

Mine Atmosphere; Ventilating Systems 02– 07
Air Distribution; Velocity and Control 07– 14
Auxiliary Ventilation; Leakage; Effect of Mining Method 14– 21
Measurements; Air Flow; Mine Resistance 21– 34
Ventilating Methods and Equipment: Natural; Mechanical 34– 44
Mine Fans: Characteristics, Applications, Selection 44– 54
Cooling and Air Conditioning 54– 64

For contents of other handbooks of this series, see pages following Index of this volume.

IDENTIFICATION AND STUDY OF MINERALS

1. DEFINITIONS

On the basis of several thousand analyses the crust of the earth for a depth of about ten miles is estimated by Clarke, "*Data of Geochemistry*," to be composed almost entirely of compounds of fourteen elements:

	Per cent		Per cent		Per cent
Oxygen	49.78	Sodium	2.33	Chlorine	0.21
Silicon	26.08	Potassium	2.28	Carbon	0.19
Aluminum	7.34	Magnesium	2.24	Phosphorus	0.11
Iron	4.11	Hydrogen	0.95	Sulphur	0.11
Calcium	3.19	Titanium	0.37		
				Total	99.29

These great elements, and the sixty or so others which form the remaining fraction of 1%, occur in approximately 1500 different chemical combinations, known as minerals; that is, as *homogeneous substances of definite chemical composition, found ready-made in nature, and not directly a product of the life or decay of an organism.*

The two conditions in which minerals may occur. A mineral, like other chemical substances, usually occurs either in crystals of characteristic shapes or in masses made up of many crystals so crowded together that the shapes are not evident, although in each grain of the aggregation the crystalline structure will be shown by the constancy of the properties in parallel directions and their variation in directions not parallel.

Any mineral may in solidifying fail to assume a crystalline structure, because of too great viscosity, or too rapid cooling, or other cause. If this condition is invariable, the mineral is said to be *amorphous*. Opal is the best example. Amorphous minerals are few in number.

2. IDENTIFICATION BY AID OF CRYSTALS

The forms of crystals are often a great aid in mineral identification. Symmetry, interfacial angles and crystal habit are also of value. Cleavage and markings on crystal faces are significant.

Symmetry. In every complete crystal there is some repetition of angles and similarly grouped faces. By considering this so-called "symmetry" crystals may be grouped in divisions, and as all crystals of any one mineral have the same grade of "symmetry," they belong to the same symmetry division.

In identifying an axis of symmetry imagine or actually cause the crystal to revolve about some prominent line through its centre. Note the groupings of faces at the initial position. Note whether at any stage of the revolution the crystal faces appear to be all coincident (rarely), or all parallel to the initial positions of other faces. Or, in other words, note whether groups of faces are replaced during the revolution by other groups containing just as many faces at exactly the angles of the first set. If so, a probable axis of symmetry has been determined. If by measurement the angles of one set correspond in value and order with those of the other sets, then the existence of the symmetry axis is confirmed. According to the number of times corresponding groups or faces recur during a complete revolution about a symmetry axis the axis is known as two-fold, three-fold, four-fold, or six-fold. These are the ordinary axes of symmetry.

If a plane so divides the crystal that on each side of that plane there are grouped the same number of faces at the same angles to it and to each other, this plane is called a **Plane of Symmetry.**

Divisions or "systems" based on symmetry. The following seven divisions result readily from this partial determination of symmetry, the statements not implying the absence of other symmetry elements:

1. Isometric........	More than one axis of three-fold symmetry. (Often also more than one of four-fold.)
2. Tetragonal.......	One axis of four-fold symmetry and one only.
3. Hexagonal.......	Rhombohedral division—one axis of three-fold symmetry and one only.
4. Hexagonal.......	Hexagonal division—one axis of six-fold symmetry.
5. Orthorhombic....	Three axes of two-fold symmetry, but nothing higher than two-fold; or one axis of two-fold symmetry at the intersection of two planes of symmetry.
6. Monoclinic.......	One axis of two-fold symmetry and one only, or one plane of symmetry, or both.
7. Triclinic.........	Without axes or planes of symmetry.

Distinguishing species by angles. Although different crystals of the same substance may differ in shape, angles, and number of faces, the angles between *corresponding* faces are constant and characteristic.

Corresponding faces on the same crystal, or on different crystals of the same substance, occupy corresponding or analogous positions with reference to the symmetry axes and usually correspond in lustre and markings. They frequently do not correspond in shape.

The measuring of a few selected angles will, therefore, usually serve to differentiate the crystal from others in the same symmetry division.

Angles may be determined within one or two degrees by a very simple apparatus, such as the Penfield No. 2 goniometer, consisting of a cardboard on which is printed a graduated semicircle, with an arm of celluloid swiveled by an eyelet in the centre of the semicircle, or better a similar apparatus of metal with removable and adjustable arms. In using, the crystal is placed so that the card edge and the swinging arm, or the two metal arms, are each in contact with a face and perpendicular to the edge of intersection of the two faces, and the mean of at least three readings is used.

The "cleavage" directions, obtained as described later, are of great service in orientating the crystal. These and the angles between them are used in the lists which follow each system.

Zones are composed of faces all parallel to the same line. Their intersections are therefore parallel to this line and to each other.

Isometric crystals. If a crystal shows more than one axis of three-fold symmetry it is an isometric crystal, and not otherwise. There will always be present, also, axes of two-fold or four-fold symmetry. The faces are often squares and equilateral triangles, or these modified by cutting off corners. The dimensions are usually approximately equal in several directions, the forms approaching sometimes to the sphere. Repetitions in any crystal of equal angles and "corresponding" faces are more frequent than in other crystal systems.

Angles. These are of the same series whatever the species. The important species may be classed by their "habit"; that is, the dominant forms of the crystals, as follows:

Tetrahedral. (Tetrahedron angles, 70° 31′) boracite, sphalerite, tetrahedrite.

Cubic. *With easy cubic cleavage:* cobaltite, galena, halite; *with octahedral cleavage:* fluorite, smaltite; *without marked cleavage:* argentite, boracite, cerargyrite, cuprite, pyrite.

Octahedral. (Octahedron angles, 109° 29′) chromite, cobaltite, cuprite, fluorite, franklinite, galena, gold, linnæite, magnetite, pyrite, spinel. Cleavages: galena, cubic; fluorite, octahedral. Partings: franklinite and magnetite, octahedral.

Dodecahedral. (Dodecahedron angles, 120°) boracite, cuprite, garnet, magnetite, sphalerite.

Trapezohedral. (24-faced trapezohedra, approximating spheres; common angles, 131° 19′, 146° 27′) analcite, garnet, leucite.

Pyritohedral. (12-faced pyritohedra; most common angles, 126° 53′ and 113° 35′) cobaltite, pyrite, smaltite.

Tetragonal crystals. If the crystal shows one axis of four-fold symmetry, and only one, it is a tetragonal crystal, and not otherwise. A section taken at right angles to the four-fold axis is usually square or octagonal, or more rarely the angles are again truncated. The dimension in direction of the four-fold axis is usually notably greater or less than in directions at right angles thereto.

Angles. In the zone of faces parallel to the four-fold axis there are no variations in angle dependent on the species. Between prominent *corresponding* faces the angles are almost always

90°, and between prominent *adjacent* faces either 90° or 135°. The characterising angles lie in other zones.

The principal tetragonal minerals may be classified by angles and cleavage as follows: Angles between corresponding faces *oblique to the four-fold axis:* chalcopyrite, 71° 20′; wulfenite, 99° 38′; scheelite, 100° 5′; apophyllite, 105°; braunite, 109° 53′; cassiterite, 121° 41′; rutile, 123° 8′; zircon, 123° 19′; vesuvianite, 129° 21′; wernerite, 136° 15′.

Braunite, scheelite, and wulfenite cleave at the angles mentioned. Wernerite and rutile cleave parallel to the four-fold axis, giving angles of 90° and 135°. Apophyllite cleaves at right angles to the four-fold axis.

Hexagonal crystals. If the crystal shows one and only one axis of three-fold symmetry it is a hexagonal crystal, rhombohedral division. If the crystal shows one and only one axis of six-fold symmetry it is a hexagonal crystal, hexagonal division. A section taken at right angles to the axis of three-fold or six-fold symmetry is usually a hexagon, or its most prominent edges form a hexagon or at least an equiangular triangle. Not infrequently each angle is replaced by one or two smaller edges. The dimension parallel to this axis is usually notably greater or less than the dimensions at right angles thereto.

Angles. In the zone of faces parallel to the three-fold (or six-fold) axis there are no variations in angle dependent on the species. The angles between prominent corresponding faces are chiefly 120° or 60°. Other angles in this zone are usually large and their occurrence leads to an apparently rounded, often nearly circular, cross-section. The characterizing angles lie in other zones.

The crystals of important hexagonal minerals may be classified by angles between corresponding faces and by cleavage as follows:

I. With evident axis of three-fold symmetry and usually rhombohedral habit:

Angles which are both interfacial and between cleavage directions. Soda nitre, 73° 30′; chabasite, 85° 14′; hematite, 86°; calcite, 105° 5′; dolomite, 106° 15′; rhodochrosite, 107°; siderite, 107°; magnesite, 107° 24′; smithsonite, 107° 40′; proustite, 107° 58′.

Angles which are interfacial only. Ilmenite, 85° 31′; alunite, 90° 50′; cinnabar, 92° 37′; willemite, 115° 30′; phenacite, 116° 36′; tourmaline, 133° 8′ or 103°.

II. With real or apparent axis of six-fold symmetry, and usually prismatic habit:

Prisms capped by faces oblique to axis and at angles, for example, corundum, 86° 4′ or 128° 2′; quartz, 94° 14′ or 133° 44′; apatite, 142° 15′.

Prisms usually capped by single face at right angles to axis. Beryl, iodyrite, mimetite, nephelite, pyrargyrite, pyromorphite, vanadinite.

Tabular. Graphite, molybdenite, iridosmine.

Orthorhombic crystals. If a crystal shows either three axes of two-fold symmetry or one axis with two planes of symmetry, and nothing of higher symmetry, it belongs to the orthorhombic system. Cross-sections taken at right angles to the axes of symmetry are unlike in angles, and tend to rectangles and rhombs or to these combined.

Angles. There is no zone of faces which has a constant series of angles for all species.

The interfacial angles in the zones parallel to the axes of symmetry are unlike (except when 90°) and vary with the species. The orientation is best obtained by reference to cleavages, and on this basis the important species may be tabulated as follows:

I. With one direction of cleavage which bisects prominent angles, for example: stibnite, 90° 26′; sillimanite, 91° 45′; goethite, 94° 52′; manganite, 99° 40′; brochantite, 104° 32′; atacamite, 113° 03′; staurolite, 129° 20′. Topaz, with one direction of cleavage, has prominent angles 124° 17′ and 90° 11′, not bisected by the cleavage.

II. Crystals with two directions of cleavage or more than two in one zone, and common angles between faces parallel to two such directions: columbite and olivine, 90°; andalusite, 90° 48′; natrolite, 91° 15′; enargite, 97° 53′; hemimorphite, 103° 51′; arsenopyrite, 112° 27′; cerussite, 117° 14′; strontianite, 117° 19′; aragonite, 118° 12′; chalcocite, 119° 35′.

III. Crystals with three or more directions of cleavage not in one zone, and common angles between faces parallel to such directions: anhydrite, 90°; barite 90° and 101° 38′; anglesite, 90° and 103° 44′; celestite, 90° and 104° 10′; stephanite, 90° and 107° 44′.

Monoclinic crystals. If a crystal shows one and only one axis of two-fold symmetry, or one and only one plane of symmetry, or both, it is a monoclinic crystal. Any face in the zone of the symmetry axis makes a 90° angle with the symmetry plane (or a face parallel to it). No other 90° angles occur. The cross-section of the zone of the symmetry axis is never rectangular, rarely rhombic and usually markedly unsymmetrical.

Angles. No zone has a constant series of angles for each species. In this system the one symmetry plane, the one symmetry axis and the cleavages, all assist in the orientation leading to the following tabulation:

Easiest cleavage	Species	Angles in zone of symmetry axis	Angles bisected by symmetry plane
Parallel to symmetry plane	Colemanite	110° 9′, 111° 36′	107° 56′, 140° 12′, 126° 9′
	Gypsum	....	131° 30′, 143° 48′, 138° 40′
	Realgar	....	74° 26′, 132° 3′
	Vivianite	....	108° 2′
	Wolframite	118° 6′, 124° 18′ 117° 6′	100° 37′, 98° 6′, 117° 49′
Perpendicular to symmetry plane	Azurite	135° 14′, 137° 10′, 132° 45′	99° 19′, 119° 13′, 90° 53′
	Borax	106° 35′	87°, 122° 33′, 96° 32′
	Cryolite	124° 58′, 124° 43′	91° 58′, 71° 32′
	Epidote	115° 23′, 128° 19′, 155° 11′	70° 4′, 70° 29′, 63° 5′
	Monazite	140° 48′, 87° 17′, 126° 29′	93° 26′
	Orthoclase	99° 42′, 129° 44′	118° 47′, 90° 7′
	Polybasite	90°	119° 58′
Angle between easiest cleavages bisected by plane of symmetry	Amphibole	130° 6′	124° 11′, 148° 28′
	Crocoite	....	93° 41′, 119° 10′
	Pyroxene	105° 50′, 148° 40′	87° 10′, 120° 49′, 131° 31′
	Spodumene	110° 20′	87°, 91° 26
	Sphene	140° 43′, 159°	113° 31′, 136° 11′, 67° 57′
No cleavage	Datolite	90° 9′, 135°	115° 13′, 120° 56′, 115° 21

The micas and chlorites are usually pseudo-hexagonal.

Triclinic crystals. If the crystal shows no axes nor planes of symmetry it is a triclinic crystal. There will be no right angles either between faces or edges. The only corresponding faces will be opposite (parallel) faces. The crystals of some of the most prominent triclinic minerals, however, approximate in angles monoclinic crystals but are usually distinguishable by the occurrence of faces which have no symmetrically placed associates.

Angles. No angle will occur more than twice in any crystal. There are comparatively few common triclinic species. The following table records a few of their most important angles.

Angles between the two easiest cleavages or the faces parallel to the cleavages		Other angles between common adjacent faces
The Plagioclases:		
Albite	93° 36′	127° 44′, 120° 46′
Anorthite	94° 10′	116° 3′, 98° 46′, 120° 31′
Labradorite	93° 56′	....
Oligoclase	93° 28′	128° 3′, 98° 8′, 120° 54′
Amblygonite	104° 30′	120° 54′
Chalcanthite	123° 10′	110° 10′, 70° 22′, 103° 27′
Cyanite	101° 30′	74° 16′, 131° 42′, 78° 58′
Rhodonite	87° 32′	107° 24′

Cleavage and its value as a test. In any crystal, whether with characteristic external form or not, the cohesion varies in different directions. Under strain there is frequently a tendency to split or cleave perpendicular to the directions of weakest cohesion *in definite* planes, which are always parallel to possible faces of simple crystals characteristic of the substance. All crystals of the same substance yield like cleavages. The number of directions of cleavage and the angles between the cleavage planes are characteristic; moreover the cleavages serve to orientate the crystals in many cases. If the individual crystals are large enough, cleavage is obtained by placing the edge of a knife or chisel upon the crystal and striking it a sharp, quick blow. If the individual crystals are very small the cleavage directions can usually be developed by crushing with pressure or a blow, and examining the fragments with a hand glass. In pyroxene, spodumene, corundum, magnetite, and some other species, some specimens break easily in definite planes, while others do not. This is not true cleavage, but a secondary phenomenon due to pressure, and is called "parting."

Cleavage and parting shapes may be microscopically determined. To do this, sieve the crushed material through a 100-mesh screen upon a 120-mesh screen. Crushed fragments of transparent minerals may be placed on a slide, covered with a transparent liquid, and examined by the petrographic microscope, as described by E. S. Larsen and H. Berman, USGS, *Bull.* 848 (1934) (Bib). Thin sections of massive, transparent minerals or rocks may be examined as described in *Thin-section Mineralogy*, by A. F. Rogers and P. F. Kerr, McGraw-Hill, N Y, 1933.

3. IMPORTANT PHYSICAL TESTS NOT DIRECTLY DEPENDENT ON CRYSTALLINE STRUCTURE

The most important of these tests or characters are Luster, Color and Streak, Hardness, and Specific Gravity.

Lustre. The luster of a mineral is dependent upon its refractive power, its transparency, and its structure. It may be called the *kind* of brilliancy or shine of the mineral.

In determinative work minerals are broadly divided into Metallic and Non-metallic. Metallic luster is the luster of metals. It is exhibited only by opaque minerals, and these, *with the exception of the native metals, have a black or nearly black streak.* Opaque dark-colored minerals not distinctly non-metallic are said to be sub-metallic. Non-metallic luster is exhibited by all transparent or translucent minerals. It may be vitreous or glassy, adamantine like the cut diamond, resinous like sphalerite, pearly like mother of pearl, silky like fibrous serpentine, greasy like nephelite, or waxy like chalcedony.

Hardness. The resistance of a *smooth* plane surface to abrasion is called its hardness and is recorded in terms of the following scale:

1.0	Talc	6.0	Orthoclase	8.5	Chrysoberyl
2.0	Gypsum	7.0	Quartz	9.0	Sapphire
3.0	Calcite	7.5	Zircon	9.5	Carborundum
4.0	Fluorite	8.0	Topaz	10.0	Diamond
5.0	Apatite				

Approximations may be reached by use of finger nail ($2\,{}^1/_2$), copper coin (3) and knife ($5\,{}^1/_2$). Some smooth surface of the mineral to be tested is selected, on which a point of the standard is pressed and moved back and forth several times one-eighth of an inch or less. If the mineral is scratched it is softer than the standard. Two minerals of equal hardness will scratch each other. Pulverulent or splintery minerals are "broken down" by the test and yield an "apparent" hardness often much lower than the true hardness. Rough surfaces also yield doubtful results.

Color and streak. The color of minerals of metallic luster and the color of the powder, or streak, when not white, are very much used in sight recognition. Minerals with non-metallic luster often vary greatly in color. The color is most safely obtained on a fresh surface. The streak is usually obtained by rubbing the mineral on a smooth but not glazed white or black surface, such as a porcelain "streak plate" or a piece of touchstone (black quartz). The excess of powder should be brushed away and the thin adhering layer considered.

Specific gravity. The specific gravity of a substance is equal to its weight divided by the weight of an equal volume of distilled water at 4° C. Ordinarily room temperature is used. Pure compact material is needed. The most accurate results are obtained by a delicate chemical balance, but for determinative purposes the following are more rapid and sufficiently accurate.

The Jolly balance. Two scale pans are attached, one below the other, to a spiral spring, parallel to which is a mirror with a graduated scale. The lower scale pan is kept submerged in distilled water. The coincidence of a bead on the wire and its image in the mirror give:

A = Reading with nothing in either scale pan.
B = " " mineral in upper scale pan.
C = " " same fragment in lower scale pan.

$$\text{Sp Gr} = (B - A) + (B - C)$$

The Westphal balance. More accurate results are obtained by substituting for the thermometer float of a Westphal balance a double scale pan, the lower pan of which must be immersed in distilled water.

A = Weight needed to balance apparatus.
B = " " " " " with mineral in upper scale pan.
C = " " " " " " " " lower scale pan.

$$\text{Sp Gr} = (A - B) + (C - B)$$

Special specific-gravity balance. An improved form, suitable for non-porous solids, has been described by Kerr. It is useful for rapid and accurate determinations. Though based upon the usual chemical balance, it has a notched beam with rollers for weighing.

Heavy liquids. If a fragment of a mineral is floating in a liquid of higher specific gravity and a diluent is stirred in, drop by drop, until the fragment if pushed down will neither sink nor rise but stay where pushed, the specific gravity of the liquid as determined by a Westphal balance will be the specific gravity of the mineral. The heavy liquids most used are: clerici solution, a mixture of thallium malonate and thallium formate (4.25), diluent, water; methylene iodide (3.32), diluent, benzol; bromoform (2.90), diluent, xylol or benzol; solution of mercuric iodide and potassic iodide (3.2), diluent, water.

4. TESTING WITH THE BLOWPIPE

Apparatus. The *essential* pieces of apparatus for all the tests given are:

1. Either a gas blowpipe, or some form of burner for gas or heavy oil and a plain blowpipe.
2. Platinum wire about 0.25 mm diameter. Six inches of it will make four wires. A holder is needed.
3. Platinum-pointed forceps.
4. Charcoal in convenient sizes and with smooth surfaces (say 4 by 1 by $^5/_8$ in).
5. Tubes of hard glass about 3 by $^3/_{16}$ in, closed at one end.
6. Pocket lens of good quality.
7. Simple goniometer.
8. Merwin Color Screen (G. M. Flint, Cambridge, Mass).

For the other apparatus considerable latitude is possible and substitutes can be improvised for the regular stock article. The needed list would be: watch glasses, bottles (1 oz) for reagents, hammer, anvil, and magnet.

About ten reagents are used, the principal being borax, salt of phosphorus, sodic carbonate, potassic bisulphate, cobaltic nitrate, and hydrochloric acid. Two others are needed in preparing the bismuth flux and there will be needed occasionally metallic tin and nitric or sulphuric acid.

A continuous blowpipe blast is obtained by distending the cheeks and using the mouth as an air reservoir, breathing regularly through the nose and from time to time admitting more air from the lungs through the throat to the mouth.

Any luminous flame may be used and, by regulating the relative amounts of air and flame, may be " blown " as a clear blue flame or a yellow flame, both of which owe their color to incomplete combustion (CO or C) and therefore tend to *reduce*, that is, to take oxygen from substances placed therein. Hereafter this flame is designated by the letters R.F. A practically non-luminous colorless envelope surrounds the blue flame and less distinctly the yellow flame. In this there is an excess of oxygen and it therefore tends to *oxidize* substances placed therein. Hereafter this flame is designated by the letters O.F.

Fusion or fusibility. The ease of fusibility and the phenomena during fusion are convenient tests. The hottest portion of the flame is just beyond the tip of the blue flame. Some substances, noticeably certain iron ores, which are infusible in the oxidising flame are fusible in the reducing flame.

The test is most safely made by first heating on charcoal a fragment of the substance the size of a pin's head, to prove presence or absence of volatile or easily-reducible elements, which are likely to alloy with platinum. If these are present the fusion test must be limited to the test on charcoal. If reducible metals or volatile constituents are absent, a small sharp-edged fragment is heated in the platinum forceps, at the tip of the blue flame, directing the flame upon the point. Fragments long enough to project beyond the platinum should be used and it is always well to examine the splinter with a magnifying glass, before and after heating. *Fragments for comparison must be approximately of same size and shape.*

The degree of fusibility is stated either in terms of a scale of fusibility, suggested by von Kobell, or more simply as easily fusible, fusible, fusible with difficulty, or infusible:

Easily fusible:
1. *Stibnite*, coarse splinters fuse in a candle flame.
2. *Chalcopyrite*, small fragments fuse in the Bunsen burner flame.

Fusible:
3. *Garnet* (*almandite*), coarse splinters easily fuse before the blowpipe. Not fusible in Bunsen burner.
4. *Actinolite*, fine splinters fuse easily before the blowpipe.

Fusible with difficulty:
5. *Orthoclase*, fused only in fine splinters or on thin edges before the blowpipe.
6. *Hemimorphite*, finest edge only rounded in hottest part of flame.

Infusible: 7. *Quartz*, infusible, retaining the edge in all its sharpness.

The result of the fusion may be a glass or slag, which is clear and transparent, or white and opaque, or of some color, or filled with bubbles; during the fusion there may be a frothing or intumescence, or a swelling and splitting (exfoliation). In certain instances the color and form may change without fusion, or the substance may take fire and burn, or fusion may follow the loss of some volatile constituent.

Solubility. Acids, especially dilute (1 : 1) hydrochloric acid, are used not only to determine composition but also to determine the ease or degree of solubility. This test fails only from carelessness. The substance must be selected as nearly pure as possible, finely ground and added to the acid in successive small quantities. A clear solution should be aimed at, acid being added if more is needed until everything has dissolved. If complete solution cannot be obtained, the liquid must be filtered and the clear filtrate slowly and partially evaporated until separation commences. If doubt exists as to solubility the *liquid must be evaporated to dryness*, a residue proving solution to have taken place. Solubility may be accompanied by effervescence with or without odor in cold acid, or only on heating. The evaporation may be difficult and incomplete, or there may be separation of a perfect jelly, or of separate lumps of jelly, or of powder, or of crystals. The solution may be of a characteristic color.

Testing for chemical components. The tests used are described in place in the determinative tables following Art 14. The manipulations and precautions are briefly as follows:

I. Testing in closed tubes. A narrow tube of hard glass, about 3 in by $^3/_{16}$ in and closed at one end, is best. Enough of the substance is slid down a narrow strip of paper, previously inserted in the tube, to fill it to the height of about $^1/_4$ in; the paper is withdrawn, and the inclined tube heated gradually at the lower end to a red heat. Soda or other reagents are sometimes mixed with the substance. The results may be: evolution of water, odorous or non-odorous vapors, sublimates of various colors, decrepitation, phosphorescence, fusion, charring, change of color, and magnetization.

II. Testing on charcoal. A shallow cavity, to prevent the substance from slipping, is bored at one end of the charcoal, and a small fragment of the mineral is placed in it. The charcoal is held in the left hand, the surface tipped at about 120° to the direction in which the flame is blown, and a gentle O.F. is blown on the substance. If no sublimate forms the heat is increased, still keeping the flame oxidizing. Another fragment is tested in the R.F., the substance being kept covered for several minutes with the yellow flame.

The sublimates, their color, position on the charcoal, ease of removal by heating in the O.F. or R.F., and the colors imparted to the flame are all noted. Chemical changes may also be indicated by reduced metal, magnetic residues, alkalinity, etc.

III. Testing with soda on charcoal. Sodic carbonate ("Soda"), heated on charcoal, acts as a flux; it also exerts a reducing action, attributed to the formation of sodic cyanide, nascent sodium, and carbon monoxide. It combines with many substances, forming both fusible and infusible compounds. The most satisfactory general method is to mix one part of the substance to be tested with three parts of moistened soda and a little borax, and treat with a good R.F. on charcoal until everything that can be absorbed has disappeared.

IV. Testing with bismuth flux on charcoal and on plaster tablets. Sublimates of brilliantly colored iodides and sulpho-iodides are obtained if bismuth flux (two parts sulphur, one part potassium iodide, and one part acid potassium sulphate) is mixed with certain powdered minerals, placed on charcoal, or a plaster tablet, and heated gently. The larger series of tests are obtained on plaster, the sublimates differing in position and to some extent in color from those obtained on charcoal. Plaster tablets are prepared by spreading a thick paste of plaster of Paris and water upon a sheet of oiled glass, and smoothing to a uniform thickness ($^1/_8$ in to $^1/_4$ in). While still soft, the paste is cut with a knife into uniform slabs, 4 in by $1^1/_2$ in. It is then dried, after which the tablets are easily detached from the glass.

V. Flame coloration. A number of minerals when heated color the flame, some at a gentle heat, some only at the highest heat attainable. Repeated dipping of the mineral in hydrochloric acid usually assists by forming volatile chlorides. A good method to cover all cases is as follows: Arrange a black background, such as a piece of charcoal, powder the substance finely, flatten the end of a clean platinum wire and dip it in dilute acid, then in the powder, and hold it first just touching the flame near the blowpipe and then at the tip of the blue flame; again dip in the acid and again heat as before.

Concentrated sulphuric acid, and also a paste made of water, $4^1/_2$ parts acid potassium sulphate and 1 part of calcium fluoride, are also used to release certain flame-coloring constituents, especially boron, phosphorus and lithium.

Red flames of calcium, strontium, lithium, and the violet flames of potassium in the presence of sodium, are most conveniently studied by Merwin's Color Scale (*Science,* Vol 80, p 571), consisting of three colored strips of celluloid; No. 1, blue, No. 2, overlapping blue and violet, No. 3, violet. These absorb different portions of the spectrum as follows:

	No. 1	No. 2	No. 3
Sodium	Absorbed	Absorbed	Absorbed
Potassium	Blue-violet	Violet and Violet-red	Violet and Violet-red
Calcium	Greenish yellow	Absorbed	Faint crimson
Strontium or lithium	Absorbed	Absorbed	Crimson

These elements are still more exactly distinguished by use of a small pocket spectroscope. The mineral is moistened with hydrochloric acid and brought on a platinum wire into the non-luminous flame of the Bunsen burner. This is viewed through the spectroscope and bright lines are seen. The yellow sodium line is almost invariably present and the position of the other lines is best fixed by their situation relative to this bright yellow line.

VI. Bead tests with borax and with salt of phosphorus. The oxides of certain elements dissolve in borax and salt of phosphorus and impart characteristic colors to the mass, which may differ when hot and cold and according to the degree of oxidation or reduction. Preliminary to bead tests, sulphides, arsenides, arsenates, etc, may be converted into oxides by treating in a shallow cavity on charcoal at a dull red heat; first with a feeble oxidizing flame, then a feeble reducing flame, then again an oxidizing flame, and so on as long as odors or fumes are noticeable.

To make a bead. Make a loop in platinum wire by bending it around a pencil point so that the end meets but does not cross the straight part. Heat the loop, dip it into the flux, and fuse to a clear bead the portion that adheres. Add more flux until the bead is of full rounded shape. With salt of phosphorus the bead should be held a little above the flame so that the ascending hot gases will help to retain the flux upon the wire. Touch the warm bead to the substance, place it in the O.F., and treat until clear. Note the colors, hot and cold. Then treat in the R.F. and note colors as before.

Flaming. Some substances heated with a strong flame will give clear glasses until saturated; but if heated slowly and gently or intermittently, will yield opaque or enamel-like beads *before* saturation.

VII. Testing with cobalt solution. Certain substances become colored, when moistened with a solution of cobalt nitrate in ten parts of water and then heated to a white heat. The test is usually made on charcoal. Certain other substances yield colors if strongly heated, cooled, and then moistened with the cobalt solution without reheating. Certain minerals boiled with cobalt solution are colored thereby.

5. X-RAY METHODS OF STUDY

Recent years have witnessed the development of X-ray methods of mineral study. X-ray powder photographs may be used to aid in identifying many minerals. Clays, bauxite, fine micaceous silicates, poorly crystallized metallics and other natural products, not readily identified in other ways, are often readily identified by comparison of X-ray diffraction photographs with known standards. The methods of X-ray study applicable to minerals have been described by Hull, Davey, Wyckoff, Bragg, and others.

Single crystals are most frequently used for X-ray studies, to yield information regarding internal structures. The earliest to be developed was the method of Laue, making use of a pinhole beam of X-rays passing through a small crystal. The Braggs later developed the X-ray spectrometer, which depends upon the reflection of X-rays from single crystal faces. Lately, students of crystal structure have found the Weissenberg X-ray goniometer especially useful.

6. POLISHED SURFACES OF METALLIC ORES

Many textures and mineral combinations, not readily visible to the unaided eye, may be observed with the reflecting microscope. Polished surfaces must be prepared in advance with considerable care to produce flat, nearly uniform surfaces, as free from scratches as possible. Such surfaces may be etched and observed under the microscope and also examined by reflected polarized light.

Microchemical technique is also applied to small fragments of metallic minerals, removed from a polished surface with a needle while the surface is under microscopic observation. Among the comprehensive treatments of microscopic examination of metallic ores are the works of Van der Veen, Schneiderhöhn and Ramdohr, and Short.

7. EXAMINATION OF FRAGMENTS OF NON-OPAQUE MINERALS

Fragments of non-opaque minerals, about 100 to 120 mesh in size, may often be studied and identified by the polarizing microscope. The fragments are placed on a glass slide and immersed in an inert liquid of known refractive index, the indices of the mineral being compared with the index of the immersion liquid. Repeated mounts, made with liquids of different indices, by comparison yield the indices of refraction of a mineral with a fair degree of precision. Other optical properties may be determined at the same time. The methods may often be applied to examination of non-opaque constituents of tailings. The optical properties of many minerals observable with the microscope have been listed by Larsen and Berman.

8. EXAMINATION OF THIN SECTIONS

The structures and textures of non-opaque minerals are best examined in thin sections beneath the microscope. The polarizing microscope of the types manufactured by E. Leitz, Zeiss-Winkel, Bausch and Lomb, or the Spencer Lens Co, are useful for this purpose. Many optical criteria not obvious in ordinary specimens may be used in such an examination. The methods have been outlined by Winchell, Johannsen, and Rogers and Kerr.

OCCURRENCE AND ASSOCIATION OF MINERALS

9. MINERALS OF ROCKS AND VEINS

Associates. Most minerals are found under a variety of conditions, and with different groups of associates. The most probable associates of any mineral in any particular occurrence are: 1. The common minerals of that deposit. 2. Minerals containing some prominent element or elements of the given mineral. In the following lists, which include the rock-forming minerals, common minerals, and those of economic importance, the species in italics are relatively rare.

Minerals of the igneous rocks. These minerals in general have either separated from a fusion solution or "magma" (each separating whenever for the existing temperature and pressure the magma is supersaturated with it), or they have formed later, as secondary minerals, by the decomposition or alteration of the primary minerals.

Principal primary minerals of igneous rocks. Amphibole (hornblende), biotite, chrysolite (olivine), enstatite, hypersthene, leucite, muscovite, nepheline (elaeolite), orthoclase, plagioclase, pyroxene (augite), quartz, sodalite.

Minor primary minerals of igneous rocks. *Analcite*, apatite, *chalcopyrite*, *chrysoberyl*, chromite, *cinnabar*, corundum, *epidote*, *garnet* (almandite, andradite, pyrope), *goethite*, *gold*, *graphite*, hematite, ilmenite, *lepidolite*, magnetite, *millerite*, *molybdenite*, monazite, pyrite, pyroxene (diopside), pyrrhotite, rutile.

Secondary minerals in igneous rocks. *Albite*, alunite, analcite, apophyllite, aragonite, *azurite*, *barite*, calcite, chabazite, chalcedony, *chalcanthite*, *chalcopyrite*, chlorite, *chrysocolla*, copper, datolite, epidote, kaolin, lepidolite, limonite, magnetite, *malachite*, muscovite, natrolite, opal, *pyrargyrite*, quartz, serpentine, siderite, *sphalerite*, stibnite, talc, *tetrahedrite*, *turquois*, wernerite.

Minerals of pegmatite veins. Vein-like portions of granites or other igneous rocks in which the minerals of the rock are found in much larger crystals and in which many other minerals occur not noticed in the adjoining rocks.

Albite, *amblygonite*, apatite, beryl, biotite, *cassiterite*, *chabazite*, *chlorite*, *chrysoberyl*, *columbite*, cryolite, *diamond*, *galena*, *garnet* (almandite and spessartite), graphite, lepidolite, magnetite, microcline, *molybdenite*, *monazite*, muscovite, nepheline, orthoclase, *pyrite*, *pyrrhotite*, quartz, spodumene, topaz, tourmaline, uraninite, zircon.

Minerals of ore veins. For convenience these have been listed under two headings: Minerals in zone of weathering or oxidation, and minerals of unoxidized zone. **In zone of oxidation.** Anglesite, azurite, brochantite, calamine, celestite, cerargyrite, cerussite, *chalcanthite*, chrysocolla, copper, crocoite, cuprite, embolite, erythrite, goethite, gold, iodyrite, limonite, malachite, manganite, mimetite, pyromorphite, rhodochrosite, siderite, silver, smithsonite, *strontianite*, *sulphur*, vanadinite, *vivianite*, wulfenite. **In unoxidized**

zone. Antimony, argentite, *arsenic*, arsenopyrite, barite, bornite, braunite, calcite, calaverite, chalcocite, chalcopyrite, cobaltite, copper, dolomite, fluorite, galena, gold, graphite, jamesonite, linnæite, marcasite, millerite, niccolite, orpiment, orthoclase, pentlandite, proustite, pyrargyrite, pyrite, pyrrhotite, quartz, realgar, smaltite, sphalerite, stannite, stephanite, stibnite, sylvanite, tetrahedrite, uraninite.

Minerals of tin veins. Albite, amblygonite, apatite, arsenopyrite, bismuth, calcite, cassiterite, chlorite, columbite, fluorite, galena, kaolin, lepidolite, *molybdenite*, pyrite, pyroxene, quartz, scheelite, wernerite, wolframite.

Minerals of apatite veins. Albite, amphibole, apatite, biotite, calcite, *enstatite*, hematite, ilmenite, magnetite, oligoclase, pyrite, quartz, rutile, sphene, tourmaline, wernerite.

Minerals due to volcanic exhalations. Alunite, sassolite, sulphur, and relatively small quantities of other species, as amphibole, hematite, sal-ammoniac, etc, occur as the result of gases given off during volcanic action.

10. MINERALS FOUND IN SALINE RESIDUES

These exist as sediments precipitated from solution in natural waters, springs, rivers, marshes, lakes, seas, and oceans.

From springs. Alunogen, aragonite, barite, bauxite (?), calcite, celestite, chalcedony, cinnabar, fluorite, hydrozincite, kalinite, limonite, pyrite, sassolite, siderite, sulphur.

From soda and borax lakes and lagoons. Anhydrite, calcite, borax, celestite, *cerargyrite*, colemanite, dolomite, *embolite*, *gold*, gypsum, halite, mirabilite, sassolite, *soda nitre*, *sulphur*, *trona*, ulexite.

From oceans, seas, lakes, and marshes. Apatite, anhydrite, bauxite, boracite, *calcite*, carnallite, *celestite*, *cerargyrite*, *dolomite*, *epsomite*, gypsum, halite, kainite, kieserite, limonite, siderite, wad.

Local saline residues (often incrustations or efflorescences). Alunite, alunogen, chalcanthite, copiapite, epsomite, kalinite, mirabilite.

11. MINERALS IN GRAVELS, SANDS, CLAYS, AND MARLS

Minerals common to all. Biotite, calcite, chlorite, *garnet*, hematite, kaolinite, limonite, *magnetite*, muscovite, orthoclase, plagioclase, pyrite, *pyrophyllite*, *pyroxene*, rutile, siderite, sphene, *tourmaline*.

Gem minerals and ores in gravels and sands. Cassiterite, chrysoberyl, chrysolite, corundum, diamond, gold, ilmenite, monazite, platinum, spinel, tourmaline, topaz, zircon.

Minor minerals in gravels and sands. *Amphibole*, *andalusite*, apatite, cyanite, *dolomite*, enstatite, epidote, *hypersthene*, *microcline*, sepiolite, serpentine, *sillimanite*.

Ores in clays. Galena, limonite, manganite, psilomelane, pyrolusite, wad.

Minor minerals in clays and marls. Amphibole, aragonite, barite, *celestite*, gypsum, halloysite, *orpiment*, realgar, strontianite, *vivianite*.

Minerals in sandstones. Chiefly quartz, orthoclase, plagioclase, limonite, muscovite. *Minor minerals* are *carnotite*, galena, *gold*, *marcasite*, *manganite*, *pyrite*, *pyrolusite*, *siderite*, *sphalerite*.

Minerals in sedimentary limestone. Aragonite, calcite, dolomite, fluorite, galena, limonite (bog ore), *nitre*, opal, *siderite*, *soda nitre*, sulphur, sphalerite.

In serpentine and soapstones. *Amphibole*, *aragonite*, *arsenopyrite*, calcite, chlorite, chromite, chrysolite, cinnabar, diamond, dolomite, enstatite, epidote, garnet (pyrope), garnierite, ilmenite, magnesite, magnetite, phlogopite, *platinum*, *pyroxene*, pyrophyllite, quartz, *sepiolite*, serpentine, talc.

12. CONTACT MINERALS

When an igneous rock penetrates a preëxisting rock the heat, pressure, and evolved vapors frequently produce new minerals at and near the surface of contact.

Contacts with limestone. Amphibole (tremolite), anorthite, biotite, bornite, chondrodite, *clinozoisite*, corundum, *danburite*, *enstatite*, epidote, *fluorite*, garnet (grossular and andradite), graphite, *lazurite*, molybdenite, phlogopite, pyrite, pyroxene (diopside), *scheelite*, spinel, tourmaline, *vesuvianite*, wernerite, wollastonite and *zoisite*.

Contacts with silicate rocks (clay, shale, slate, or crystalline schists). Amphibole (hornblende), andalusite (chiastolite), biotite, chlorite, corundum, kyanite, epidote, garnet, ilmenite, magnetite, pyroxene (augite), quartz, rutile, sillimanite, spinel, staurolite, sphene, tourmaline, topaz, wernerite, zircon.

Minerals of Metamorphic Rocks

The minerals of the metamorphic rocks include many species of the original rocks, and many species already listed under contact minerals. A partial list follows: In *Crystalline limestones, and dolomites*: amphibole (tremolite), apatite, aragonite, calcite, *chondrodite*, corundum, dolomite, franklinite, *molybdenite*, phlogopite, pyroxene, pyrrhotite, rhodonite, serpentine, smithsonite, spinel, *talc*, willemite, zincite, zircon. In *Gneisses and Schists*: the contact minerals of the second list (contacts with silicate rocks). Also actinolite, apatite, beryl, biotite, calcite, chalcopyrite, chrysoberyl, *datolite*, *fluorite*, *gibbsite*, graphite, hematite, molybdenite, monazite, muscovite, orthoclase, plagioclase, pyrite, pyrophyllite, pyrrhotite, talc, *tetrahedrite*, vesuvianite, zeolites.

THE USES OF MINERALS

This list includes only the principal uses of the minerals as such, and their uses as the material from which other substances are directly extracted or manufactured. The secondary products derived from these primary products are not mentioned.

13. USES OF MINERALS IN THEIR NATURAL STATE

Abrasives. Quartz, garnet, opal (tripolite and diatomaceous earth), corundum and emery, diamond (bort), orthoclase. Leucite and alunite rocks have been used as millstones.

Building stones. Quartz, orthoclase, plagioclase, muscovite, biotite, pyroxene and amphibole in varying proportions, forming igneous rocks commercially known as granite and trap; talc and pyrophyllite (soapstones), serpentines, calcite and dolomite (limestones and marbles), quartz (sandstone).

Electrical insulators. Muscovite, phlogopite, calcite (marble), andalusite, kyanite, sillimanite, and dumortierite.

Fertilizers. Carnallite and kainite for potash; soda nitre for nitrogen; gypsum and calcite for lime; apatite (phosphate rock) for phosphoric acid. Muscovite and biotite as retainers of moisture.

Fluxes. Calcite, fluorite, borax, pyrolusite.

Glass. Chiefly quartz (sand and sandstone) and calcite (limestone); to a less extent orthoclase, plagioclase, cryolite, and pyrolusite.

Lubricants. Graphite, talc, muscovite.

Paints and pigments. Hematite and limonite as "metallic paint"; the same minerals associated with clay, "ocher." Calcite (chalk) as "whiting"; wad, barite, gypsum, asbestos, muscovite, talc, kaolin, quartz, magnesite, azurite, graphite, asphaltum, rutile.

Paper manufacture. Talc (fibrous), gypsum (selenite), as constituents of sheets. Barite, calcite, kaolin, magnesite, bauxite, muscovite, for weight and glaze.

Porcelain, pottery, etc. Kaolin and other clays, quartz, orthoclase, albite, halite, gypsum and pyrophyllite.

Precious stones. Diamond, beryl, emerald, corundum (sapphire and ruby), chrysoberyl (alexandrite), garnet (demantoid), spinel (ruby spinel). **Semi-precious stones.** Other varieties of beryl, corundum, chrysoberyl, spinel, and garnet. Also opal, chrysolite (peridot), quartz (amethyst and yellow), topaz, tourmaline, turquoise, zircon, spodumene (kunzite, hiddenite), orthoclase (moonstone). **Ornamental stones.** Amber, chalcedony (onyx, carnelian, sard, agate, etc), quartz (rose cat's eye, aventurine, smoky, etc), orthoclase (amazon stone), plagioclase (labradorite and sunstone). Amphibole (jade), lazurite (lapis lazuli), malachite, azurite, calamine, smithsonite, chrysocolla, fluorite, gypsum (satin spar), serpentine, hematite, pyrite, rhodonite, talc. Occasional faceted stones are cut from apatite, andalusite, cassiterite, chondrodite, cyanite, pyroxene (diopside), enstatite, epidote, prehnite, staurolite, sphene and vesuvianite.

Refractory materials and heat insulators. Asbestos, bauxite, chromite, dolomite, graphite, ilmenite, kaolin, magnesite, muscovite, opal (diatomaceous earth), serpentine (chrysotile), quartz, pyrophyllite, talc (soapstone), sillimanite, andalusite, kyanite and vermiculite.

Rubber manufacture. Sulphur, stibnite, barite, calcite, talc, pyrophyllite.

Soap and washing powders, toilet articles. Borax, opal (diatomaceous earth), talc, quartz, magnesite, orthoclase.

Sundries. *Coloring or decolorizing:* pyrolusite, psilomelane, rutile. *Condiments:* halite. *Explosives:* nitre, sulphur. *Filters:* opal (tripolite). *Enamels:* fluorite, borax. *Matches:* stibnite sulphur. *Optical:* quartz, calcite, fluorite, gypsum, muscovite. *Pencils:* graphite, talc, pyrophyllite. *Pipes:* sepiolite (meerschaum), succinite (amber).

14. PRODUCTS EXTRACTED OR MANUFACTURED DIRECTLY FROM MINERALS

Aluminum from bauxite, possibly gibbsite, with cryolite as flux.

Alundum (Al_2O_3) from bauxite.

Aluminium sulphate and alum from alunite, cryolite, bauxite, kaolin.

Antimony from stibnite and its alteration products and lead ores carrying antimony.

Arsenic from arsenopyrite and sometimes from smaltite, cobaltite, enargite, etc.

Barium hydroxide and barium sulphide from barite.

Beryllium and beryllium oxide from beryl.

Bismuth from native bismuth, bismutite, and bismite.

Borax and boric acid, from colemanite, ulexite, borax, and sassolite.

Bromine from halite (salt brine).

Cadmium from sphalerite and smithsonite containing greenockite.

Calcium oxide (*lime*) from calcite (limestone).

Calcium sulphate (*hemi-hydrate*) *or plaster* from gypsum.

Calcium superphosphate from apatite.

Cements from calcite and clays.

Carbonic acid from magnesite and calcite.

Chlorine from hydrochloric acid and pyrolusite, the former being derived from halite.

Chromium alloys, especially ferrochrome from chromite.

Cobalt oxide and cobalt arsenate (*zaffre*) from smaltite, cobaltite, and cobaltiferous limonite.

Copper principally from chalcocite, native copper, chalcopyrite, bornite, cuprite, malachite, and azurite, although enargite, tetrahedrite, atacamite, brochantite, chalcanthite, and chrysocolla are all sources of copper in certain districts. In addition to these the iron sulphides often carry copper which is extracted after burning for sulphuric acid.

Copper sulphate from chalcopyrite.

Gold from gold and the gold tellurides (sylvanite, calaverite, petzite), from silver and copper ores and from pyrite, arsenopyrite and pyrrhotite, and sphalerite and other sulphides or tellurides.

Hydrochloric acid from halite.

Hydrofluoric acid from fluorite and cryolite.

Iodine from sodium iodate obtained from soda nitre.

Iridium from iridosmine.

Iron from hematite, limonite, magnetite, and siderite, goethite, and turgite (commercially included with limonite), some ilmenite, and rarely residues from the roasting of pyrites.

Iron sulphate (ferrous) or "copperas" from pyrite and chalcopyrite.

Iron manganese alloy from franklinite and certain manganiferous hematites and siderites; also from pyrolusite, psilomelane, manganite and other manganese oxides.

Lead, chiefly from galena and cerussite. Anglesite and pyromorphite sometimes occur in quantity.

Lead sulphate (sublimed white lead and blue lead) from galena.

Lithium carbonate from spodumene, lepidolite, and amblygonite.

Magnesium from carnallite.

Magnesium carbonate from dolomite. Basic carbonate from kieserite.

Magnesium oxide from magnesite, and indirectly kieserite.

Magnesium chloride from carnallite.

Magnesium sulphate (epsom salts) from kieserite and less often from magnesite and dolomite.

Manganese alloys from pyrolusite, psilomelane and braunite, or with intermixed rhodochrosite and rhodonite.

Manganese salts from pyrolusite.

Mercury from cinnabar.

Molybdenum and ammonic molybdate from molybdenite.

Nickel from pentlandite, garnierite, nickeliferous pyrrhotite, and to a less extent from millerite, niccolite and the cobalt minerals, cobaltite and linnæite.

Nitric acid from soda-nitre and nitre.

Palladium from copper ores and platinum.

Phosphorus from an impure calcium phosphate (sombrerite), or from bone ash.

Platinum from native platinum and sperrylite, and from some gold and copper ores.

Potassium from carnallite.

Potassium dichromate from chromite.

Potassium sulphate from kainite.

Potassium nitrate from soda nitre and carnallite.

Radium chloride from uraninite, carnotite, and autunite.

Rhodium from platinum.

Selenium from sulphur, chalcopyrite, and pyrite.

Silicon carbide (carborundum) from quartz and coke.

Silicon alloys (ferro-silicon) from quartz.

Silver from native silver, argentite, cerargyrite, embolite, proustite, pyrargyrite, and less important, hessite, polybasite, and iodyrite. Included in other minerals, notably, galena and cerussite, but also in copper ores, manganese ores and with gold in pyrite and arsenopyrite.

Sodium borate (borax) from colemanite, ulexite, sassolite, kernite, and native borax.

Sodium stannate from cassiterite.

Sodium sulphate (salt-cake) from halite, and from this, caustic soda, carbonate, bicarbonate.

Strontium nitrate and chloride from strontianite.

Sulphuric acid, sulphurous acid, from native sulphur, pyrite, marcasite, chalcopyrite, sphalerite, pyrrhotite, and other sulphide ores.

Tantalum from columbite.

Thorium nitrate and thorium oxide from monazite, thorite, thorianite.

Tin and sodium stannate from cassiterite.

Titanium, titanium oxide, and ferro-titanium from ilmenite.

Titanium carbide from rutile.

Tungsten, ferro-tungsten, from wolframite and scheelite.

Tungstate of soda from wolframite.

Uranium yellow or sodium diuranate from uraninite, carnotite.

Vanadium, and ferro-vanadium from carnotite, patronite, roscoelite, vanadinite, descloizite.

Vanadic oxide from mottramite.

Zinc, "*zinc dust*," *and zinc oxide* from sphalerite, smithsonite, and calamine; and in New Jersey, willemite and zincite.

Zinc sulphate from sphalerite.

Zirconium oxide from zircon.

DESCRIPTIVE AND DETERMINATIVE TABLES

Rare species without economic value are omitted. Their inclusion would greatly increase the complexity of the tables and also increase the difficulty of determination.

Rare minerals require special methods beyond the scope of a simple set of mineral tables; chemical analyses, optical, and X-ray determinations are usually necessary.

Due to the limited space the species are described only in the tables, and the accompanying diagrammatic index will enable the user to find a brief description of any species. (For example, scheelite. A reference to 22 in the diagram will give composition, crystal system, hardness, specific gravity, colors, solubility, flame coloration, behavior with fluxes and general appearance.)

The uses and occurrence of minerals are summarized in separate tables. In using the tables the customary precautions are understood to be taken:

1. Tests must be made upon homogeneous materials, and lusters and colors observed on fresh fractures.
2. Classifying tests must be decided; not weak, nor indefinite. If undecided, the species on both sides of the dividing line must be considered.
3. Hardness tests should be assumed to be within say one half; that is, a determination H = 5 should for safety be taken as 4.5 to 5.5.

As shown by the accompanying key, the principal subdivision is between metallic and non-metallic luster. The blowpipe test is made subordinate for minerals of metallic luster and minerals of non-metallic luster with colored streaks; but, for minerals of non-metallic luster with white streaks, experience proves that the blowpipe or the microscope lead to a determination with less repetition than such qualities as color and hardness.

A novel feature of the tables is the "scheme within a scheme," by which the order of testing may be varied. For instance, in 16, 17, 18 the arrangement is by blowpipe tests in order of hardness, but the parallel columns permit color to be used as the classifying test; that is, the order of testing may be color and hardness or blowpipe test and hardness.

Similarly in 5, 6 the arrangement of the metallic white and gray minerals is by streak and hardness, but the parallel columns permit the behavior on charcoal in oxidizing and reducing flame to be used as the classifying test; that is, the order of testing may be color, streak and hardness, or color and behavior on charcoal.

Chemical symbols are used only for the formulas of the species and for the common solvents, HCl, H_2SO_4, HNO_3, KOH, etc. Aside from these a few abbreviations are used, the principal being:

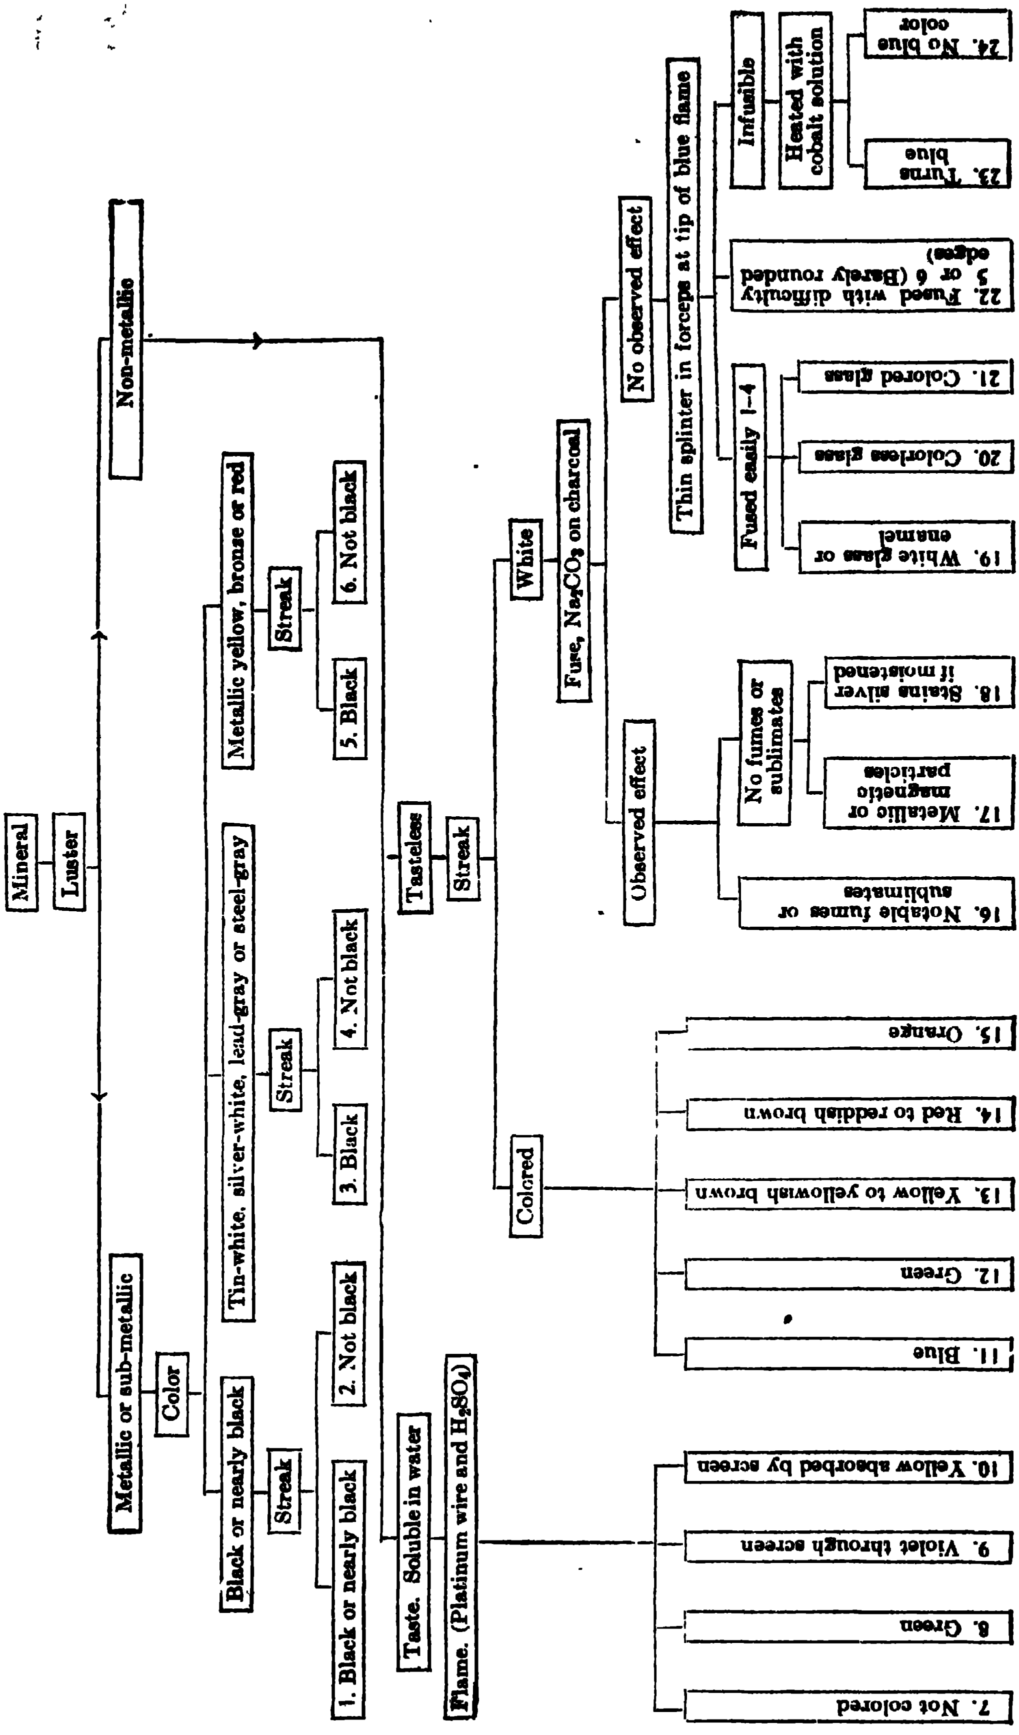
Systems of crystallization are indicated by the letters: I (Isometric), T (Tetragonal), O (Orthorhombic), M (Monoclinic), Tri (Triclinic), H (Hexagonal).

Terms in blowpipe tests. Soda for sodic carbonate, S. Ph. for salt of phosphorus, O. F. and R. F. for oxidizing and reducing flame, Co. Sol. for cobalt solution, coal for charcoal.

The + sign in any column opposite any mineral indicates that the quality indicated is a character of that mineral.

The following diagram furnishes at a glance the procedure to be followed in identifying an unknown mineral:

OUTLINE OF DETERMINATIVE TABLES



Minerals of Metallic or Sub-Metallic Luster, Black or Nearly Black in Color

(Including arbitrarily some dark-colored minerals of doubtful luster)

1. WITH BLACK OR NEARLY BLACK STREAK

Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Fusibility on coal	Solubility	Heated in closed tube	Other tests	Appearance
	Odor		Sublimates	Residue			Not included					
	As	SO$_2$		None	Metallic	Magnetic						
H. Graphite C H = 1 to 2 G = 2.1 to 2.2	....	....	....	....	....	....	+	Infus. Slowly burned	Insoluble	....	In CuSO$_4$ solution in contact with zinc *quickly* copper-plated. (Molybdenite is slowly plated)	Shining flakes and masses or dull, impure masses. Soft, greasy and cold to the touch. Shining mark on paper.
Pyrolusite MnO$_2$ H = 1 to 2.5 G = 4.7 to 4.8	....	....	....	....	....	....	+	Infus. Becomes brown	Sol. HCl (evolution of Cl)	Yields oxygen and often water	Colors borax amethystine in O. F.	Bright, easily bruised needles or fibers or dull masses. Dull mark on paper.
O. Stibnite Sb$_2$S$_3$ H = 2 G = 4.5 to 4.6	....	+	Dense white	+	....	....	....	1	Sol. (with odor H$_2$S)	Fuses. Sublimate black hot, red cold	Made yellow by KOH and partially dissolved. HCl gives orange ppt.	Bright columnar, bladed or fine-grained masses, less frequently in prismatic crystals or interlaced bunches of needle crystals.
I. Argentite Ag$_2$S H = 2 to 2.5 G = 7.2 to 7.6	....	+	....	....	+	....	....	1.5	Sol. HNO$_3$. (Residue S. Ppt. with HCl)	Fuses: No sublimate	With soda, metallic Ag and S reaction	Coatings and disseminated plates. Rarely crystals. Cuts like metallic lead. Streak is shining.
O. Stephanite Ag$_5$SbS$_4$ H = 2 to 2.5 G = 6.2 to 6.3	....	+	White, later reddens	...	+	...	...	1	Sol. HNO$_3$ (white residue)	Fuses. Slight red sublimate	Decomposed by KOH. HCl gives orange ppt.	Fine-grained, often disseminated. Sometimes crystals. Soft but brittle.
I. Galena PbS H = 2.5 G = 7.4 to 7.6	....	+	White O. F. Yellow R. F.	+	+	....	....	2	Sol. excess hot HCl	Decrepitates. A little white sublimate	"Bismuth Flux" on coal gives greenish yellow sublimate	Granular and cleavable masses and cubic crystals which cleave into cubes.

1. WITH BLACK OR NEARLY BLACK STREAK

O. Jamesonite............ $Pb_2Sb_2S_5$ H = 2.5 G = 5.5 to 6	......	+	Dense white. Some yellow	+	+	....	....	1	Sol. (with odor H_2S)	Brownish red sublimate	"Bi. Flux" on coal gives greenish yellow sublimate	Needle crystals, or hair-like or felted; also compact and fibrous massive.
O. Polybasite............ $(Ag \cdot Cu)_9SbS_6$ H = 2 to 3 G = 6 to 6.2	......	+	Dense white	....	+	....	....	1	Sol. HNO_3. (Ppt. with HCl)	Fuses. No sublimate	Metallic residue ignited with HCl gives azure blue flame	Best known in six-sided plates. In thin splinters is cherry red by transmitted light.
O. Chalcocite............ Cu_2S H = 2.5 to 3 G = 5.5 to 5.8	......	+	....	....	+	....	....	2 to 2.5	Sol. HNO_3 (residue S)	Fuses. No sublimate	Emerald green flame made azure blue by HCl	Compact masses, nodules and disseminated. Often coated with the green carbonate. Rarely crystals.
O. Enargite............. Cu_3AsS_4 H = 3 G = 4.4	+	+	Volatile white	....	+	....	....	1	Sol. HNO_3	Decrepitates Yellow subl. then fuses and gives red subl.	Metallic residue ignited with HCl gives azure blue flame	Columnar, granular and compact masses and prisms, sometimes radiating.
Tenorite............... CuO H = 3 G = 5.8 to 6.2	......	......	....	....	+	....	....	Infus. O. F. Fus. R. F.	Soluble	....	Like enargite	Dull earthy masses, powder and shining scales.
I. Tetrahedrite........... $Cu_8Sb_2S_7$ H = 3 to 4.5 G = 4.5 to 5.1	Sometimes	+	Dense white	....	+	....	....	1.5	Sol. HNO_3	Decrepitates. Fuses. Dark red sublimate	Like enargite	Fine-grained masses and "tetrahedral" crystals. Sometimes coated with chalcopyrite.
Psilomelane............. MnO_2, BaO, H_2O, etc. H = 5 to 6 G = 4.5 to 5	......	......	....	....	....	....	+	Infus.	Sol. HCl (evolution Cl)	Oxygen and water	Colors borax amethystine O. F. Solutions usually give white ppt. with H_2SO_4	Massive with smooth rounded surfaces, or stalactitic. Never crystallized.
H. Ilmenite............. $FeTiO_3$ H = 5 to 6 G = 4.5 to 5	......	......	....	....	....	+	+	Infus. O. F. Fus. diff. R. F.	Sol. (boiled with tin is violet)	....	S. Ph. bead. O.F. red. R. F. violet	Thin plates, imbedded grains, sand and tabular hexagonal crystals.
I. Uraninite............. $UO_3 \cdot UO_2$, PbO, etc. H = 5.5 G = 9 to 9.7	Sometimes	......	....	....	....	....	+	Infus.	Sol HNO_3 (yellow)	....	Solutions give yellow ppt. with ammonia. Borax O. F. "flames" yellow enamel near saturation	Massive botryoidal or granular. Pitch-like luster. Rarely small crystals.

Minerals of Metallic or Sub-Metallic Luster, Black or Nearly Black in Color—*Continued*

	Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Fusibility on coal	Solubility	Heated in closed tube	Other tests	Appearance
		Odor		Sublimates	Residue			Not included					
		As	SO_2		None	Metallic	Magnetic						
STREAK BLACK OR NEARLY BLACK	I. Magnetite Fe_3O_4 H = 5.5 to 6.5 G = 4.9 to 5.2						+		5.5 in R. F.	Sol. HCl		Magnetic before heating but loses magnetism in O. F.	Coarse- and fine-grained masses and sand and octrahedral crystals. Strongly attracted by a steel magnet. Sometimes itself a magnet (lodestone).
	O. Columbite $Fe(CbTa)_2O_6$ H = 6 G = 5.4 to 6.5							+	Infusible	Insoluble		Fused $KHSO_4$ and boiled HCl and tin give deep blue	Prismatic crystals, often iridescent, in pegmatite dikes. Also massive.
	T. Braunite Mn_2O_3 H = 6 to 6.5 G = 4.7 to 4.8							+	Infusible	Sol. HCl (evolution Cl)	A little water no oxygen	Colors borax amethystine in O. F. Solution often yields silica jelly	Fine-grained masses and occasional small pyramids almost isometric.
2. WITH STREAK NOT BLACK	H. Pyrargyrite Ag_3SbS_3 H = 2.5 G = 5.7 to 5.8		+	Dense white		+			1	Sol. HNO_3. White residue	Subl. black hot, red cold	Decomposed by KOH. HCl produces orange ppt.	Veins or crusts with a brilliant adamantine luster showing red tint. in thin layers. Rare crystals. Streak purplish-red.
	I. Sphalerite ZnS H = 3.5 to 4 G = 3.9 to 4.1		+	Yellow hot, White cold	+				Infusible (or fus. with difficulty)	Effervesces. Gives odor H_2S	No sublimate	Sublimate on coal made bright green by ignition with cobalt solution	Black and gray crystals and cleavable to fine-grained masses. Streak pale brown.
	O. Manganite MnO (OH) H = 4 G = 3.7 to 4.7							+	Infusible. (Becomes brown)	Sol. HCl. (Evolves Cl)	Much water. A little oxygen	Borax O. F. amethystine	Crystals often grouped in bundles, rarely massive, granular or stalactitic. Streak dark brown.

2. WITH STREAK NOT BLACK

Limonite $Fe_2(OH)_6 \cdot Fe_2O_3$ H = 5 to 5.5 G = 3.6 to 4	.....	.....	.....	....	....	+	....	5 to 5.5 to slag	Soluble	Reddens. Yields much water	Often reacts for manganese and may give jelly residue	Cellular and pulverulent or as compact masses often radiated or stalactitic and with varnish-like surfaces. Never crystallized. Streak yellowish-brown.
O. Goethite FeO (OH) H = 5 to 5.5 G = 4 to 4.4	.....	.....	.....	....	....	+	...	5 to 5.5 to slag	Soluble	Reddens. Yields water	Often reacts for manganese. (Soda bead O. F. bluish green)	Occurs massive but is best known as crystals, often flattened like scales, or needle-like, or in parallel position. These shade into feather-like and velvety crusts.
T. Hausmannite Mn_3O_4 H = 5 to 5.5 G = 4.7 to 4.8	.....	.....	.....	....	....	...	+	Infusible	Sol. HCl. (Evolves Cl)	....	Borax O. F. amethystine	Granular masses occasionally in twinned pyramids. Streak chestnut brown.
M. Wolframite (FeMn) WO_4 H = 5 to 5.5 G = 7.1 to 7.5	.....	.....	.....	....	....	+ (if fused)	....	3 to 4 (crystalline bead)	Partial	....	Solutions become deep blue on addition of tin. Solution of S. Ph. bead in HCl best	Heavy monoclinic crystals and cleavable, bladed and granular masses. Streak brownish black.
Ilmenite $FeTiO_3$ H = 5 to 6 G = 4.5 to 5	.....	.....	.....	....	....	+	+	Infus. O. F. Slightly R. F.	Partial	....	Filtered solution boiled with tin becomes violet	Usually compact masses, often thin plates or imbedded grains or as sand. Rarely in tabular hexagonal crystals. Streak brownish red.
I. Uraninite $UO_3 \cdot UO_2$, etc H = 5.5 G = 9 to 9.7	.....	.....	.....	....	....	....	+	Infusible (or fused with difficulty)	Sol. HNO_3 (to yellow liquid)	....	Solution gives yellow ppt. with ammonia. Borax R. F. green, near saturation blackens	Botryoidal or granular with pitch-like luster. Rarely in small isometric crystals. Streak dark green.
I. Chromite $FeCr_2O_4$ H = 5.5 G = 4.3 to 4.6	.....	.....	.....	....	....	....	+	Infusible O. F. Slightly R. F.	Insoluble	....	Borax or S. Ph., O. F. or R. F., emerald green cold	Granular or compact or rarely in small octahedral crystals. Pitch-like luster. Often with serpentine. Streak dark brown.

Minerals of Metallic or Sub-Metallic Luster, Black or Nearly Black in Color—*Continued*

2. WITH STREAK NOT BLACK

Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Fusibility on coal	Solubility	Heated in closed tube	Other tests	Appearance
	Odor		Sublimates	Residue			Not included					
	As	SO_2		None	Metallic	Magnetic						
H. Hematite Fe_2O_3 H = 5.5 to 6.5 G = 4.9 to 5.3	......	....	....	....	....	+	....	Infusible	Soluble	....	....	Coarse to fine micaceous masses and tabular or coarser crystals with brilliant luster. Occasionally kidney-shaped. Streak brownish red.
O. Columbite Fe $(CbTa)_2O_6$ H = 6 G = 5.4 to 6.5	....	....	....	...	..	....	+	Infusible	Insoluble	....	Fused with KOH and boiled with HCl and tin gives blue solution.	Masses and brilliant, often iridescent, prismatic crystals. Streak dark red.
I. Franklinite (FeMnZn) O $(FeMn)_2O_3$ H = 6 to 6.5 G = 5 to 5.2	.....	.....	Slight white	..	..	+	....	Infusible	Slowly in HCl evolving Cl	....	Soda bead O. F. bluish green	Compact masses, rounded grains and octahedral crystals. Slightly magnetic. Red zincite and yellow to green willemite are associates. Streak dark brown.
T. Rutile TiO_2 H = 6 to 6.5 G = 4.1 to 4.2	.....	....	....	...	...	...	+	Infusible	Insoluble	....	S. Ph. bead in R. F. violet	Masses and crystals with considerable luster. Streak pale yellow.
T. Cassiterite SnO_2 H = 6 to 7 G = 6.8 to 7.1	......	.....	Some varieties give white sublimate	.	..	..	+	Infusible	Insoluble	....	With soda or sulphur on coal in strong heat a subl. yellow hot, white cold, made bluish green by ignition with cobalt solution	Brilliant crystals, usually with brown tinge. Streak pale yellow.

3. WITH BLACK STREAK

Minerals of Metallic Luster, Tin-White, Silver-White, Lead-Gray or Steel-Gray in Color

Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Solubility	Heated in closed tube	Other tests	Appearance
	Odor		Sublimates	Residue			Fusibility				
	As	SO_2		None	Metallic	Magnetic					
O. Stibnite Sb_2S_3 H = 2 G = 4.5	......	+	Dense white. Volatile	+	....	....	1	Sol. HCl hot (odor H_2S)	Fuses, yields subl. black hot, brownish red cold	Solution in upper part test tube repptd. as orange by H_2S from dissolving portion	Lead-gray columnar or fine-grained masses or prisms. Cleaves into lath-shaped fragments.
I. Galenite PbS H = 2.5 G = 7.4 to 7.6	......	+	White, O. F. Yellow R. F.	+	+	....	2	Sol. HCl hot. (Crystals on cooling)	Decrepitates. A little white sublimate	Greenish yellow subl. on coal with Bi flux	Lead-gray granular and cleavable masses and cubic crystals which cleave into cubes.
O. Jamesonite $PbSb_2S_5$ H = 2.5 G = 5.5 to 6	......	+	Dense white. Some yellow, volatile	+	+	....	1	Sol. (with odor H_2S)	Subl. brownish red cold	Like galenite	Steel-gray to dark-gray needle crystals, or hair-like or felted; also compact and fibrous massive.
I. Tetrahedrite $Cu_8Sb_2S_7$ H = 3 to 4.5 G = 4.5 to 5.1	Sometimes	+	Dense white	....	+	....	1.5	Sol. HNO_3	Fuses. Dark-red sublimate	Metallic residue ignited with HCl gives azure blue flame	Steel-gray fine-grained masses and tetrahedral crystals.
I. Stannite (Cu·Sn·Fe) S H = 4 G = 4.5	......	+	Non-volatile white sublimate (yellow hot)	....	+	....	1.5	Sol. HNO_3 (green with white residue)	....	Subl. on coal becomes bluish green by ignition with cobalt solution	Steel-gray, massive, granular. Often intermixed with yellow chalcopyrite.
I. Linnæite $(Co·Ni)_3S_4$ H = 5.5 G = 4.8 to 5	......	+	....	....	....	+	2	Sol. HNO_3 (red with sulphur residue)	Slight yellow sublimate	Borax deep blue O. F. and R. F.	Steel-gray granular or compact masses, or small octahedral crystals.
I. Cobaltite $CoAs_2$ H = 5.5 G = 6 to 6.1	+	+	Volatile white sublimate	....	....	+ (weak)	Easy	Sol. HNO_3 (red with white residue)	Unaltered	Like linnæite	Gray masses and tin-white crystals. Often a red tarnish.

Minerals of Metallic Luster, Tin-White, Silver-White, Lead-Gray or Steel-Gray in Color—*Continued*

4. WITH STREAK NOT BLACK

Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Solubility	Heated in closed tube	Other tests	Appearance
	Odor		Sublimates	Residue			Fusibility				
	As	SO_2		None	Metallic	Magnetic					
I. Smaltite $CoAsS$ H = 5 to 6 G = 6.4 to 6.6	+	......	Volatile white sublimate	....	...	+	Easy	Sol. HNO_3 (red to green)	Mirror and black sublimate	Like linnæite	Steel-gray masses and tin-white crystals usually cubes, often with erythrite.
O. Arsenopyrite $FeAsS$ H = 5.5 to 6 G = 6 to 6.2	+	+	Volatile white sublimate	....	....	+	2	Sol. HNO_3 (sulphur residue)	Brownish red subl. Later mirror and black	After short ignition on coal, dissolves in HCl with odor of H_2S and yellow ppt.	Tin-white to gray masses or crystals often striated, the sections of which are rhombic and rectangular.
I. Sperrylite $PtAs_2$ H = 6 to 7 G = 10.6	+	......	Slight vol. sublimate	....	+	....	Easy	Insoluble	....	In open tube white subl. and spongy residue	Tin-white grains and minute crystals
Mercury Hg H = – G = 13.6	......	......	....	+	....	....	Volatilizes	Sol. HNO_3	Subl. of small metallic globules	With Bi flux on plaster, volatile, scarlet and yellow subl.	A tin-white liquid found in scattered globules or in cavities with cinnabar.
H. Molybdenite MoS H = 1 to 1.5 G_1 = 4.6 to 4.9	......	+	Slight white and bronze	....	....	..	Infus.	Sol. conc. HNO_3 (luminous)	....	Colors flame yellowish green and is reddened	Bluish gray scales and foliated masses cleaving to flexible non-elastic plates. Streak greenish-gray on glazed porcelain.
Gold tellurides $(Au \cdot Ag)Te_2$ H = 1.5 to 2.5 G = 7.9 to 9	......	......	Grayish white	....	+	....	1	Sol. HNO_3 (gold residue). In hot H_2SO_4 purple.	....	The sublimate placed on porcelain moistened with conc. H_2SO_4 and warmed is violet	Steel gray to silver white, sometimes inclined to yellow. Incrusting or in small veins. Streak silver white to gray.
H. Bismuth Bi (often with As) H = 2 to 2.5 G = 9.7 to 9.8	Sometimes	......	Yellow and white sublimates	+	+	....	1	Sol. HNO_3 (white ppt. by water)	....	Chocolate brown and red subl. with Bi flux on plaster tablet	Silver white with reddish tinge, often "branching" or in isolated grains. Streak silver white.

4. WITH STREAK NOT BLACK

I. Hessite (Au·Ag)Te H = 2 to 2.5 G = 8.3 to 8.6	......	......	Slight gray sublimate	....	+	....	Easy	Sol. HNO_3. In hot H_2SO_4 purple	....	Like gold telluride	Gray, fine-grained to coarse-grained or in isometric crystals. Streak gray.
H. Tellurium Te with Se·S H = 2 to 2.5 G = 6.1 to 6.3	......	......	Slight gray sublimate	+	....	....	Easy	In hot H_2SO_4 is purple	....	Like gold telluride	Tin-white, fine-grained or minute hexagonal prisms. Streak tin-white.
I. Silver Ag H = 2.5 to 3 G = 10.1 to 11.1	......	......	....	....	+	....	2	Sol. HNO_3 or H_2SO_4	....	Solutions plate copper and give curdy white ppt. with HCl	Pale "silver" white branching crystals, wire flakes and masses. Tarnishes brown to black. Malleable. Streak silver-white.
Antimony Sb H = 3 to 3.5 G = 6.5 to 6.7	Sometimes	......	Dense white volatile	+	....	....	1	Soluble	....	Burns with yellow-green flame	Tin-white, fine-grained or radiated. Very brittle.
H. Arsenic As H = 3.5 G = 5.6 to 5.7	+	......	Volatile white	+	....	....	Volatilizes	Sol. HNO_3	Mirror	Burns with light-blue flame	Tin-white, tarnishing almost black. Usually massive, with rounded surfaces. Sometimes in concentric layers. Streak tin white.
I. Tetrahedrite $Cu_8Sb_2S_7$ H = 3 to 4.5 G = 4.5 to 5.1	Sometimes	+	White volatile	....	+	...	1.5	Sol HNO_3 (green with white residue)	Decrepitates brownish red sublimate	Solutions blue with ammonia. Roasted residue ignited with HCl azure blue flame	Steel-gray fine-grained masses and tetrahedral crystals. Streak cherry red.
I. Platinum Pt (Fe) H = 4 to 4.5 G = 14 to 19	......	......	....	....	+	+	Infus.	Sol. aqua regia only	....	....	Steel-gray to tin-white grains, scales and nuggets. Malleable and sometimes attracted by the magnet. Streak shining steel-gray.
H. Iridosmine (Ir·Os) H = 6 to 7 G = 19 to 21	......	......	....	....	+	....	Infus. (Unpleasant odor)	Insoluble	....	Open tube, pungent, unpleasant odor	Tin-white or gray, very hard flat grains and hexagonal plates. Streak steel gray.

Minerals of Metallic Luster, Metallic Yellow, Bronze or Red in Color

3. WITH BLACK STREAK

Crystal system: name, composition, hardness and specific gravity	On coal in O. F. and R. F.							Solubility	Heated in closed tube	Other tests	Appearance
	Odor		Sublimates	Residue			Fusibility				
	As	SO_2		None	Metallic	Magnetic					
I. Bornite Cu_5FeS_4 H = 3 G = 4.9 to 5.4		+				+	2.5	Sol. HNO_3 (residue S)	Blackens	Magnetic globule is brittle with red fracture and ignited with HCl gives azure blue flame	Red bronze on fresh fracture. Tarnishes in blue, purple and black tints. Very brittle and usually massive.
H. Millerite NiS H = 3 to 3.5 G = 5.3 to 5.6		+				+	1.5 to 2	Sol. aqua. regia		Roasted colors borax O. F. red hot, brown cold	Brass colored in hair-like or needle crystals. Crusts made up of radiating needles.
T. Chalcopyrite $CuFeS_2$ H = 3.5 to 4.1 G = 4.1 to 4.3		+				+	2 to 2.5	Sol. HNO_3 (residue S)	Darkens, may give yellow sublimate	Like bornite except gray "fracture"	Bright-yellow brassy masses and crystals, tarnishing in peacock colors.
I. Pentlandite (Fe·Ni) S H = 3.5 to 4 G = 4.6 to 5		+				+	1.5 to 2			Fused globule yellow on fracture. Borax O. F. reddish brown	Light bronze-yellow masses resembling pyrrhotite but not attracted by a steel magnet. Cleavage octahedral.
H. Pyrrhotite FeS H = 3.5 to 4.5 G = 4.5 to 4.6		+				+	Easy	Effervesces (odor H_2S)	A little S	Slightly magnetic before fusion	Bronze-yellow masses, tarnishing brown. Powder attracted by a steel magnet.
H. Niccolite NiAs H = 5 to 5.5 G = 7.2 to 7.7	+		Volatile, white			+	2	Partial	Mirror sublimate	Borax and roasted material give blue, green, brown, successively as borax is changed	Pale copper-red masses sometimes enclosed in white metallic crust.
I. Pyrite FeS_2 H = 6 to 6.5 G = 4.9 to 5.2		+				+	2.5 (burns)	Sol. HNO_3 (residue S)	Fusible sublimate red hot, yellow cold	Fused mass effervesces in HCl with odor H_2S	Pale brass-yellow cubes or other crystals, isolated or grouped in crusts or bounding a mass. Also massive globular, nodular stalactitic.
O. Marcasite FeS_2 H = 6 to 6.5 G = 4.6 to 4.9		+				+	2.5 (burns)	Sol. HNO_3 (residue S)	Fusible sublimate red hot, yellow cold	Like pyrite	Pale brass-yellow "spear," "cockscomb" and simple tabular crystals. Often radiated. Fresh fracture whiter than that of pyrite.

6. WITH STREAK NOT BLACK	I. Gold Au H = 2.5 to 3 G = 15.6 to 19.3	.....	.....	....	....	+	....	2.5	Sol. aqua regia	....	The fused mass is yellow	Golden yellow to pale yellow nuggets, grains and scales or distorted crystals, passing into wire, fern and leaf forms. Malleable. Streak golden yellow to pale yellow.
	I. Copper Cu H = 2.5 to 3 G = 8.8 to 8.9	.....	.....	....	....	+	....	3	Sol. HNO_3 (green)	....	Fused mass is red and ignited with HCl gives azure blue flame	Copper red, disseminated grains, sheets and irregular masses or groups of extended and branching crystals. Malleable. Streak copper red and shining.

Minerals of Non-Metallic Luster and with Decided Taste (Soluble in Water)

		Crystal system: name, composition, hardness and specific gravity	Taste	Heated on charcoal	Heated in closed tube	Recrystallisation in a drop of water	Appearance
FUSED, POWDERED, MOISTENED WITH CONC. H_2SO_4 AND IGNITED ON PLATINUM WIRE	7. FLAME NOT COLORED	M. Alunogen $Al_2(SO_4)_3\ 18\ H_2O$ H = 1.5 to 2 G = 1.6 to 1.8	Astringent	Fuses, loses water becomes infusible. Deep blue with Co. sol.	Much water, SO_2 and SO_3 at high heat	Feathery	White efflorescence or fibrous crusts.
		O. Epsomite $MgSO_4\ 7\ H_2O$ H = 2 to 2.5 G = 1.7	Bitter	Like alunogen but pink with Co. sol.	Water. Acid at high temperature	Lath shaped	White fibers or crusts.
		M. Copiapite $Fe_2(OH)_2(SO_4)_5\ 18\ H_2O$ H = 2.5 G = 3.1	Metallic, nauseous	Fuses, becomes magnetic	Much acid water	No recrystallisation	Yellow scales or granular masses.
	8. FLAME GREEN	M. Borax $Na_2B_4O_7 + 10\ H_2O$ H = 2 to 2.5 G = 1.7	Sweetish alkaline	F. = 1 to 1.5. Swells and gives clear glass	Puffs up. Gives much water	Unsymmetrical polygons	Show white crystals, crusts or porous masses.
		M. Kernite $Na_2B_4O_7 + 4\ H_2O$ H = 3 G = 1.953	Trace of sweetish taste	F. = 1. Swells and gives a clear glass	Puffs up; gives much water	Unsymmetrical polygons	Transparent, cleavable, colorless crystals, resembling selenite.
		Tri. Sassolite H_3BO_3 H = 1 G = 1.4	Acid	F. = 2. With intumescence to clear glass	Water and a little ammonia	Six-sided plates and threads	White pearly scales or plates.
		Tri. Chalcanthite $CuSO_4\ 5\ H_2O$ H = 2.5 G = 2.1 to 2.3	Metallic, nauseous	Fuses. Reduces with effervescence to copper button	Swells, whitens. Yields water	Blue crystals	Blue glassy crystals, veins and crusts.

Minerals of Non-Metallic Luster and with Decided Taste (Soluble in Water)—*Continued*

		Crystal system: name, composition, hardness and specific gravity	Taste	Heated on charcoal	Heated in closed tube	Recrystallization in a drop of water	Appearance
FUSED, POWDERED, MOISTENED WITH CONC. H_2SO_4 AND IGNITED ON PLATINUM WIRE	9. FLAME VIOLET THROUGH COLOR SCREEN	O. Carnallite $KCl.MgCl.6\ H_2O$ $H = 1$ $G = 1.6$	Salty and bitter	$F. = 1$ to 1.5. Ignited with Co. sol, pink	Much water	Rectangles	White to reddish granular masses. Very deliquescent.
		O. Nitre KNO_3 $H = 2$ $G = 2.1$	Salty and cooling	$F. = 1$. Deflagrates	With $KHSO_4$ brown vapor	Lath shaped	White needles or thin crusts.
		I. Kalinite $KAl\ (SO_4)_2 + 12\ H_2O$ $H = 2.5$ $G = 1.7$	Astringent	$F. = 1$. Swells, froths, will stain silver	Much water. Acid at high heat	Octahedron. (Three-six- and four-sided polygons)	White fibers or mealy efflorescence.
		M. Kainite $MgSO_4KCl + 3\ H_2O$ $H = 2.5$ to 3 $G = 2$ to 2.2	Salty and bitter	Fuses easily and if fused with soda will stain silver	Water	Rectangles	White to brownish red granular masses.
		I. Sylvite KCl $H = 2$ $G = 1.97$ to 1.99	Bitter	$F. = 1.5$	Residue alkaline on moist test paper	Square (cubes)	White or colorless. May be bluish or yellowish red.
	10. FLAME YEL., ABSORBED BY COLOR SCREEN	H. Soda nitre $NaNO_3$ $H = 1.5$ to 2 $G = 2.2$	Cooling	$F. = 1$. Deflagrates	With $KHSO_4$ brown vapor	Rhombic outlines	White, pale red or pale yellow masses and crystals with forms and angles of calcite.
		M. Mirabilite $Na_2SO_4 + 10\ H_2O$ $H = 1.5$ to 2 $G = 1.5$	Bitter	Fuses and will stain silver	Water	Lath shaped	White efflorescence or powdery crust.
		I. Halite $NaCl$ $H = 2.5$ $G = 2.4$ to 2.6	Salty	$F. = 1.5$	A little water	Square (cubes)	White or colorless or impure brown, yellow or red masses and crystals with cubic cleavage.
		M. Trona $NaCO_3.\ NaHCO_3 + 2\ H_2O$ $H = 2.5$ to 3 $G = 2.1$	Alkaline	Fuses easily	Water	Spherulitic	White glistening crusts.

Minerals of Non-Metallic Luster, Tasteless and with Colored Streak

	Crystal system: name, composition, hardness and specific gravity	In powder boiled with hydrochloric acid				Fusibility on coal	Heated in closed tube	Other tests	Appearance
		There is effervescence	There is a residue of jelly	Simple solution	Insoluble				
11. WITH BLUE STREAK	M. Vivianite $Fe_3(PO_4)_2 + 8\,H_2O$ $H = 1.5$ to 2 $G = 2.6$ to 2.7			+		2 to 2.5 (Magnetic)	Water. Turns brown	Momentary blue flame with H_2SO_4 (conc.). Yellow pt. with ammonic molybdate	Bluish-green to dark blue, often earthy and filling shells, horn, etc. Rarely as colorless or glassy crystals, gradually becoming blue.
	—. Chrysocolla $CuSiO_3 \cdot 2\,H_2O$ $H = 2$ to 4 $G = 2$ to 2.3			+ (Separation of silica)		Infusible. (Blackens)	Blackens. Yields water		Enamel-like crusts, veins, or masses.
	M. Azurite $Cu_3(OH)_2(CO_3)_2$ $H = 3.5$ to 4 $G = 3.8$	+				3 (Black)	Blackens. Yields water	Emerald-green flame. Solutions blue with ammonia	Dark-blue glassy crystals, lighter blue crusts, velvety, dull or earthy masses.
	I. Lasurite $Na_4(NaS,Al)Al_2(SiO_4)_3$ $H = 5$ to 5.5 $G = 2.6$ to 2.9	+ (Odor H_2S)	+			3.5 (White)	Water. Green glow	Yellow flame	Deep-blue fine-grained masses, usually spangled with pyrite and intermixed with other minerals.
12. WITH GREEN STREAK	Chlorite group $H = 1$ to 2.5 $G = 2.6$ to 2.9 (Micaceous dark-green minerals such as clinochlore $H_8Mg_5Al_2Si_3O_{18}$)				+	Fuses. (Colored)	Much water	Milky solutions with concentrated H_2SO_4	Dark-green masses of coarse to very fine scales. Tabular and curiously twisted six-sided crystals and fan-shaped groups which cleave into thin soft pliable but not elastic plates. Also as a pigment in other minerals.
	Garnierite $H_2(Ni \cdot Mg)SiO_4 + H_2O$ $H = 2$ to 3 $G = 2.3$ to 2.8			+ (Separation of silica)		Infusible. (Magnetic)	Blackens. Yields water	Borax O.F. violet hot, brown cold	Dark emerald-green masses, often cellular and very crumbly and paler-green masses and crusts. Luster dull.
	O. Atacamite $Cu_2(OH)_3Cl$ $H = 3$ to 3.5 $G = 3.7$ to 3.8			+ (Green)		3 to 4 (Copper)	Acid water	Azure blue flame. White and red sublimates	Deep emerald-green, confused aggregates and slender prisms. Formerly found as a sand.

Minerals of Non-Metallic Luster, Tasteless and with Colored Streak—*Continued*

	Crystal system: name, composition, hardness and specific gravity	In powder boiled with hydrochloric acid				Fusibility on coal	Heated in closed tube	Other tests	Appearance
		There is effervescence	There is a residue of jelly	Simple solution	Insoluble				
12. WITH GREEN STREAK	M. Malachite $Cu_2(OH)_2CO_3$ H = 3.5 to 4 G = 3.9 to 4	+				3. (Black)	Blackens. Much water	Green flame, blue with HCl	Bright-green radiating fibers or crusts, often banded in shades of green, sometimes stalactitic. Also dull green and earthy. Rarely, slender crystals.
	O. Brochantite $CuSO_4 \cdot 3Cu(OH)_2$ H = 3.5 to 4 G = 3.9			+		Fuses. (Copper)	Water. May blacken. Acid at high temperature	Green flame, blue with HCl. Fused with soda, stains silver	Emerald-green needle crystals. Fibrous veins and crusts.
	Turquois $Al_2(OH)_3PO_4H_2O$ H = 6 G = 2.6 to 2.8			+		Infusible. (Brown)	Blackens. Yields water	Yellow ppt. as in vivianite. Green flame, blue with HCl	Sky-blue to green nearly opaque nodules or veins, with luster of wax.
13. WITH YELLOW TO YELLOWISH-BROWN STREAK	H. Iodyrite AgI H = 1 G = 5.6 to 5.7				+	Fuses. (Silver)	Fuses, orange hot, yellow cold	Closed tube with $KHSO_4$ violet vapor and globule deep red hot, yellow cold. Unchanged by sun	Yellow or yellowish-green, thin veins or flexible plates or crystals. Cuts like wax and is not affected by sunlight. Streak yellow.
	Sulphur, S H = 1.5 to 2.5 G = 2.0 to 2.1				+	1 SO_2 odor. Blue flame)	Fusible subl. brown hot, yellow cold		Sulphur yellow to brown, translucent crystals, irregular masses, crusts, stalactites and powder. Streak pale yellow.
	O. Orpiment As_2S_3 H = 1.5 to 2 G = 3.4 to 3.6				+	1 (Arsenical odor. Blue flame)	Boils. Transparent yellow sublimate	Soluble in nitric acid with separation of sulphur	Lemon yellow, foliated and cleavable to flexible scales, also granular, and as small crystals. Streak lemon yellow.
	O. Autunite $Ca(UO_2)_2(PO_4)_2 + 8H_2O$ H = 2 to 2.5 G = 3 to 3.2			+ (Green)		Easy (Black and crystalline)	Fades. Yields water	Yellow ppt. as in vivianite. Borax colorless O. F., green R. F.	Yellow tabular nearly square crystals and scales and foliated aggregates. Streak pale yellow.
	H. Greenockite CdS H = 3 to 3.5 G = 4.9 to 5	+ (Odor H_2S)				Infusible but brown sublimate	Carmine hot, yellow cold	The coal may show also a variegated tarnish	Bright yellow coating or inclusion with zinc minerals. Streak orange yellow.

18. WITH YELLOW TO YELLOWISH-BROWN STREAK

H. Vanadinite $Pb_5Cl(VO_4)_3$ H = 3 G = 6.6 to 7.8	....	....	+ (Residue)	....	1.5 (Black)	With $KHSO_4$. Red hot, yellow cold	On coal greenish yellow subl. with Bi flux. With S. Ph. O. F. amber, R. F. green	Red, yellow or brown. Sharp hexagonal prisms, sometimes hollow. Also globular masses. Streak pale yellow.
H. Pyromorphite $Pb_5Cl(PO_4)_3$ H = 3.5 to 4 G = 5.9 to 7.1	....	....	+ (Residue)	....	2 (Recrystallizes)	....	Yellow ppt. as in vivianite. Greenish yellow subl. on coal with Bi flux	Green, brown or gray. Hexagonal prisms and tapering groups in parallel position. Also rounded and moss-like aggregations.
H. Siderite $FeCO_3$ H = 3.5 to 4 G = 3.8 to 3.9	+ (Slowly in cold acid)	....			5 (Black and magnetic)	Blackens, becomes magnetic	Solution gives dark-blue ppt. with potassic ferricyanide (ferrous iron)	Brown crusts of curved (rhombohedral) crystals, or massive with cleavage at 107°, or granular. Streak pale yellow.
I. Sphalerite ZnS H = 3.5 to 4 G = 3.9 to 4.1	+ (Odor H_2S)	....			Infusible or with difficulty	No sublimate	On coal subl. yellow hot, white cold, bright green if ignited with cobalt solution	Yellow-brown or black transparent to translucent crystals and cleavable masses with strong resinous luster, and compact fine-grained masses or alternate concentric layers with galena. Streak pale brown.
O. Goethite FeO (OH) H = 5 to 5.5 G = 4 to 4.4	....	....	+	....	5 to 5.5 (Black. Magnetic)	Water. Reddens	On coal R. F. strongly magnetic	Occurs massive but is best known as yellowish to brown and red needles, scales and velvety crusts. Streak yellow to yellowish brown.
Limonite $Fe_2O_3 \cdot Fe_2(OH)_6$ H = 5 to 5.5 G = 3.6 to 4	....	....	+	....	5 to 5.5 (Black. Magnetic)	Much water. Reddens	Like goethite	Brown dull-lustered heterogeneous bog ore, cellular stalactitic and pipe-like concretions of rusty brown to nearly black, often fibrous smooth masses.
T. Rutile TiO_2 H = 6 to 6.5 G = 4.1 to 4.2	....	....	....	+	Infusible	....	S. Ph. O. F. slowly to yellow, made violet R. F.	Brownish red to nearly black crystals with brilliant luster often parallel or netted. More rarely massive. Streak pale brown.
T. Cassiterite SnO_2 H = 6 to 7 G = 6.8 to 7.1	....	....	....	+	Infusible	....	On coal strongly heated and aided by soda or sulphur gives button and subl. yellow hot, white, cold, bluish green if ignited with cobalt solution	Brown to red and nearly black. Dull, kidney-shaped and rounded pebbles. Brilliant crystals, and disseminated grains. Streak pale brown.

Minerals of Non-Metallic Luster, Tasteless and with Colored Streak—*Continued*

14. WITH RED TO REDDISH-BROWN STREAK

Crystal system: name, composition, hardness and specific gravity	In powder boiled with hydrochloric acid				Fusibility on coal	Heated in closed tube	Other tests	Appearance
	There is effervescence	There is a residue of jelly	Simple solution	Insoluble				
M. Erythrite $Co_3(AsO_4)_2 \cdot 8H_2O$ H = 1.5 to 2.5 G = 2.9	....	....	+ (Light red)	....	Fuses. (Garlic odor)	Water	Borax deep blue, O. F. and R. F.	Pink earthy crusts or powder or crimson fibers. Streak pink to crimson.
H. Cinnabar HgS H = 2 to 2.5 G = 8 to 8.2	....	....	....	+	Volatilizes without fusion	Black subl., red if rubbed	Closed tube with soda metallic mirror which can be collected into visible globules. Soluble aqua regia	Vermilion, scarlet and dark brownish-red fine-grained masses. Crystalline crusts. Streak scarlet.
H. Proustite Ag_3AsS_3 H = 2 to 2.5 G = 5.6 to 5.7	....	....	....	+	1 (Garlic odor. Silver)	Fuses. Slight red subl., yellow cold	Soluble HNO_3. Decomposed by boiling KOH and a yellow ppt. by HCl	Scarlet to vermilion crusts or masses. Rare six-sided prisms with brilliant adamantine luster. Streak scarlet.
H. Pyrargyrite Ag_3SbS_3 H = 2.5 G = 5.8	....	....	....	+	1 (White subl. Silver)	Fuses. Subl. black hot, red cold	As with proustite but ppt. is orange	Blackish red veins or crusts with a brilliant adamantine luster. Red tint stronger in thin layers. Rare crystals. Streak purplish red.
Bauxite $Al_2O(OH)_4$ H = 1 to 3 G = 2.4 to 2.5	....	....	+	....	Infusible	Water at high heat	Deep blue if ignited with cobalt solution	Red to reddish-brown masses of rounded grains or clay-like. Dull in luster. Streak reddish brown.

14. WITH RED TO REDDISH-BROWN STREAK	I. Cuprite Cu_2O H = 3.5 to 4 G = 5.8 to 6.1			+ (Brown)		3 (Copper)		Ignited with HCl, azure-blue flame	Dark-red to brick-red masses. Deep-red to crimson isometric crystals, sometimes hair-like. Streak brownish red, shining.
	H. Ilmenite $FeTiO_3$ H = 5 to 6 G = 4.5 to 5			+ (Slowly)		Infusible O. F. with difficulty R. F.		Solution boiled with tin becomes violet. Fused with soda is magnetic	Brownish-black to rusty-brown plates, grains and masses and thin tabular crystals. Streak brownish red.
	H. Hematite Fe_2O_3 H = 5.5 to 6.5 G = 4.9 to 5.3			+		Infusible (Magnetic)		Dark-blue ppt. with potassic ferrocyanide	Dull dark red, massive, oölitic, or earthy, sometimes kidney-shaped and fibrous. Streak brownish red.
15. WITH ORANGE STREAK	M. Realgar As_2S_2 H = 1.5 to 2 G = 3.4 to 3.6				+	1 (Burns blue flame)	Boils, gives subl. black hot, red cold	Soluble KOH. HCl ppts. yellow flakes. Soluble HNO_3	Orange-red granular masses of resinous luster and transparent crystals. Streak orange red.
	M. Crocoite $PbCrO_4$ H = 2.5 to 3 G = 5.9 to 6.1			+		1.5 (Lead)	With $KHSO_4$ dark violet hot, greenish cold	In S. Ph. O. F. and R. F. bright green. On coal Bi flux greenish yellow	Hyacinth red prisms. Streak orange yellow.
	O. Descloizite $(PbOH)\ VO_4\ (Pb, Zn)$ H = 3.5 G = 5.9 to 6.2			+		Fuses (Lead)	Some water	In S. Ph. O. F. amber, R. F. green. On coal with Bi flux greenish yellow	Black, brown or red crusts of minute crystals. Streak brownish orange.
	H. Zincite ZnO H = 4 to 4.5 G = 5.4 to 5.7			+		Infusible (Sublimate)	Blackens	Sublimate ignited with cobalt solution is bright green	Deep red to brick-red adamantine masses. Granular or cleavable. Very rare crystals. Streak orange yellow.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding Reactions on Charcoal with Sodic Carbonate

FUSED ON CHARCOAL WITH SODIC CARBONATE YIELDS:

16. NOTABLE FUMES OR SUBLIMATES

Crystal system name, composition, hardness and specific gravity	The color of the mineral is								Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
	Blue	Green	Yellow	Brown	Red	Gray	Colorless or white	Black					
O Sulphur S H = 1.5 to 2.5 G = 2 to 2.1		+	+	+					Insoluble	Blue	Yellow fusible Sublimate brown hot	Takes fire and burns with odor SO_2	Bright translucent crystals and masses or powder with resinous or dull luster
—Hydrozincite $Zn_3CO_3(OH)_4$ H = 2 to 2.5 G = 3.6 to 3.8							+		Sol with effervescence		Water Yellow hot	On coal R. F heavy white subl made bright green by ignition with cobalt solution	Chalk-like masses or crusts on other zinc minerals
O Valentinite Sb_2O_3 H = 2.5 to 3 G = 5.6							+		Soluble	Yellow green (Coal R F)	Fuses, partly sublimes	Volatile white subl on coal	White silky minute crystals or radiating fibers
O Anglesite $PbSO_4$ H = 3 G = 6.1 to 6.4						+	+		Insoluble		Decrepitates	Bright yellow subl on coal with Bi flux	Simple crystals, often transparent and colorless. White brittle masses and compact granular masses of gray color from intermixed galena
T Wulfenite $PbMoO_4$ H = 3 G = 6.7 to 7			+	+	+	+			Partial to green solution		Darkens Decrepitates	Like anglesite Also solution, cooled, diluted boiled with tin is blue	Tabular square crystals of resinous luster.

FUSED ON CHARCOAL WITH SODIC CARBONATE YIELDS:

16. NOTABLE FUMES OR SUBLIMATES

H. Vanadinite............ $Pb_5Cl(VO_4)_3$ H = 3 G = 6.6 to 7.2	....	....	+	+	+	...	...	..	Sol. HNO_3 to yellow solution	....	With $KHSO_4$ yellow to red hot, yellow cold	S. Ph. O. F. amber, R. F. green	Sharp hexagonal prisms, sometimes hollow. Also parallel groups and globular masses.
O. Cerussite............ $PbCO_3$ H = 3 to 3.5 G = 6.5 to 6.6	....	....	+	+	...	+	+	...	Sol. with effervescence in hot HCl. Crystals on cooling	....	Turns yellow then red, cools yellow	Like anglesite	Twinned crystals or interlaced fibers or granular masses, often with galena.
H. Pyromorphite......... $Pb_5Cl(PO_4)_3$ H = 3.5 to 4 G = 5 9 to 7.1	....	+	+	+	...	+	....	...	Sol. HNO_3	....	....	Like anglesite. Also fuses O. F. and on cooling has facets	Hexagonal prisms and tapering groups in par'l'el position. Also rounded and moss-like aggregations.
I. Sphalerite............ ZnS H = 3.5 to 4 G = 3.9 to 4.1	...	....	+	+	+	...	+	+	Sol. with effervescence and odor H_2S	....	....	On coal R. F. heavy white subl. made bright green by ignition with cobalt solution	Transparent to translucent crystals and cleavable masses with strong resinous luster. Compact masses or alternate layers with galena. Rarely a white powder.
Hemimorphite (calamine) $(ZnOH)_2SiO_3$ H = 4.5 to 5 G = 4.3 to 4.5	+	+	+	+	....	....	+	...	Sol. with jelly	....	Water	Like sphalerite (best if soda and borax added in ignition)	White masses, the cavities lined with crystals, often showing only ends, usually parallel, forming ridges. The fracture shows the crystals like parallel fibers.
H. Smithsonite........... $ZnCO_3$ H = 5 G = 4.3 to 4.5	+	+	+	+	...	+	+	...	Sol. with effervescence	....	Yellow hot, if pure	Like sphalerite	Porous, cellular masses. Crusts with smooth rounded surfaces. Occasional drusy surfaces, the crystal ends being three-faced.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding Reactions on Charcoal with Sodic Carbonate—*Continued*

FUSED ON CHARCOAL WITH SODIC CARBONATE YIELDS:	Crystal system: name, composition, hardness and specific gravity	The color of the mineral is:								Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
		Blue	Green	Yellow	Brown	Red	Gray	Colorless or white	Black					
16. NOTABLE FUMES OR SUBLIMATES	H. Willemite Zn_2SiO_4 H = 5.5 G = 3.9 to 4.2		+	+	+	+				Sol. with jelly			Like sphalerite	Granular masses intermixed usually with black and red grains. Rarely large reddish or brownish crystals. Luster resinous.
	T. Cassiterite SnO_2 H = 6 to 7 G = 6.8 to 7.1			+	+				+	Insoluble			On coal with soda non-volatile subl. made bluish green by ignition with cobalt solution	Crystals with brilliant adamantine luster, disseminated grains and rounded heavy pebbles dull and often with radiating structure.
17. NO FUMES OR SUBLIMATES BUT IS REDUCED TO METALLIC OR MAGNETIC PARTICLES	I. Cerargyrite AgCl H = 1 to 1.5 G = 5 to 5.5				+		+			Insoluble		With $KHSO_4$ yellow hot, white cold, violet in sun	On coal acrid odor and silver button	Thin crusts which darken in sunlight and cut like wax with shining surface after cutting.
	I. Embolite Ag (Cl·Br) H = 1 to 1.5 G = 5.3 to 5.8		+							Insoluble		With $KHSO_4$ dark red hot, dark yellow cold, dark green in sun	Like cerargyrite	Like cerargyrite.
	Chrysocolla $CuSiO_3 \cdot 2H_2O$ H = 2 to 4 G = 2 to 2.3	+	+							Sol. with residue	Emerald green	Blackens. Yields water	With soda on coal, a copper button	Enamel-like crusts, veins or compact masses. Never crystals.
	H. Siderite $FeCO_3$ H = 3.5 to 4 G = 3.8 to 3.9				+		+			Slow effervescence in cold acid		Black and magnetic	On coal becomes black and magnetic	Compact, fine-grained and cleavable masses and rhombohedral curved crystals. Cleavage angles 107°.

FUSED ON CHARCOAL WITH SODIC CARBONATE YIELDS:

18. NO FUMES, SUBLIMATES OR REDUCED PARTICLES, BUT IF MOISTENED WILL STAIN SILVER

M. Gypsum $CaSO_4\,2\,H_2O$ H = 1.5 to 2 G = 2.3	....	....	....	+	+	+	+	....	Soluble. Recrystallises on evaporation	Yellowish red	Whitens. Yields water	....	Soft, colorless or slightly tinted masses, which may be scaly, silky fibrous or compact or may be masses and crystals, cleaving in three directions to a rhombic plate of 66°.
O. Barite $BaSO_4$ H = 2.5 to 3.5 G = 4.3 to 4.6	+	....	+	+	+	+	+	....	Insoluble	Yellowish green	....	....	Granular, cleavable and fibrous. Crystals common. Cleaves in three directions to rhombic plates of 78½°.
O. Celestite $SrSO_4$ H = 3 to 3.5 G = 4	+	....	....	....	....	+	+	....	Insoluble	Crimson	....	....	Colorless to white crystals and fibrous, lamellar and granular masses. Cleaves in three directions to rhombic plates of 76°.
O. Anhydrite $CaSO_4$ H = 3 to 3.5 G = 2.9 to 3	+	....	....	....	+	+	+	....	Soluble. White ppt. with $BaCl_2$	Yellowish red	....	....	Cleavable and fine-grained masses. Cleaves in three directions at 90°.
H. Alunite $K\,(AlO_2)\,(SO_4)_2+3\,H_2O$ H = 3.5 to 4.5 G = 2.6 to 2.7	....	....	....	....	....	....	+	....	Partial	Violet. (Color Screen)	Water at high heat	Blue by ignition with Co. solution	Fibrous or lamellar or small cuboids, usually mixed with hard, siliceous material.
I. Lasurite (Lapis Lasuli) $Na_4\,(NaS_3Al)$ $Al_2\,(SiO_4)_3$ H = 5 to 5.5 G = 2.4	+	....	....	....	....	....	....	....	Sol. with jelly and odor H_2S	Yellow	Water and green glow	Blue in fine powder	Fine-grained, usually spangled with pyrite and intermixed with other minerals.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding No Tests with Sodic Carbonate

A THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

19. FUSES EASILY (1 to 4) TO WHITE GLASS OR ENAMEL

Crystal system: name, composition, hardness and specific gravity	The color of the mineral is:								Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
	Purple or violet	Blue	Green	Yellow	Brown	Red	Gray	Colorless or white					
M. Lepidolite $(KLi)_3Al\ (SiO_3)_3$ H = 2 to 2.5 G = 2.8 to 3.2	+	...	...	...	...	+	+	...	Slight in HCl	Crimson	...	...	Masses of coarse or fine scales with easy cleavage into thinner plates.
M. Cryolite $AlNa_3F_6$ H = 2.5 G = 2.9 to 3	...	...	...	...	+	...	+	+	Soluble	Yellow	Etches tube	Blue if ignited with Co. solution	Translucent masses resembling watery snow. Rarely small six-sided monoclinic crystals nearly cubes.
I. Fluorite CaF_2 H = 4 G = 3 to 3.3	+	+	+	+	+	+	...	+	Soluble	Red to orange	Phosphorescent. With $KHSO_4$ etches tube	...	Transparent cubes and masses of glassy luster which cleave in four directions at angles 70° 31′. Color usually brilliant. Sometimes banded.
M. Stilbite $H_4R_2Al_2\ (SiO_3)_6 + 4\ H_2O$ H = 3.5 to 4 G = 2.1 to 2.2	...	...	...	+	+	...	...	+	Soluble with residue	...	Water	Swells greatly during fusion	Sheaf-like groups or many small crystals forming a crust or lining. One easy cleavage giving symmetrical pearly face.
H. Chabazite $(CaNa_2)Al\ (SiO_4)_3\ 6\ H_2O$ H = 4.5 G = 2.0 to 2.1	...	...	...	...	...	+	...	+	Soluble with lumps jelly	...	Much water	Intumescence during fusion	Groups of small rhombohedral crystals which are nearly cubes.
T. Apophyllite $H_{14}K_2Ca_8\ (SiO_3)_{16}\ 9\ H_2O$ H = 4.5 to 5 G = 2.3 to 2.4	...	...	...	...	...	+	...	+	Soluble with lumps jelly	Pale violet (Color Screen)	Much water	Exfoliates during fusion	Tabular or "cubic" or pointed crystals with internal opalescence. Occasionally lamellar. One easy cleavage.

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

19. FUSES EASILY (1 TO 4) TO A WHITE GLASS OR ENAMEL

T. Wernerite Group Silicates of NaCaAl H = 5 to 6 G = 2.7	....	+	+	....	....	+	+	+	Imperfect	Yellow	....	Bubbles in fused material	Coarse thick crystals with octagonal or square cross-section. Cleavage angles 135° or 90°. Cleavages faintly fibrous. More rarely massive columnar or fine-grained aggregates.
Tri Plagioclase $nNaAlSi_3O_8+$ $mCaAl_2Si_2O_8$ H = 5 to 7 G = 2.6 to 2.7	....	....	....	....	....	....	....	....	....	....	....	....	Masses and crystals with two easy cleavages, nearly but not exactly 90°. Often show parallel striations. Sometimes opalescent.
(Albite)	....	....	....	....	....	....	....	+	Insoluble	Yellow	....	....	
(Labradorite)	....	....	....	....	....	....	+	....	Partial				
Tri. Amblygonite Li (AlF) PO_4 H = 6 G = 3 to 3.1	....	....	....	....	....	....	....	+	Insoluble	Crimson to yellowish red	Water and etching of tube	Momentary blue-green flame with H_2SO_4	Cleavable masses and rough crystals. One easy cleavage.
O. Prehnite $H_2Ca_2Al_2(SiO_4)_3$ H = 6 to 6.5 G = 2.8 to 2.9	....	....	+	+	....	....	....	....	Soluble	....	A little water	After fusion dissolves leaving jelly	Lining cavities as smooth rounded crusts or as sheaf-like groups of tabular crystals. Sometimes in barrel-shaped crystals.
H. Tourmaline $R_{18}B_2(SiO_5)_4$ H = 6 to 6.5 G = 2.8 to 2.9	....	....	....	....	+	....	....	....	Insoluble	Green with $KHSO_4$ $+CaF_2$	....	After ignition dissolves leaving jelly	Prismatic crystals often hemimorphic and roughly triangular in cross-section.
I. Boracite H = 7 G = 2.9 to 3	....	....	....	....	....	....	....	+	Soluble	Yellowish green	....	Violet if ignited with cobalt solution	Minute glassy crystals.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding No Tests with Sodic Carbonate—*Continued*

THIN FRAGMENT HEATED IN PLATINUM FORCEPS

30. FUSES EASILY (1 TO 4) TO COLORLESS GLASS

Crystal system: name, composition, hardness and specific gravity	The color of the mineral is:								Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
	Purple or violet	Blue	Green	Yellow	Brown	Red	Gray	Colorless or white					
Ulexite $CaNaB_5O_9 \cdot 8\,H_2O$ H = 1 G = 1.65	....	....	....	....	....	....	....	+	Soluble	Reddish yellow	Much water	Green flame with $KHSO_4$ and CaF_2	Nodular masses of silky fibers.
M. Colemanite $Ca_2B_6O_{11} \cdot 5\,H_2O$ H = 4 to 4.5 G = 2.2 to 2.3	....	....	....	....	....	....	....	+	Soluble (with crystals on cooling)	Green	Water	Decrepitates before fusing	Highly modified crystals with one easy cleavage, cleavable or fine-grained compact "porcelain-like" or loose, chalk-like masses.
O. Natrolite $Na_2Al_2Si_3O_{10} + 2H_2O$ H = 5 to 5.5 G = 2.2	....	....	....	+	....	....	....	+	Soluble with jelly	Yellow	Water	....	Slender prisms with square cross-section and flat pyramid at end.
I. Analcime $NaAl(SiO_3)_2 \cdot H_2O$ H = 5 to 5.5 G = 2.2 to 2.3	....	....	....	....	....	+	....	+	Soluble with lumps jelly	Yellow	Water, but keeps luster	Becomes opaque before fusion	Trapezohedral crystals usually forming a lining. Rarely granular.
M. Datolite $Ca\,(BOH)SiO_4$ H = 5 to 5.5 G = 2.9 to 3	....	....	....	....	....	....	....	+	Soluble with jelly	Green	Water at high heat	....	Brilliant small highly modified glassy crystals lining a cavity, also porcelain masses. No easy cleavage.

THIN FRAGMENT, HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

20. FUSES EASILY (1 TO 4) TO A COLORLESS GLASS

H. Nephelite $Na_8Al_8Si_9O_{34}$ H = 5.5 to 6 G = 3.2 to 3.6	....	....	+	....	+	+	+	+	Soluble with jelly	Yellow	....	Blue if ignited with cobalt solution	Translucent masses and coarse hexagonal crystals with peculiar greasy luster. More rarely highly modified small white crystals.
Pyroxene (diopside) $CaMg (SiO_3)_2$ H = 5 to 6 G = 3.2 to 3.6	....	....	+	....	....	....	....	+	Insoluble	....	....	....	Usually prismatic crystals with eight-sided cross-section and angles between alternate faces 90° or 87°. Cleavage angle of 87°.
M. Amphibole (tremolite) $CaMg_3 (SiO_3)_4$ H = 5 to 6 G = 2.9 to 3.4	....	....	+	....	....	....	+	+	Insoluble	....	....	....	Fibrous and columnar, often radiating. Also crystals with cross-section, a rhomb of 124° or six-sided section. Cleavage at 124°.
Tri. Plagioclase $nNaAlSi_3O_8 + mCaAl_2Si_2O_8$ H = 5 to 7 G = 2.6 to 2.7	....	....	....	....	....	....	....	....	....	....	....	....	Masses and crystals with two easy cleavages, nearly but not exactly 90°. Often show parallel striations. Sometimes opalescent.
(Albite) $NaAlSi_3O_8$	....	....	....	....	....	....	+	+	Insoluble	Yellow	....	....	Usually pure white, often granular with curved cleavage surfaces.
(Anorthite) $CaAl_2Si_2O_8$	....	....	....	....	....	+	+	+	Soluble with jelly	....	....	White ppt. with H_2SO_4	Highly modified glassy crystals or grayish-white larger crystals
(Oligoclase) $Ab_{2 \text{ to } 6}An$	....	....	....	....	....	....	+	+	Insoluble	Yellow	....	....	Broad cleavages. Good striations. Sometimes spangled (Sunstone).
(Labradorite) $AbAn_{1 \text{ to } 3}$	....	....	....	....	....	....	+	....	Partial	....	....	....	Good striations. Beautiful play of color.
M. Spodumene $LiAl (SiO_3)_2$ H = 6.5 to 7 G = 3.1 to 3.2	+	....	+	....	....	....	....	+	Insoluble	Crimson	....	Sprouts and becomes opaque during fusion	Coarse, flattened prisms with cleavage at 87°. Often separate in broad plates (bisecting cleavage angle). Often striated and etched or roughened.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding No Tests with Sodic Carbonate—*Continued*

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

21. FUSES EASILY (1 TO 4) TO A COLORED GLASS

Crystal system: name, composition, hardness and specific gravity	The color of the mineral is: Blue	Green	Yellow	Brown	Red	Gray	Colorless or white	Black	Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
M. Sphene $CaSiTiO_5$ H = 5 to 5.5 G = 3.4 to 3.5	....	+	+	+	...	......	....	+	Soluble slowly	....	May become yellow	S. Ph. O. F. slowly soluble. Undissolved portion milk white, R. F. violet	Wedge-shaped or tabular crystals, with adamantine luster. Also massive. Easy cleavages give monoclinic shapes.
Pyroxene $RSiO_3$. Many varieties (Augite) (R = CaMgFeAl) H = 5 to 6 G = 3.2 to 3.6	...	+	....	+	......	....	...	+	Insoluble or nearly	....	....	....	Usually eight-sided prisms with angles between alternate faces 90° and 87°. Cleavage angle 87°.
M. Amphibole $RSiO_3$ H = 5 to 6 G = 2.9 to 3.4													
(Actinolite) Ca $(MgFe)_3$ $(SiO_3)_4$	..	+	....	....	+	...	..	....	Insoluble	....	....	....	Bladed non-terminated crystals, divergent fibers and granules.
(Hornblende) CaMgFeAl, etc	....	+	..	..	......	....	...	+	Insoluble or nearly	....	....	....	Crystals six-sided cross-section, with angles 124° and 116°, also fibrous and compact masses. Sometimes with luster of horn.
O. Hypersthene $(Mg \cdot Fe)\ SiO_3$ H = 5 to 6 G = 3.4 to 3.5	....	+	....	....	......	....	...	+	Partially soluble	....	....	After fusion attracted by magnet	Foliated aggregates sometimes with peculiar "Schiller" or pearly effect.
Tri. Rhodonite $MnSiO_3$ H = 6 to 6.5 G = 3.4 to 3.7	...	....	....	+	+	......	....	....	Soluble with white residue	....	....	Borax, O. F. amethystine	Fine-grained or cleavable masses and disseminated grains, often coated with a black oxide. Sometimes in crystals.
M. Epidote $Ca_2\ (Al \cdot Fe)_2$ $(AlOH)\ (SiO_4)_3$ H = 6 to 7 G = 3.2 to 3.5	....	+	...	....	+	......	....	....	Insoluble or nearly	....	Water at high heat	After fusion will gelatinize	A secondary mineral often with the original mineral as grains or needles. Less frequently in distinct crystals.

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

21. FUSES EASILY (1 TO 4) TO COLORED GLASS	T. Idocrase (vesuvianite).... $Ca_4Al_3(OH\cdot F)(SiO_4)_6$ H = 6.5 G = 3.3 to 3.4	....	+	+	+	....	....	....	....	Insoluble or nearly	....	Water at high heat	After fusion will gelatinize	Square and octagonal prisms and radiated columnar or granular masses or compact resembling jade.
	I. Garnet.................. $R_3R_2(SiO_4)_3$ H = 6.5 to 7.5 G = 3.1 to 4.3 (most varieties)	....	+	+	+	+	....	....	+	Insoluble	....	....	After fusion will gelatinize	Imbedded crystals, often nearly spherical or in druses and granular, lamellar and compact masses. Also found in alluvial material as rounded grains.
	H. Tourmaline............. $R_{13}B_2(SiO_5)_4$ H = 7 to 7.5 G = 3 to 3.2	+	+	...	+	...	...	....	+	Insoluble	Green with $KHSO_4\cdot CaF_2$	....	After fusion will gelatinize	Prismatic crystals, the cross-section often showing a triangular prism. Often the color is different at opposite ends or center and outer shell. Also radiating aggregates and in compact masses.
22. FUSES WITH DIFFICULTY (5 TO 6) SOMETIMES BARELY ROUNDING EDGES	Pyrophyllite.............. $HAl(SiO_3)_2$ H = 1 to 2 G = 2.8 to 2.9	....	+	....	....	+	...	+	....	Partial	....	Water	Blue if ignited with cobalt solution	Radiated foliæ or fibers and compact masses. Smooth and soft like talc.
	O. Talc..................... $H_2Mg_3(SiO_3)_4$ H = 1 to 1.5 G = 2.5 to 2.9	....	+	..	....	....	+	+	...	Insoluble	....	Water	Pink if ignited with cobalt solution	Foliated compact and fibrous masses with soapy feeling. The foliated talc cleaves into non-elastic plates.
	M. Chlorite Group (Prochlorite).............. $H_9(Mg, Fe)_5Al_3Si_3O_{10}$ H = 1 to 2 G = 2.8 to 2.9	....	+	....	....	....	....	....	....	Milky solution with conc. H_2SO_4	....	Much water	....	Masses of coarse to very fine scales. Tabular and curiously twisted six-sided crystals and fan-shaped groups which cleave into thin, soft pliable but not elastic plates. Also as a pigment in other minerals.
	(Clinochlore).............. $(H_8Mg_5Al_2Si_3O_{18})$ H = 1 to 2.5 G = 2.6 to 2.9	....	+	....	....	....	....	....	....	Like prochlorite	....	Much water	....	
	—Sepiolite................. $H_4Mg_2Si_3O_{10}$ H = 2 to 2.5 G = 1 to 2	....	+	....	....	....	....	+	....	Sol. with jelly	....	Water	Pink if ignited with cobalt solution	Soft, compact, smooth feeling masses of very light weight. Rarely fibrous.

Minerals of Non-Metallic Luster, Tasteless and with White Streak, and Yielding No Tests with Sodic Carbonate—*Continued*

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

22. FUSES WITH DIFFICULTY (5 TO 6) SOMETIMES BARELY ROUNDING EDGES

Crystal system: name, composition, hardness and specific gravity	The color of the mineral is: Blue	Green	Yellow	Brown	Red	Gray	Colorless or white	Black	Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
M. Muscovite. (HK) AlSiO$_4$ H = 2 to 2.5 G = 2.8 to 3	....	+	+	+	....	+	....	....	Insoluble even in H$_2$SO$_4$	....	Water at high heat	....	Plates and masses of scales and crystals, often large and rough, with rhombic or hexagonal cross-section. Luster pearly, cleavage very easy into thin elastic plates.
M. Biotite. (H·K)$_2$ (Mg·Fe)$_2$ Al$_2$ (SiO$_4$)$_3$ H = 2.5 to 3 G = 2.7	....	+	..	...	....	....	....	+	Like prochlorite	....	Water at high heat	....	Scales or aggregates. Rarely large sheets or pseudo hexagonal crystals cleaving easily into thin elastic plates. Luster pearly.
M. Phlogopite. (K·H)$_3$Mg$_3$Al (SiO$_4$)$_3$ H = 2.5 to 3 G = 2.8	....	....	....	+	+	....	....	....	Like prochlorite	....	Water at high heat	....	Rough prisms with hexagonal or rhombic sections. Also disseminated scales. Cleaves easily into thin elastic plates.
—Serpentine. H$_4$Mg$_3$Si$_2$O$_9$ H = 3 to 4 G = 2.5 to 2.6	...	+	+	+	+	....	+	+	Soluble with residue	....	Water	Pink or brownish red if powder ignited with cobalt solution	Compact masses with little luster and smooth somewhat greasy feel, often with veins of silky fibers or foliated.
O. Strontianite. SrCO$_3$ H = 3 to 3.5 G = 3.7	...	...	....	...	...	....	+	....	Effervesces in cold dilute acids	Crimson	....	Sprouts and glows intensely during fusion	Masses of parallel or radiating imperfect needle crystals. More rarely fine granular.
M. Wollastonite. CaSiO$_3$ H = 4 to 5 G = 2.8 to 2.9	...	..	....	...	....	+	+	....	Soluble with jelly	Pale red	....	....	Fibrous to compact masses. Rarely tabular crystals. Usually intermixed with calcite.
T. Scheelite. CaWO$_4$ H = 4.5 to 5 G = 5.9 to 6.1	...	....	....	+	....	+	+	....	Soluble with yellow residue made blue by tin	Pale red	....	S. Ph. O. F. colorless to milk white. R. F. deep blue	Very heavy masses with resinous luster. Square pyramids and drusy crusts.

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME	22. FUSES WITH DIFFICULTY (5 TO 6) SOMETIMES BARELY ROUNDING EDGES	H. Apatite................. $Ca_5 (Cl \cdot F) (PO_4)_3$ H = 4.5 to 5 G = 3.2	+	+	+	+	+	+	+	+	Soluble	Yellowish red. Momentary green with H_2SO_4	....	Solution added to nitric solution of ammonium molybdate gives bright yellow ppt.	Usually hexagonal prisms. Luster of oiled glass, dull if altered. Also compact, dull, massive bone phosphate.
		Collophane (amorphous)..... essentially $Ca_3P_2O_8 \cdot H_2O$ with $CO_2 \cdot F \cdot SO_4$ H = 2-5 G = 2.6-2.9	....	....	+	+	...	+	...	+	Soluble	Yellowish red. Momentary green with H_2SO_4	Water	Yellow ppt. with HNO_3 and ammonium molybdate	Usually massive and without form. May be oölitic or show bone structure.
		O Enstatite............... $(Mg \cdot Fe)SiO_3$ H = 5.5 G = 3.1 to 3.3	....	+	....	+	....	+	..	..	Insoluble or nearly	....	....	Like serpentine	Lamellar to fibrous masses, often with pearly luster.
		Orthoclase................. $KAlSi_3O_8$ H = 6 to 6.5 G = 2.5 to 2.6	....	+	+	...	+	...	+	..	Insoluble	Violet (Color screen)	....	....	Masses and crystals which cleave in two directions at exactly 90°. Except in the variety microcline the surfaces resulting are not grooved. Sometimes opalescent.
		H. Tourmaline............... $R_{18}B_2 (SiO_5)_4$ H = 7 to 7.5 G = 3 to 3.2	+	+	....	+	...	...	..	+	Insoluble	Green with $KHSO_4$ CaF_2	....	After fusion will gelatinize	Prismatic crystals, often showing a triangular prism. The color may differ at opposite ends or center and outer shell. Also radiating aggregates and in compact masses.
		H. Beryl................. $Be_3Al_2 (SiO_3)_6$ H = 7.5 to 8 G = 2.6 to 2.8	+	+	+	...	+	....	+	....	Insoluble	....	....	Often becomes white on fusion	Hexagonal prisms, from mere threads to several feet in length. Sometimes also in columnar or granular masses.

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

24. INFUSIBLE AND IS *NOT* MADE DEEP BLUE, BY IGNITION WITH COBALT SOLUTION

Crystal system: name, composition, hardness and specific gravity	The color of the mineral is:									Solubility	Flame coloration	Heated in closed tube	Other tests	Appearance
	Purple or violet	Blue	Green	Yellow	Brown	Red	Gray	Colorless or white	Black					
Turquois $Al_2(OH)_3PO_4H_2O$ H = 5 to 6 G = 2.6	....	+	+	...	....	....	....	...	....	Sol. HNO_3	Green (Cu)	....	Like monazite	Nearly opaque material with wax-like luster found filling cracks and cavities in igneous rocks.
M. Chondrodite $H_2Mg_{19}Si_8O_{34}F_4$ H = 6.5 G = 3.1 to 3.2	....	....	....	+	+	+	....	....	....	Sol. with jelly	....	....	Heated in open tube with fused S. Ph. etches glass	Compact masses, disseminated grains and crystals of great complexity.
O. Chrysolite $(MgFe)_2SiO_4$ H = 6.5 - 7 G = 3.3 to 3.6	....	....	+	+	....	....	....	....	....	Sol. with jelly	....	....	Whitens on heating	Transparent to translucent granular masses or glassy grains, or sand.
Opal SiO_2nH_2O H = 5.5 to 6.5 G = 2.1 to 2.2	....	+	+	+	+	+	+	+	...	Insoluble	....	A little water; becomes opaque	Slowly soluble in caustic alkali	Translucent veins or lining with internal color reflections, or without "opalescence" and with waxy luster, and shell-like fracture. Also dull like pumice and like drops of melted glass.
T. Rutile TiO_2 H = 6 to 6.5 G = 4.1 to 4.2	....	....	....	....	+	+	....	....	+	Insoluble	....	....	In S. Ph. R. F. gives violet	Crystals with brilliant luster often parallel or netted. More rarely massive.
Chalcedony SiO_2 H = 6.5 G = 2.6	....	+	+	....	...	+	+	+	+	Insoluble.	....	....	....	Translucent crusts and cavity linings with smooth rounded surfaces, often in concentric layers with wax-like luster. Never in crystals.

THIN FRAGMENT HEATED IN PLATINUM FORCEPS AT TIP OF BLUE FLAME

24. INFUSIBLE AND *NOT* MADE DEEP BLUE BY IGNITION WITH COBALT SOLUTION

H. Quartz.... SiO_2 H = 7 G = 2.6	+	+	+	+	+	+	+	+	+	Insoluble	....	....	....	Glassy hexagonal crystals and glassy shapeless material between crystals of other minerals. Also nearly opaque material, containing much iron and alumina.
I. Garnet (Cuvarovite).... $Ca_3Cr_2(SiO_4)_3$ H = 7 G = 3.1 to 4.3	....	..	+	....	....	....	....	....	....	Insoluble	....	....	....	Crystals only.
T. Zircon.... $ZrSiO_4$ H = 7.5 G = 4.7	...	....	+	+	+	+	+	+	....	Insoluble	....	....	Glows intensely on heating	Sharp-cut square prisms, long or short, usually imbedded in the associated mineral. Luster usually adamantine or greasy. Also rounded pebbles.
O. Staurolite.... Fe $(AlO)_4$ $(AlOH)$ (SiO_4) H = 7.5 G = 3.6 to 3.7	...	....	....	....	+	....	...	....	....	Insoluble	....	A little water	....	Prisms often twinned, or in threes, crossing at 90° and 120°. Surfaces bright if unaltered.
H. Tourmaline.... $R_{13}B_2(SiO_5)_4$ H = 7 to 7.5 G = 3 to 3.2	....	+	+	..	....	+	....	+	....	Insoluble	Green with $KHSO_4$ CaF_2	....	....	Glassy hexagonal prisms differently faced at the two ends. Cross-section often suggests a triangle.
I. Diamond.... C H = 10 G = 3.5	....	....	....	+	+	+	....	+	+	Insoluble	....	....	In powder is burned to CO_2	Crystals often rounded with luster suggesting oiled glass, and cleavage in four directions at 70° 31′.

MINERAL SUBSTANCES NOT EASILY DETERMINABLE BY A SCHEME

The following mineral substances of economic importance have not been included in the determinative tables, some because they lack fixed characters, others because their characters are lost in those of their associated substances and others because they occur only in one known locality.

Amber, once the most prized of gems, now used sometimes in jewelry, oftener as a mouthpiece for pipes, is a name given to those fossil resins which contain succinic acid and were derived from a particular extinct species of pine. The amber of the Baltic Sea and the Sicilian amber are the most valued. Color, garnet red, reddish, yellow, brownish, sometimes with bluish fluorescence. Luster resinous, streak white, H = 2 to 2.5. G = 1.096. Melts quietly at 125° to 150° C. and gives off a choking vapor.

Asphalts are rather indefinite mixtures of hydrocarbons and their oxidized products. They vary from thick, highly viscous liquids to solids, are generally black in color with pitch-like luster, and burn easily with a pitchy odor. They are slightly heavier than water. Examples: the pitch lakes of Trinidad and of Bermudez, Venzuela; the manjak of Barbados; the elastic elaterite of Derbyshire, England; the albertite of New Brunswick, and the gilsonite of Utah. Sandstones and limestones impregnated with asphalt occur in many localities.

Brucite $Mg(OH)_2$. A white, compact, finely-crystalline mineral, with slightly greenish tint. Soluble in dilute HCl, yielding tests for Mg; also yields water in closed tube. Found in a large deposit on western side of Paradise Range, Nevada, associated with magnesite and dolomite, along a contact of granite with a magnesite-dolomite series. Other forms, of non-commercial importance, sometimes associated with serpentine, are apt to be micaceous or fibrous.

Carnotite, $2UO_3V_2O_5K_2O \cdot 3\,H_2O$ (?). A canary yellow, pulvurulent mineral, in minute scales, filling the interstices of sandstone in several counties in Colorado. Rarely compact and wax-like. It contains radium, and is an impure vanadate of uranium and potassium, or uranium and lime, or both. Is a commercial source of radium, uranium, and vanadium.

Clays are mixtures of mineral fragments, due to rock decay. They are usually plastic when wet, can be molded, and harden on heating. By analysis they are principally silica and alumina, with some iron oxide and small amounts of other elements. Mineralogically they contain hydrous silicates of alumina, free quartz, and varying amounts of many other minerals. In origin they may have resulted from decay in place (residual clays) or may have been transported by water, ice, or wind (sedimentary clays). The most important clays are:

Kaolins. White-burning, residual clays, often not plastic, approaching kaolinite in composition, but not necessarily composed chiefly of that mineral. They are the basis of white wares and porcelain, etc.

Ball clays. White-burning sedimentary clays. They are highly plastic and are added to kaolin to give plasticity.

Fire clays. Either sedimentary or residual clays, which stand high degrees of heat without fusion. Composition very variable and apparently best with little free silica, lime, magnesia, or alkalis.

Fuller's earth. A montmorillonite-bearing clay, greenish in color when moist. Is a natural adsorbent for coloring matter in oil.

Stoneware clays. Clays sufficiently plastic and tough to be turned on a potter's wheel.

Terra-cotta clays. Usually buff-burning clays, with low shrinkage and dense-burning character.

Sewer pipe and paving-brick clays. Vitrifiable, high in fluxes.

Brick clays. Low-grade clays, with considerable plasticity, which harden at a comparatively low temperature.

Slip clays. Melt at a comparatively low temperature and form a glaze.

Paper clays. White clays free from sand; used for mixing with pulp fiber.

Bentonite. Composed essentially of the mineral montmorillonite, usually formed by alteration of volcanic ash. Many bentonites swell in water. Some bentonitic clays extensively used for clarifying oil.

Diatomite. An extremely light porous, white, mass of microscopic, opaline, organisms (diatoms), chiefly silica, but yielding much water in the closed tube. Used as a heat insulator, also for brick or in filtration.

Gilsonite. An asphaltite. Sp gr = 1.01 to 1.10; melting point, 230° to 400° F; found in veins in NE Utah. Was probably distilled by heat from the underlying Green River shale. Used for varnishes and japans, printing and rotogravure inks, and in various commercial products; 32 227 tons reported mined in 1933.

Grahamite or Glance Pitch. An asphaltite. Sp gr of about 1.15 or more. Largely mined in Cuba, where found in sedimentary and serpentinous rocks. Formerly mined in Pushmatoka Co, Okla, and Ritchie Co, W Va.

Kieserite ($MgSO_4 + H_2O$) is the source of Epsom salts, and an important source of magnesium oxide and basic carbonate (magnesia alba). It occurs at Stassfurt, Prussia, as about one-fifth of a layer 190 ft thick, chiefly halite and carnallite, and as one of the constituents of the overlying mixed salts. Exposed to the air it becomes epsomite. After removal of associates there remains a mass slowly soluble in water and easily fusible. H = 3 to 3.5, G = 2.5. Rarely orthorhombic crystals.

Livingstonite ($HgSb_4S_7$). Found in Mexico at Huitzuco and Guadalcazar and said to have been used as a source of mercury. It resembles stibnite in appearance, has metallic luster, lead-gray color, red streak, H = 2, G = 4.81, and occurs in groups of slender prismatic crystals.

Mottramite $(CuPb)_5V_2O_{10}\cdot 2\ H_2O$). The vanadium of commerce was formerly obtained from thin, blackish incrustations of mottramite upon the Keuper sandstone, Cheshire, England. Streak yellow, H = 3, G = 5.9.

Ocher, commercially, is a golden-yellow intimate mixture of clay with 20% or more of hydrated ferric oxide. Mineralogists use the name also for pulverulent yellow iron oxide (xanthosiderite) and for pulverulent red hematite.

Ozocerite, or mineral wax, is essentially a paraffine, colorless to white when pure, but oftener greenish or brown, and possessing all the properties of beeswax except its stickiness. A little is mined in Utah and about 3 000 tons are imported annually from Galicia and Moldavia. Used in crude state as insulation for electric wires. By distilling it yields ceresine, used for candles, burning oils, paraffine, a product like vaseline and a residuum which, with india-rubber, constitutes the insulating material called okonite.

Patronite (vanadium sulphide). At the one locality of Cerro de Pasco, Peru, there is a vein 7 or 8 ft thick of a nearly black material resembling slaty coal. About two-thirds of this is patronite and one-third metallic sulphides and free sulphur. Below it is 1 to 2 ft of coke-like material, chiefly carbon, which blends into a lustrous black material 4 to 6 ft thick, containing more sulphur than carbon, but known as asphaltite. The ashes of these two associates are also rich in vanadium, and the roasted or burned material is exported.

Petroleum is a mixture of hydrocarbons, obtained from the earth. It varies from a light, easily flowing liquid, to a thick viscous oil, and is usually of a dark brown or greenish color, with a distinct fluorescence. Chemically the American petroleum consists principally of hydrocarbons of the paraffine series C_nH_{2n+2}, with smaller amounts of the series C_nH_{2n} and C_nH_{2n-6}. The oils from Baku, on the Caspian, Rangoon, Galicia, and the Caucasus, contain more of the C_nH_{2n} or olefin series.

Roscoelite (vanadium mica). A mica of brown to brownish-green color, long known as an associate of gold in certain mines of California, and containing approximately 25% V_2O_3, is now commercially obtained from a soft Colorado sandstone of greenish color, in which the roscoelite fills the interstices between the grains.

Thorianite ($ThO_2U_3O_8$). Small water-worn blackish cubic crystals found in the Ceylon gem gravels and used as a source of thoria. H = 5.5 to 6, G = 9.3. It is radioactive.

Thorite ($ThSiO_4$). Black or orange-yellow, zircon-like crystals and masses, occurring in Norway in small quantity; used as a source of thoria. H = 4.5 to 5, G = 4.8 to 5.2. Infusible; gelatinizes with acids.

Tripoli. A fine, siliceous powder, containing chalcedony or opal; used as abrasive; clay-like in appearance, but quite gritty.

Umber is drab-colored mixture of iron and aluminum silicates, containing manganese oxide. It becomes reddish brown on burning. Sienna is similar, but with less manganese and lighter in color.

Vermiculite. Various forms of soft, pliable or inelastic mica; when heated, slowly expanded material useful in heat insulation.

Wad. Earthy to compact indefinite mixtures of oxides, especially of manganese, cobalt or copper, are known as wad. They have no constant characters, but may be valuable ores. Usually dark brown to black in color.

GEOLOGY

1. INTRODUCTION

A rock is a mineral or aggregate of minerals, forming an essential part of the earth; but many important mineral bodies, such as ores of metals, are not to be considered as rocks. Of about 1 500 species of minerals, only 20 or 30 are important as rock constituents.

The three great classes of rocks are: IGNEOUS, solidified from fusion; SEDIMENTARY, deposited in water or air; METAMORPHIC, recrystallized or otherwise altered igneous and sedimentary rocks, such that their original character has been obscured. Igneous rocks are believed to have been the predecessors and source of all others (1, 2, 3).

An analysis, illustrating GROSS COMPOSITION of the outer 10 miles of the earth, is given in Sec I, Art 1. Compared with the percentages there stated, nickel and iron probably become increasingly abundant toward the earth's center.

Most abundant elements of rock-forming minerals are: silicon, oxygen, aluminum, iron, magnesium, calcium, sodium, potassium, and hydrogen; secondarily, carbon, chlorine, phosphorus, titanium, manganese, and sulphur. All other elements, even the familiar copper, lead and zinc, and the precious metals, or an abundant atmospheric gas, as nitrogen, are small in amount.

2. CHEMICAL COMPOSITION OF ROCK-FORMING MINERALS

Rock-forming minerals comprise silicates, oxides, carbonates, sulphates, chlorides, phosphates, sulphides, and native elements.

Silicates are the most important, whence silicic acid, in various forms, is the foremost acid in Nature. Three principal forms of silicic acid are represented in the rock-making minerals: H_2SiO_3 (metasilicic), H_4SiO_4 (orthosilicic), and $H_4Si_3O_8$. Pyroxenes, amphiboles, and leucite are salts of metasilicic acid. Micas, olivine, anorthite, nephelite, garnet, and many minor minerals are orthosilicates. Orthoclase and albite are salts of $H_4Si_3O_8$. Some silicates have only the usual bases, aluminum, iron, magnesium, calcium, and the alkalies, and are called ANHYDROUS; others, usually formed by weathering or alteration of the first, contain hydrogen and oxygen in such proportions as to be driven off as water, and are called HYDRATED SILICATES. This distinction is rendered important by the general secondary character of hydrated silicates. The chief anhydrous silicates in igneous rocks embrace the following mineral groups: feldspars and feldspathoids, pyroxenes, amphiboles, micas, and olivine. Rarer and less important are: zircon, sphene, tourmaline, and analcime. On weathering or other alteration, the hydrated silicates, kaolinite, chlorite, and serpentine, usually result. Metamorphic rocks contain a few characteristic silicates, besides the common ones of igneous rocks, viz: staurolite, sillimanite, kyanite, andalusite, scapolite, and epidote.

Oxides are next important, of which quartz (SiO_2) stands first, being abundant in the great classes of rocks. The related forms of silica, chalcedony, cristobalite and tridymite, and the hydrated variety, opal, should also be noted. Next are the oxides of iron, magnetite and hematite, and the hydrated form, limonite. With magnetite are associated chromite and ilmenite ($FeO \cdot TiO_2$). Water, whether liquid or ice, is technically a mineral.

Carbonates are calcite, dolomite, and siderite, with their intermediate mixtures. They are of chief importance in sedimentary and metamorphic rocks, occurring rarely in igneous rocks, except as products of weathering. There are two common SULPHATES, anhydrite and gypsum. One CHLORIDE, common salt, alone merits attention. The PHOSPHATES are apatite and collophane. Two SULPHIDES, pyrite and pyrrhotite, are widely distributed. The one NATIVE rock-forming element is graphite.

3. ROCK-FORMING MINERALS (1, 2, 3)

Minerals of the igneous rocks are grouped according to their usual order of crystallization into: 1. Iron ores and minute associates. 2. Ferromagnesian silicates (olivine, pyroxenes, amphiboles, and micas). 3. Feldspars and feldspathoids (plagioclase, orthoclase, nephelite, leucite, and analcime). 4. Quartz, in acidic and higher medium rocks only. For descriptions, see Sec I, Determinative Tables.

Minerals of the sedimentary rocks are ordinarily fragments of minerals from igneous rocks. Quartz is most resistant to solution, alteration, and abrasion, and therefore appears in almost all sands and sandstones. The others are less frequent. After quartz, carbonates are of chief interest. Calcite and dolomite constitute the limestones, sometimes with slight admixture of siderite. Kaolinite, montmorillonite and hydromica enter the fine sediments. The two sulphates, gypsum, the more abundant, and anhydrite, appear only in sedimentary rocks. The same is true of the chloride, rock salt.

Minerals of the metamorphic rocks. The components of both sedimentary and igneous rocks, when deeply buried, with attendant heat and pressure, recrystallize at times to distinctively metamorphic minerals. Silica, being omnipresent, survives as quartz. The aluminous components afford andalusite, sillimanite, and kyanite. Magnesian, iron, and aluminous compounds yield abundant biotite and occasional epidote. Lime, in association with ferric iron or alumina, makes garnet possible, but orthoclase may become muscovite. The feldspars are important components. The ferromagnesian minerals (chlorite and serpentine) are derived from magnesium- and iron-bearing originals.

Summary of Rock-forming Minerals

Igneous Rocks. QUARTZ
FELDSPARS: orthoclase, plagioclase
FELDSPATHOIDS: nepheline, leucite, analcime, melilite
PYROXENES: hypersthene, diopside, augite, soda-pyroxenes
AMPHIBOLES: hornblende, soda-amphiboles
MICAS: biotite, muscovite
OTHER MINERALS: olivine, magnetite, ilmenite, apatite, zircon
Sedimentary Rocks. Fragments from igneous rocks, especially quartz and feldspars; kaolinite, montmorillonite, hydromica, calcite, dolomite, siderite, limonite
Metamorphic Rocks. Quartz, feldspars, biotite, muscovite, hornblende, epidote, garnet, sillimanite, andalusite, calcite, dolomite, serpentine, talc, chlorite

4. IGNEOUS ROCKS

Structures and textures. In a broad way, igneous rocks, as contrasted with sedimentary and metamorphic, have a massive structure; that is, their minerals are not arranged in parallel or distinct layers. Massive is in many respects a synonym of igneous. Examined more in detail, as in hand-specimens, they have 4 common textures. Where the molten mass has been too quickly chilled to crystallize, the texture is GLASSY. This texture appears on outer borders of thin masses, on upper surfaces of lava flows, and, in relatively infusible varieties, it may extend through an entire flow. It is most frequent in siliceous rocks, which have high fusing points; it is rare in the medium, and scarcely known in the basic. Where molten masses have cooled rather rapidly, and yet not so quickly as to prevent crystallization, very fine-grained textures result, called FELSITIC. But, if older, larger, and already well-formed crystals at the time be swimming in the magma, which then crystallizes in relatively small components, the texture is called PORPHYRITIC. The large crystals are called PHENOCRYSTS and the matrix the GROUND-MASS. Phenocrysts of acidic rocks are chiefly quartz and feldspars; the dark ferromagnesian silicates are much less common. In medium rocks, quartz practically fails, and feldspars are associated with more of the ferromagnesian minerals. In basic porphyritic rocks, feldspars decline, while augite and olivine, and very rarely biotite and hornblende, gradually replace them. When a molten magma crystallizes into an aggregate of fairly coarse components of about the same size, the texture is GRANITOID (like granite). Rarely, in these coarsely crystalline rocks, the feldspars become unusually large and stand out in contrast with the rest.

As a result of explosive outbreaks at volcanic vents, igneous rocks are sometimes blown out as fragments of all sizes, from impalpable dust to large bombs. The fragments settle down on the sides of the cone or at greater distances, and yield rocks with marked fragmental texture, allied to sediments. If coarse, they are called BRECCIAS; if fine, TUFFS.

Chemical composition of igneous rocks. SILICA ranges from about 80% to a theoretical minimum of 0% in certain igneous iron ores; only in rare cases does it fall below 40%. Igneous rocks containing above 65% silica are called ACIDIC; those with 55 to 65%, MEDIUM; below 50%, BASIC. Of ALUMINA the superior limit is 25 to 30%; general range, 12 to 18%; minimum, nearly 0. IRON OXIDES are low, 1% or less, in the most acidic rocks, but increase in the basic to 10 to 20%; in rare extremes, 90 to 95%. MAGNESIA sinks to a mere trace in the acidic, rising with fall of silica to 30% in the extremely basic. LIME is low in the acidic, gradually increasing to about 15% maximum in certain basic rocks. POTASH is highest in the rare leucite rocks, reaching 10 or 12%; it ranges from

4 to 7% in medium rocks with much orthoclase, and disappears in basic types. SODA has a similar maximum in the rare nepheline rocks, and the same range in medium rocks rich in albite, approaching extinction in the extremely basic. WATER, of 0.5 or 1%, usually indicates weathered rocks.

It is important to connect chemical compositions with the resultant minerals and vice versa. Chemical composition obviously determines the minerals, and, in so far as extremely acidic rocks have relatively high fusing points and chill more easily, it also influences texture.

Classification of igneous rocks shown in Table 1 has general acceptance by geologists. Rocks range from acidic on left of table to basic on right; from quickly-chilled rocks above to slowly-cooled rocks below, a still lower line of fragmentals marking transition to sediments. The forms assumed in Nature are in extreme left-hand column; to be defined after the descriptions. The rocks are further subdivided in vertical columns on basis of mineralogy. Feldspars and feldspathoids are the fundamental basis of subdivision; other minerals are subordinate.

The table gives a general view of the igneous rocks and defines those commonly met in mining. For close determination greater refinement may be desirable. In some mining districts in the western U S are found the GRANO-DIORITES (intermediate between granites and quartz-diorites), not mentioned in the table; they have about the same amounts of orthoclase and plagioclase. Intermediate between syenites and diorites are the MONZONITES. If they have a little quartz, but not as much as grano-diorites, they are termed quartz-monzonites. Butte granite, containing the copper veins, is usually described as quartz-monzonite. Several great bodies of "porphyry coppers" are in monzonite-porphyries. The varieties of gabbro containing hypersthene instead of common augite are called NORITE; important because they contain the nickel-copper ores at Sudbury, Ont. (For meaning of names of other rare igneous rocks, sometimes appearing in reports, see glossary in later editions of Kemp's "Handbook of Rocks.")

Glassy rocks are the most evident results of cooling from fusion. They are almost always acidic and are represented by the rhyolites and dacites, described later. More basic varieties are known, but are less frequent. Commonest glasses are the OBSIDIANS, black, red, and brown, with 0.5 to 1% water. They may be assumed to be quickly-chilled rhyolites or dacites. PUMICE is an excessively cellular obsidian. A rarer glass, which chills into an aggregate of shot-like spheroids, is PEARLITE or PEARL-STONE, usually containing 2 to 4% water. The last glass deserving mention is the rare, resinous PITCHSTONE, having 5 to 10% water and is more easily fusible with blowpipe than the others.

Rhyolite-granite series embraces igneous magmas containing: silica, 65 to 80%; alumina, 12 to 15%; iron oxides, 1 to 3%; magnesia, less than 1%; lime, 1 to 2%; potash and soda, 5 to 8%. They are common in Nature, and on crystallizing yield finely to coarsely crystalline rocks, consisting chiefly of orthoclase, acidic plagioclase, and quartz, together with relatively small amounts of the dark silicates, biotite, hornblende, and augite, stated in order of frequency. Light-colored minerals are in great excess.

Rocks of this series are: RHYOLITE (syn, liparite), felsitic or partly glassy texture, few phenocrysts; RHYOLITE-PORPHYRY (syn, quartz-porphyry), felsitic ground-mass, abundant phenocrysts; GRANITE-PORPHYRY, predominant phenocrysts, subordinate ground-mass; GRANITE, granitoid texture, components of about the same size, but feldspars sometimes abnormally large. PEGMATITES: crystallization of granite is often accompanied by separation of portions of the magma, in association with abnormally large admixtures of dissolved gases. These portions pass outward into wall-rocks as dikes, often for great distances and in large size; on crystallizing, they yield very coarse aggregates of same minerals as appear in granite itself, with many rare elements concentrated in them, and are called pegmatite.

In this series the prominent minerals are feldspars and quartz; dark silicates are subordinate. They are closely related to the dacite-quartz-diorite series, from which to distinguish them microscopic examination may be necessary. The distinction is practically of small moment. This series is very abundant and widely distributed. Its tuffs and breccias are also frequent.

Trachyte-syenite series embraces igneous magmas containing: silica, 55 to 65%; alumina, 15 to 20%; iron oxides, 1 to 3%; magnesia, 1 to 2%; lime, 1 to 3%; potash and soda, 7 to 12%. They are much less common than the rhyolite-granite series. On crystallizing they yield finely to coarsely crystalline rocks, consisting of orthoclase, acidic plagioclase, and usually notable proportions of the dark silicates, biotite, hornblende, and augite, one or several. Quartz fails, or, at most, is extremely subordinate. Light-colored minerals are in excess.

Rocks of this series are: TRACHYTE, felsitic texture, few phenocrysts; TRACHYTE-PORPHYRY (syns, porphyry, orthoclase-porphyry), felsitic ground-mass, abundant phenocrysts; SYENITE-PORPHYRY, predominant phenocrysts, subordinate ground-mass; SYENITE, granitoid texture, sometimes varied by abnormally large feldspars. Syenitic-pegmatities are known, but are less frequent than granitic.

In this series, feldspars are most prominent; dark silicates, subordinate. Lack of quartz is the chief distinction from rhyolites and granites. Tuffs and breccias are known.

Phonolite-nepheline-syenite series embraces igneous magmas containing: silica, 50 to 60%; alumina, 18 to 22%; iron oxides, 1 to 3%; magnesia, 1 to 2%; lime, 1 to 2%; potash and soda, 10 to 15%. They occur infrequently. On crystallizing they yield finely to coarsely crystalline rocks, consisting of orthoclase, less abundant plagioclase, nepheline (more rarely leucite), and pyroxene. Though rare, they are of great scientific interest.

Rocks of this series are: PHONOLITE, felsitic or porphyritic, with few phenocrysts; PHONOLITE-PORPHYRY, felsitic ground-mass, abundant phenocrysts, of which orthoclase is chief, nepheline being usually confined to ground-mass; NEPHELINE-SYENITE-PORPHYRY, predominant phenocrysts, subordinate ground-mass; NEPHELINE-SYENITE, granitoid texture, from rather fine to extremely coarse varieties, shading into pegmatites.

In most of these rocks, orthoclase is most prominent, but in the last-named, nepheline is at times abundant. Many varieties have been recognized, depending on entrance of minerals less usual than those named, and the decline of normal components. Sodalite is sometimes very prominent. Biotite and hornblende are not so frequent as pyroxene. Rocks with leucite are known, but are far less common than those with nepheline.

Dacite-quartz-diorite series embraces igneous magmas containing: silica 60 to 70%; alumina, 12 to 15%; iron oxides, 1 to 3%; magnesia, 1 to 3%; lime, 2 to 4%; soda and potash (soda in excess), 4 to 7%. They are common in eruptive centers. On crystallizing they yield finely to coarsely crystalline rocks, consisting of plagioclase, less orthoclase, and quartz, as the most prominent minerals, with biotite, hornblende, and pyroxene, one or several. The light-colored minerals are in excess.

Rocks of this series are: DACITE, felsitic or partly glassy textures, few phenocrysts; DACITE-PORPHYRY, felsitic ground-mass, with abundant phenocrysts; QUARTZ-DIORITE PORPHYRY, predominant phenocrysts, subordinate ground-mass; QUARTZ-DIORITE, granitoid texture.

Andesite-diorite series embraces igneous magmas containing: silica, 50 to 65%; alumina, 15 to 18%; iron oxides, 4 to 9%; magnesia, 2 to 7%; lime, 3 to 8%; soda, 3 to 5%; potash, 2 to 3%. They are very widespread. On crystallizing, they yield finely to coarsely crystalline rocks, consisting of plagioclase, a little orthoclase, and biotite, hornblende, or augite, one or several. The light-colored minerals are in excess and are the chief phenocrysts. The rocks have usually light gray colors.

Rocks of this series are: ANDESITE (varieties, mica-andesite, hornblende-andesite, augite-andesite), felsitic textures, few phenocrysts; ANDESITE-PORPHYRY, felsitic ground-mass, with abundant phenocrysts; DIORITE-PORPHYRY, predominant phenocrysts, ground-mass subordinate; DIORITE, granitoid texture. Andesites are important in many western mining districts; in the recently extinct and active volcanoes along Pacific coast, in Mexico, and in other parts of world.

Basalt-gabbro series embraces igneous magmas containing: silica, 40 to 55%; alumina, 16 to 20%; iron oxides, 6 to 15%; magnesia, 5 to 10%; lime, 6 to 12%; soda, 2 to 4%; potash, 1 to 2%. They are very widespread. On crystallizing they yield finely to coarsely crystalline heavy rocks, consisting of plagioclase, little or no orthoclase, and large proportions of pyroxene, olivine, and magnetite. The dark silicates are in excess and give rocks dark gray or black colors.

Rocks of this series are: BASALT, felsitic textures, few phenocrysts; BASALT-PORPHYRY, felsitic ground-mass, abundant phenocrysts; GABBRO-PORPHYRY, predominant phenocrysts, subordinate ground-mass; DIABASE, granitoid texture, feldspars long rectangular, pyroxene irregular, in spaces among the well-crystallized feldspars; GABBRO, granitoid, components as broad as long.

Basalt-gabbro rocks are very abundant. Phenocrysts are almost entirely olivine and pyroxene. The peculiar texture of diabase, due to feldspars completing their crystallization before the pyroxenes, contrary to rule, gives it a special place. Varieties of pyroxene afford special varieties of both basalts and gabbros. Hornblende and biotite are rarely observed; nepheline, leucite, analcite, and melilite sometimes appear and may displace the plagioclase. All feldspars and feldspathoids may fail, giving the rare basalts, limburgite and augitite, and the rare gabbros, peridotite and pyroxenite (Table 1).

Ultra-basic rocks. There are a few rare igneous rocks with less than 40% silica and correspondingly high bases. The most important are the igneous magnetites, often titaniferous; in some places they are independent dikes and sheets, in others, segregations in igneous rocks.

Determination of igneous rocks. Their crystalline, massive character usually serves to identify them as igneous, but a warning may be given respecting certain dense contact-products, called HORNFELS. First decide on predominance of light- or dark-colored minerals; next, on texture. If light-colored minerals are in excess, feldspar is determined as orthoclase (no striations on cleavage faces), or plagioclase (striated). Quartz is looked for. Having thus decided general name, the dark silicate is determined. If dark-colored minerals are in excess, and phenocrysts are also dark, the rock is placed in the basalt-gabbro series and identified more sharply by its textures. A rock so finely crystalline that no minerals can be identified is called felsite, if light-colored; or basalt, if dark. Microscopic examination is necessary for further refinement. Greatly altered rocks, such as are commonly adjacent to mineral veins, can often be determined through surviving characters only discernible with microscope. If stained with chlorite, they are called GREENSTONES.

5. SEDIMENTARY ROCKS

There are 4 groups (Table 2): (*a*) Breccias and mechanical sediments, not limestones; (*b*) Limestones; (*c*) Organic remains, not limestones; (*d*) Precipitates from solution.

Table 2. Sedimentary Rocks

Breccias	Fragmentals, not Limestones			Transition to Limestone	Limestones		Organic Rocks, not Limestones		Precipitates from Solution
		Loose	Consolidated	Consolidated	Loose	Consolidated			
Fault-breccias Talus-breccias	Coarse	Gravel	Conglomerate	Calcareous conglomerate	Limestone-rubble Gravel Coral heads, etc	Rubble-limestone Calcirudites	Alkaline	....	Rock salt, gypsum, stalactites, stalagmites, "Mexican onyx," travertine
	Fine to Medium	Sands	Sandstone	....	Shell or coral sands	Sand-limestones Coquina Calcarenites	Siliceous	Infusorial or diatomaceous earth Some cherts Some sinters	Silicified wood Some cherts Some sinters
Eruptive-breccias		Mud	Argillaceous sandstone Shale	Calcareous sandstone Calcareous shale	Shell or coral muds	Mud limestones Calcilutites	Ferruginous	Some limonite	Some limonite
		Silt	Clay	Marl	Calcareous slimes or ooze	Lithographic limestone	Carbonaceous	Peat Lignite Bituminous coal Anthracite	Asphaltites

Determination of sedimentary rocks. Almost all may be recognised on sight. It is important to make effervescing tests with acid, to identify limestones, calcareous shales, etc. Scraping up a little heap of powdered rock favors effervescence. Warming a corner or edge of the rock even in flame of a match does the same, and may make stubborn dolomite yield to acid.

The rocks of group (*a*) may be arranged from coarse to fine, as follows:

Coarse			to		Fine
Breccia	Gravel and Conglomerate	Sand and Sandstone	Argillaceous sandstone, Calcareous sandstone	Silt and Shale, Calcareous shale	Clay, Marl

Breccias consist of angular fragments and are of 3 kinds: fault, talus, and eruptive, the names being equivalent to definitions. Mechanical sediments, or gravels, contain rounded or water-worn fragments, and when consolidated are CONGLOMERATES. They pass into SANDS as the boulders or pebbles disappear; and when consolidated, SANDSTONES

Table 3. Metamorphic Rocks

Contact			Regional							
Internal	External		Gneisses corresponding in Mineralogy to the Granitoid Igneous Rocks. A few others		Crystalline Schists		Quartzites and Slates	Crystalline Limestones	Ophicalcites, Serpentines, Soapstones	Products of Weathering
			Derived from Igneous	Derived from Sedimentary						
Glasses	Conglomerates and sandstones	Effects relatively slight Quartzites (Buchite)	Granite gneiss or gneiss proper	Granitic gneiss or gneiss proper	Mica	Mica schists often with garnet, staurolite, etc Phyllites	Quartzites (Quarts schists)		Serpentinous marble or ophicalcite, verd-antique	Residual soils
Felsites	Shales and clays	Andalusite hornfels Lime-silicate hornfels Spotted slates	Syenite gneiss Diorite gneiss	Syenitic gneiss Dioritic gneiss, etc	Hornblende	Hornblende schists often with garnet, epidote, scapolite Amphibolites	Graywackes Slates (Phyllites)	Marbles often with mica, tremolite, etc	Serpentine, often with chromite, garnet, etc	Subsoil Saprolites in general
Porphyries	Limestones	Garnet, diopside, vesuvianite, epidote, wollastonite, scapolite, ores	Gabbro gneiss Pyroxenite gneiss	Conglomerate gneiss Gneisses with a prominent mineral, such as biotite-gneiss, etc.	Various schists	Chlorite schist or green schists Talc schists Eclogite Glaucophane schists Quartz schists		Dolomites often with mica, tremolite, etc.	Soapstone or steatite	Laterites, especially from basalt
	Coals	Natural coke Anthracite	Peridotite gneiss							

result. Sands, with admixture of clay or mud, become SHALES; as the sand disappears, SILTS and CLAYS; if calcareous, they are calcareous sandstone, calcareous shale, and MARL. **Limestones** may be coarsely or finely fragmental, but are almost always derived from remains of organisms. **Other organic remains** yielding rocks are the siliceous diatoms and sponges, and carbonaceous plants in coal seams. **Precipitates** are rock salt, gypsum, and stalagmitic marbles. Certain ferruginous rocks also are probably of this nature.

6. METAMORPHIC ROCKS

These are of 3 great classes: CONTACT ROCKS, produced by intrusive igneous rocks from their immediate walls; REGIONALLY METAMORPHIC TYPES, which extend over great areas; and PRODUCTS OF WEATHERING.

Contact rocks embrace both the chilled border facies of intrusive (internal or ENDOMORPHIC), and the recrystallized products from shales, slates, or limestones (external or EXOMORPHIC). Other rocks, such as sandstones and regionally metamorphic varieties, are much less influenced by intrusives. The general name for densely crystalline, altered shales is HORNFELS. From limestones a series of lime-silicates results; among them, garnet, pyroxene, epidote, and vesuvianite are commonest. Copper ores and magnetite often occur with them.

Regionally metamorphic rocks embrace representatives of both igneous and sedimentary types, mineralogically resembling sometimes one, sometimes the other. They include gneisses, mica-, hornblende-, and chlorite-schists, quartz-schists, quartzites, slates, marbles, ophicalcites, serpentines, and soapstones. GNEISSES are banded or foliated rocks of the granitoid-igneous types, but are most commonly like the granites. MICA-SCHISTS are more finely foliated, and richer in mica than the gneisses. HORNBLENDE-SCHISTS are finely foliated, roughly parallel aggregates of prismatic hornblende, with relatively few other minerals. CHLORITE-SCHISTS, QUARTZ-SCHISTS, etc, are finely foliated, with the characteristic mineral prominently developed. QUARTZITES are sandstones hardened and solidified with newly deposited silica. SLATES are derived from shales and clays, with a new cleavage produced by pressure, but having no definite relation to original bedding. Irregularly breaking, metamorphosed, sandy shales, and volcanic tuffs and breccias, are called GRAYWACKE. MARBLES are recrystallized limestones, often dolomites mineralogically. They may be mottled with serpentine, forming OPHICALCITES. SERPENTINES are usually metamorphosed peridotites. SOAPSTONES are higher in silica, and consist of talc. They may be old pyroxenites or siliceous magnesian limestones.

Products of weathering constitute the mantle of decomposition products, resting upon fresh bedrock to a greater or less degree, which is due partly to mechanical breaking up of the original rock, partly to alteration and disintegration by removal of soluble ingredients. Quartz and aluminous hydrated silicates, with ferric hydrate, become relatively enriched, while the other oxides go off in solution. Soils and subsoils result, and sediments are afforded for making sedimentary rocks General names for the mantle of weathered products are: SAPROLITE or rotten rock; LATERITE, residual soils, etc. Laterization is most pronounced in tropical climates.

Determination of metamorphic rocks is rarely difficult. Definitions convey the idea of characters. Dense hornfelses sometimes resemble felsites, and may require microscopic determination Gneisses, with increasingly fine foliation, shade into mica-schists and mica-schists into slates, so that distinctions may be matters of judgment. The other rocks of this series give little difficulty

7. FORMS ASSUMED BY IGNEOUS ROCKS

In the field, igneous rocks are found in dikes, necks, bosses, stocks, surface flows, intrusive sheets or sills, laccoliths, and batholiths. The size and shape of these bodies exercise an important influence on texture of the component rock. Small bodies chill quickly and are glassy or felsitic; large bodies cool slowly and are porphyritic or granitoid. Designating one horizontal dimension as length (L), the horizontal dimension at right angles to L as breadth (B), and the vertical dimension as depth (D), a mathematical expression can be roughly formulated for each type.

Dikes are long, narrow bodies of igneous rock, filling fissures in older rocks, into which it has entered in molten condition. In dikes, L and D are great, B relatively small; they vary from less than 1 in wide and a few yards long, to fractions of a mile in width and many miles in length. They usually have steep dips; are often intimately associated with orebodies, and in one place or another embrace all varieties of igneous rocks. They may mark the last outbreaks in a series of eruptions in a particular district, and are then usually very basic, as at Cripple Creek, Colo.

Dikes may radiate from an igneous center for miles into the surrounding strata, as in the Crazy Mts, Mont, or the Trinidad coal region, Colo. They may appear hundreds of miles from other known igneous rocks, as in the coal measures of S W Pennsylvania. A dike derived from solidified molten rock, even though a magma be regarded as a solution, practically all of which crystallises *in situ*, is contrasted with a vein, similar in shape and in relations to the walls, but which is deposited from solution, the solvent passing on. Yet, in the case of pegmatites, it is not clear whether the term dike or vein should be used; they may be considered the result of aqueo-igneous processes of fusion.

Neck is the solidified mass of lava that remains in the throat of a volcano after its last outbreak. When first congealed, it connects the lava that has poured from the crater with the unerupted residue in depth, just as a human neck connects head and trunk. As seen in the field, it is usually a decapitated neck, in that it is exposed to view only after removal of the lava flow and much of the cone by erosion. *L* and *B* are small, *D* great.

In volcanoes, which yield both lavas and explosive products, the neck may be part solid lava and part breccia. Necks project in a rudely columnar manner from remnants of the old crater and from débris furnished by their own disintegration.

Bosses are roughly cylindrical masses of igneous rock, projecting above surrounding wall rocks like the boss on an old-time circular shield. Coarse granite or pegmatite, because of its relative resistance to erosion, often projects from surrounding mica-schists or other softer rocks. Bosses differ from necks in not being due to volcanic activity. As in case of necks, however, *L* and *B* are relatively small, *D* great.

Stocks are large, roughly cylindrical masses of intrusive porphyritic or granitoid rock in the midst of older walls. They do not necessarily stand in relief, but otherwise resemble bosses; *L* and *B* are small with respect to *D*, although absolutely rather large.

The name "stock" is the German word for floor or story in a house, and was applied to masses of igneous rock of cylindrical shape, because certain granite bodies of rounded outline, containing disseminated cassiterite, were formerly mined in horizontal slices or floors. Finally the mass of rock itself came to be called a stock. For good illustrations, see Telluride folio of U S Geol Surv.

Surface flows are produced when lava wells out from a vent, and flows over surface in a relatively thin sheet; *L* and *B* are large, *D* small. In upper and under portions are many cavities, caused by expanding gases; the middle part is usually dense, and in a thick flow may be comparatively coarse-grained. The cavities are flattened and rounded like an almond, whence, from the Greek, they are called AMYGDALOIDS.

The top of a flow may be a rough, slaggy scoria, even consisting of cakes of chilled and broken crust. Where dissolved gases have all escaped before consolidation and while lava is yet molten, the final chilled surface may be comparatively smooth. Surface flows may bury one another in succession, or be covered with later sediments. They are distinguished from intrusive sheets, because their heat can at most affect only underlying rocks, not those formed above them after cooling; whereas intrusive sheets bake both walls. More than 100 successive surface flows of basalt have been cut by deep shafts in the Lake Superior copper district.

Intrusive sheets or sills are masses of igneous rock which have been forced between strata of older rocks, and have solidified parallel with them. *L* and *B* are great, *D* small. The shape resembles that of a surface flow, and when a surface flow resting on sediments is buried under subsequent beds the result is much the same. The heat of intrusive sheets, however, always affects the sediments above and below them, and sometimes produces important contact zones.

Intrusive sheets vary from a few feet thick, and of no great known extent, to such a sill as the Palisades of Hudson River, visible 50 miles, traceable by drill 25 miles more; its thickness reaches 600 ft, but is usually less. Intrusive sheets doubtless rise from the depths along fissures, like dikes, but then turn sidewise between strata along a line of least resistance. They are sometimes associated with ore-deposits, as at Leadville, Colo, and Mercur, Utah.

Laccoliths are a variation of the intrusive sheet and are lenticular in shape. If a sill be supposed to start from its feeding dike, sidewise between strata, and to find it easier to raise the overlying beds of a limited area than to force its way with uniform thickness far and wide, a lenticular mass will result, tapering from a central maximum thickness to a thin edge. Hence, *L* and *B* are relatively large, *D* smaller but variable. Laccoliths which are fed outwardly from a central supply fissure are symmetrical; but this fissure is sometimes a fault, with hard strata opposite soft ones, so that the intrusive can penetrate outwardly only on one side. Unsymmetrical masses, practically half-laccoliths, result. Laccoliths heave up overlying strata in domes, and when these are eroded the laccolith is exposed in midst of outwardly dipping beds. The entrance of laccoliths may have been aided by incipient folding or arching of beds under compression. Laccoliths are widespread in the western states. The name was coined by G. K. Gilbert from the Greek word for cistern, as the shape suggested the ancient dome-covered vaults for storing water.

Chonoliths are irregular intrusive bodies, either filling a pre-existing cavity, or rending apart the rocks to make a way for itself. The name was coined by R. A. Daly from the Greek word for a mould in which metal is cast. No definite expression in terms of *L*, *B*, and *D* is possible.

Batholiths are huge masses of intrusive rock, of irregular shape and great extent; *L*, *B*, and *D* are all great. Granite masses, square miles in area and sometimes cubic miles in volume, are illustrations. They are specially abundant in pre-Cambrian strata.

8. FORMS ASSUMED BY SEDIMENTARY AND METAMORPHIC ROCKS

The distinguishing feature of sedimentary rocks is their arrangement in parallel layers, during formation. Variations in deposition of sediment from high and low tides, storms and calms, floods and droughts, produce contrasts in coarseness and fineness. At the outset they are flat, except for the slight inclination of the sea bottom, and irregularities due to delta formation and swift currents. The inclined position often seen in exposures today is due to subsequent disturbances.

Stratification. The smallest division of a sedimentary rock is a LAYER or LAMINA. It may be a fraction of an inch thick and marks one period of especially abundant deposit. Layers go together to form BEDS, the natural units of sedimentary rocks. Bedding planes are recognizable and thick- and thin-bedded sedimentaries are distinguished. Beds combine to constitute a STRATUM, or tabular mass of one kind of sedimentary rock between others which are different. A stratum may range from 1 to 1 000 ft thick. Thin strata are called SEAMS, as of coal. Limestones, shales, and sandstones afford thick strata. In geological mapping, a thick and persistent stratum is often called a FORMATION.

Sedimentary rocks present all the features of the bottom, or of the strand between high and low water: as ripple marks, tracks, stranded shells, rill-marks, mud-cracks, flow and plunge from swift currents, irregular beddings, and cross-bedding in individual layers, as in deltas. Since the greatest thickness of sediments gathers along subsiding shore lines, with attendant advances of sea over land, there are found in normal succession: conglomerates, which represent old shore shingle, followed by sandstones, representing off-shore shallows; next shales, corresponding to deeper, quieter water; lastly, as representing still deeper water, free of mechanical sediments, are limestones, consisting largely of organic remains. This normal succession is not always found, since estuaries and rivers destroy uniformity, but it is not infrequent. There are also desert accumulations, wherein wind-blown particles are important, and are associated with beds from temporary streams, lakes, and floods. Land accumulations are characteristically red, from oxidation of iron.

9. ROCK DISTURBANCES

World-wide observation has shown that the rocky outer portion of the earth has been subject to many disturbances. Great masses may rise or sink without changing the local attitude of the rocks. These continental movements are of scientific interest, but seldom of importance to the engineer. Localized movements, due to elevation of a long and relatively narrow belt in a mountain chain, and disturbances incident to intrusive entrance of bodies of igneous rock, are more important. The results of these movements are termed FOLDS and FAULTS.

Folds are bendings in strata, whereby each layer assumes a curved form, approximating a portion of a cylinder. When classified in order from least to greatest, folds embrace MONOCLINES, ANTICLINES, and SYNCLINES of several types, also DOMES AND BASINS.

Monoclines (Fig 1) are terrace-like bendings of strata, with inclination varying in amount, but always in same direction, as the name implies. A roll at top of the terrace marks a belt of especial strain in the strata affected, and may be accompanied by numerous cracks. At foot of the terrace is a second roll in reversed direction, with attendant strains and cracks. In the upper roll, overlying beds are subject to tension, underlying to compression; in the lower roll, the upper beds are compressed, the lower tense. Between these areas is necessarily a surface of no strain.

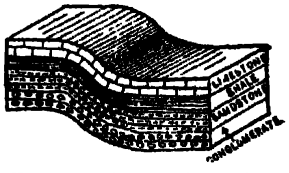

Fig 1. Monocline, in a Succession of Beds

Monoclines which involve porous beds, such as open-textured sandstones between tight shales, are sometimes important places for accumulation and storage of natural gas and petroleum. The search for these is essentially an endeavor to locate, with the drill, favorable monoclines or gentle anticlines. Monoclines have been described as arrested anticlines. In a series of sediments comprising shales or other soft strata, monoclines or even more violent folds in stiffer strata may at depth disappear entirely in the adjustment of soft underlying shales, the plastic movement of which takes up and distributes the fold until it is diffused and lost. The name monocline (or monoclinal structure) is sometimes applied to a remaining half of an eroded anticline or syncline, the other half of which is not apparent; inclination of the beds is all in one direction.

Anticline and syncline (Fig 2) are complementary terms; one rarely appears without the other. An anticline is an arch-like bend, a syncline a corresponding trough. The upper part of an anticline is called the CREST; its sloping sides, LIMBS or LEGS; the central portion, running parallel with the axis of the concentric partial cylinders, the surfaces of which are represented by each folded bed, is the AXIS. The bottom of a syncline is the trough. Beneath anticlinial crest and synclinal trough the beds are especially strained and cracked; the cracks tending to gape upward in the anticline and downward in the syncline. The limbs of each type of fold are less strained than crest or trough. Thus, good building stone will be found on the limbs rather than at crest or in trough. On the contrary, veins and mineral deposits from circulating waters find natural resting places in crest and trough.

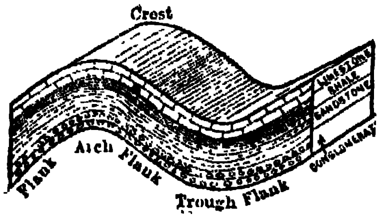

Fig 2. Anticline and Syncline, with Horizontal Axis

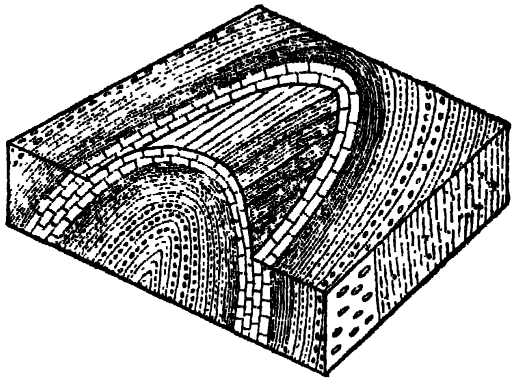

Fig 3. Pitching Anticline, Showing Concentrically Curving Outcrops of Eroded Beds

Anticlines and synclines, when followed for a mile or more, seldom have horizontal axes as shown in Fig 2. The axes usually pitch downward (Fig 3), though they may afterward rise again. In Fig 2, the component beds, if eroded, would appear at surface in parallel bands. When pitching folds are eroded, the several beds appear at surface as concentric curves (Fig 3). In anticlines the upper or later beds are outside, the under or older, inside; in synclines the under or older beds are outside, the upper or later, inside. Because of these relations, geologic structure may sometimes be inferred from a colored geologic map.

Anticlines received their name because the observer was assumed to stand at the crest, from which the beds inclined outwardly in opposite directions; hence the prefix "anti," for "opposed." Standing in the trough of the syncline the observer sees the inclined beds sloping toward him, hence the prefix "syn," for "together." Anticlines and synclines of which the inclination is the same on both sides of axis (see diagrams) are called SYMMETRICAL. Symmetrical folds may vary from those of comparatively slight disturbance to tightly compressed folds. In the former, where the limbs of a bed are separated by other beds, the fold is called OPEN; but where from extreme compression the limbs of a single bed are brought tightly together, the fold is CLOSED. Fig 2 shows open symmetrical folds; Fig 4 closed symmetrical folds. A limiting case of the anticline, speaking mathematically, is the DOME, in which the beds pitch radially in all directions from a central point. The variable direction of the inclination has suggested the name QUAQUAVERSAL. A dome is an anticline of which the axis is reduced to a point. Domes are chiefly developed above laccoliths; seldom in other relations. A BASIN is a syncline the axis of which is a point, toward which the strata converge. Basins in this strict sense are rare, and result from local removal of support and collapse of strata. The term is also used in the geology of coal for a synclinal arrangement of strata, wherein a rising pitch of the axis in opposite directions brings the measures to the surface. The seams thus form concentric canoe-shaped or spoon-bowl synclines.

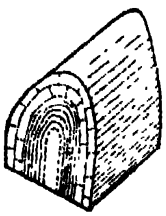

Fig 4. Closed Fold

Unsymmetrical folds. Strains which caused a fold may have pushed one limb under or over the other, thus producing unsymmetrical inclinations. From relatively slight differences, the overturn may increase until the overturned portion rests on an underlying portion. Such folds may even be S-shaped (SIGMOID) or RECUMBENT. On a small scale, these often occur in metamorphic districts; on a large scale they occur mainly in regions of violent disturbance.

Type names may be used, such as the Jura type for symmetrical folds; Appalachian type for those steeper on one side than the other (Fig 5). Closed folds are those of which the limbs are squeezed so tightly at one spot as to cause a great bulge of an upper or under core of rock. When the surrounding strata incline away radially from the compressed area, like ribs of a fan, the fold is called a fan-fold.

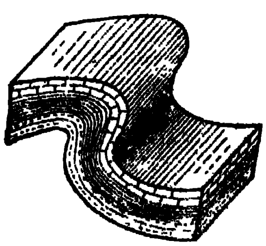

Fig 5. Overturned Fold of Appalachian Type

Folds vary in size from small wrinkles and puckers, as in schists, to arcs having chords of yards, miles, or hundreds of miles. Folds are sometimes designated as of the first, second, third, or higher orders. A mountain range, consisting of an anticline or a syncline, is respectively called an ANTICLINORIUM or SYNCLINORIUM, the Greek word for mountain being added to type of fold. When great flat folds occupy an appreciable part of earth's surface, they are called respectively geanticlines and geosynclines, prefixing Greek word for earth to name of fold. Folds are of great importance in engineering work, not only in mining bedded minerals like coal, salt, and some iron ores, or in the discovery of petroleum and gas, but also in connection with railway tunnels, aqueducts, and other engineering work.

Dip and strike. Dip is the angle of inclination of a vein or bed below horizontal. Strike (course or bearing) is the direction of line of intersection of an inclined vein or bed with a horizontal plane.

The dip angle is the angle between two perpendiculars, one in the inclined plane, the other in the horizontal, let fall from a common point on their line of intersection (the strike). The strike is stated in degrees and minutes, E or W of N or S, for example N 25° 30′ E. Since plane of dip is at right angles to line of strike, it is recorded in degrees E or W of strike; thus, a strike of N 25° E and dip of 50° N W signifies that the plane in which dip is measured runs 65° west of north. Some observers note exact direction and amount of dip, leaving strike to be inferred. Thus, a record of a sandstone bed dipping 50° in a direction N 65° W, implies a strike of N 25° E. First mode of statement is customary in America. A geologist's compass has one flat side, and usually a pendulum, swinging around a graduated semi-circle, so as to give direct dip reading. In plotting, each observation of strike may be corrected for variation of needle, or, in more elaborate compasses, the graduated circle may be turned to read directly observations referred to true north.

10. FAULTS

A fault is a dislocation in otherwise continuous strata or masses. It results when rocks are so excessively strained that they yield along a crack or series of cracks, one side altering its position with respect to other. One side may rise, sink, move laterally, or (as resultant of all 3 movements) diagonally, with respect to other side. In nearly all cases the fault plane or planes are inclined to horizontal, the upper and under sides being designated by the miner's terms, hanging wall and foot wall. Limiting cases are vertical and horizontal faults.

Classification of faults (11, 12). The commonest are: normal, reverse and shift faults (Fig 6, 7 and 8). In normal fault ("normal" here meaning "usual" or "common") the hanging wall has slipped down with reference to foot wall. The movement is rarely directly down line of dip of fault plane, but usually on a diagonal. The position of any point in dislocated portion is referred to the 3 axes of solid geometry: the vertical component is the throw; horizontal component perpendicular to the strike of the fault plane is the heave; and horizontal component in fault plane is the shift. These mathematical factors assist in determining direction and amount of movement, the line of which is the diagonal of the rectangular prism the edges of which are the heave, throw, and shift.

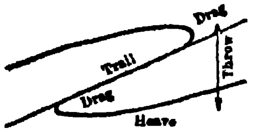

Fig 7. Reverse Fault, Begun as an Overturned Fold. Cross-section

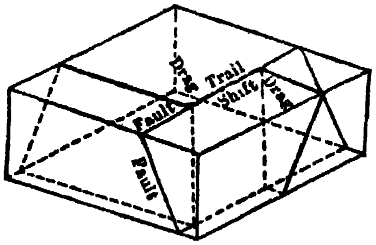

Fig 8. Shift Fault in Vein Dipping 50°. Same Effect would be Produced by Normal Fault, with Diagonal Displacement Involving Shift Component Away from Observer; or by a Large Throw, Straight Down the Dip

Fault-breccia. Movement of fault walls, or of one wall on the other, often crushes adjacent rock to a mass of angular fragments, mixed with more finely comminuted material. Circulating waters may cement the whole into a solid mass, by depositing new minerals, sometimes producing valuable ore. This mass is a fault-breccia. Fragments of any bed, dike, or vein, involved in the fault movement, will be dragged along from stationary side in direction of movement; or will be left behind by moving side; and if followed along fault plane, will indicate direction of movement. Such fragments furnish valuable evidence and by F. T. Freeland have been aptly termed the trail of the fault. Should a vein be cut off by a fault, with attendant breccia, fragments of the vein should be sought in the breccia and the trail followed to pick up continuation of vein.

Drag. Faults often cut relatively soft beds, as shales or shaly sandstones. Friction of the walls upon each other causes a downward bend in the beds of stationary or lifted side and an upward bend in those of the moving or dropped side. These bends, called drag, show the direction of movement (Fig 6). Drag is not found in strong rocks, like granites or heavily-bedded limestones.

Slickensides are polished and usually grooved surfaces, often caused by movement of walls of a fault or vein. Upon the wall-rock the grooves indicate direction of movement, but do not necessarily show which side has gone up, or down, or laterally.

Some observers have thought that by scraping finger nail or finger across the grooves, one side of them will be found steeper than the other. If the grooves are tested in slickensides on underside of plane of movement, such steep ridge is considered to be the lower side of groove, or the side which resisted bearing down of hanging wall while moving diagonally downward in fault plane. It will thus indicate the actual direction of movement. Should the steep ridge be on upper side of grooves, an upward movement of hanging wall is indicated. Others have thought that when the finger is moved along the groove the greater roughness is felt in the direction of movement of the part felt. Slickensides on fragments in fault-breccia are of little significance, since they are not *in situ*.

Horses are large disconnected masses of wall rock, involved in faults, or produced by forking of a fault fissure around a split-off fragment, and especially when related to subsequent vein-formation along fault.

Shear-zones. When a fault movement is distributed along a number of parallel planes not widely spaced, the wall rocks are broken into parallel tabular masses, and are said to be SHEETED. The resulting fault is "distributed," and the sheeted strip is a SHEAR-ZONE. GOUGE is a sheet of clay, often occurring along the outer edge of fault breccias, especially those subsequently mineralized by circulating waters. Other names are: SELVAGE and FLUCAN.

Fault-scarp. If a fault involves an appreciable vertical component, the relatively lifted side may stand out as a terrace or escarpment, the fault-scarp. Erosion soon wears it down, so that fresh fault-scarps are rarely recognizable. Faults have sometimes aided the deposition of ore bodies by furnishing waterways. When they are developed across an older mineral deposit. serious displacement may be caused.

Rules for solving faults have been formulated by Schmidt (13), Zimmermann (15), Freeland (9) and others. In studying a fault, observe trail, drag and slickensides. Stratigraphical succession, if known, will reveal amount of displacement. Bore-holes are useful. Models assist, and are sometimes superior to projections on paper. If there be no evidence to contrary, the assumption that fault is normal is justified, because most faults are such. Nevertheless, experience shows that a reverse fault occasionally appears in a series of normal faults, that shift faults may occur, and that fault movement may be rotational (normal at one extreme of fault plane, reverse at other). On encountering a fault, a mathematical solution is attractive, but, despite many text-book discussions, the necessary data are seldom obtainable. Attention should be concentrated on the fault plane and the movement along it (14). The dislocated portion of a tabular body is to be sought, presenting a broad surface, if rightly attacked. As a rule, it is easier to drift horizontally, than to sink or raise; the procedure is largely determined by the way the vein or bed lies.

Assume a series of stratified rocks, the succession and thickness of which are known by previous mining operations, by study of the surface, or by borings. If a bed on far side of fault is recognizable, and its place in the series known, the direction and amount of movement may be determined. As gulches often occur on faults, because of easy erosion of crushed rock, faults may sometimes be solved more readily by study of surface exposures than by observation solely underground. Directions of slickensides, drag, and trail, commonly found in faulted stratified rocks, are highly significant. If none of these evidences is decisive in dealing with a mineral deposit cut by a fault, there is strong probability that the fault is normal. On this assumption, if a fault be encountered on its under side the rule is to cross it and sink; if on its upper side, to cross it and raise. This is expressed in the old rule: "follow the obtuse angle." But, if the fault happens to be reverse, the rule would lead in wrong direction.

In dealing with steeply dipping veins in massive rocks, or steeply dipping stratified rocks containing coal seams or other interstratified deposits, the succession of strata must be known to determine the movement. Then, solving tentatively as a normal fault, due weight must be given to throw and shift, as possible components of diagonal movement. That is, besides the heave and throw of a normal fault, a large shift-component might cause displacement opposite to that anticipated, instead of straight down the dip. The occurrence of slickensides, trail, and drag may then be essential to correct solution.

Zimmermann's rule (15), for steep faults, cutting steeply dipping veins. Suppose (Fig 9), in driving a level on vein *so*, striking N 30° W and dipping 60° W, a fault *ff* is met, striking N 80° E and dipping 45° S. At intersection *o*, draw *ob* perpendicular to strike of fault, and prolong it toward *l*, beyond the fault. Project upon plane of level the intersection *og* of fault and vein. Line *og* is horizontal, and passes obliquely through *o*, into unexplored ground, toward *h*, on one side or other of *ol*. Then, if exploratory drift on far side of fault be turned from *oh* toward *ol*, and parallel to strike of fault, the displaced segment *xy* of vein will in most cases be found.

The horizontal projection *og* is found as in small diagram of Fig 9. Draw horizontal line *mn*, lay off *ma* and *mb* to represent dips of vein and fault; draw *mo* perpendicular and *ob* parallel to *mn*. Then *oa* and *ob* are the distances by which, in descending a vertical distance *mo*, the planes of vein and fault depart horizontally from vertical. In main part of Fig 9, *oa* and *ob* are drawn respectively perpendicular to strikes of vein and fault; and *ac* and *de*, passing through *g*, are parallel to those strikes. Whence *g* lies in the horizontal projection of intersection of vein and fault.

In Fig 10 is shown a similar relation of vein and fault, except that the vein lies east and exploratory drift should turn east, as shown. Both solutions depend on assumption that the hanging wall of fault (*i e*, its south wall) has slipped with little shift down on its foot wall. With strongly diagonal movement the fault might still be normal, but the solution might lead miner in wrong direction. Therefore check all rules by trail, drag, slickensides, etc.

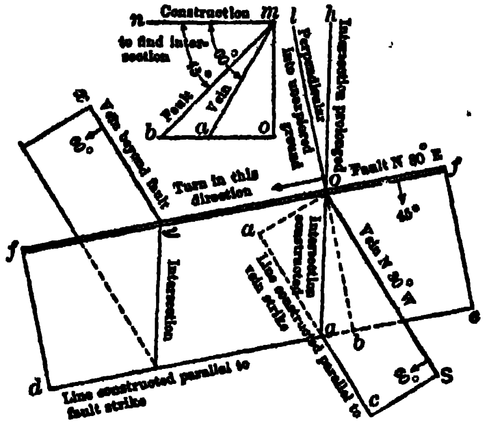

Fig 9. Zimmermann's Solution of a Fault (Projection on Horizontal Plane)

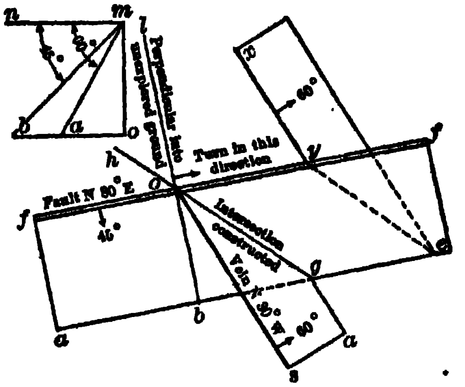

Fig 10. Zimmermann's Solution of a Fault. Construction as in Fig 9, but Vein Dips *East*, whence Exploratory Drift Turns East

The following additional terms apply to faults. In tilted, stratified rocks, faults striking parallel with the strata are STRIKE-FAULTS, often resulting when folds pass into faults. Faults running across strike and parallel with line of dip are DIP-FAULTS. STEP-FAULTS are series of parallel faults, dipping in same direction. The HADE is the angle made by a fault plane with a vertical plane; hence, hade is the complement of dip, and is a superfluous term.

Various puzzling cases of faulting have become classic. Fig 11 shows a Cornish case, from de la Beche; Fig 12, a case of two contrasted pegmatites in Sweden, observed by A. G. Högbom. Two parallel veins may be so faulted as to bring dislocated part of one opposite sundered end of another, and temporarily conceal the existence of a fault. In a certain shift fault, cutting a vein at right angles to vein's strike, the amount of shift was observed to grow gradually less in depth, leading to inference of a HINGE-FAULT, or possibly a ROTATIONAL FAULT.

Normal faults are often explained as due to tension strains in earth's crust, leading to drawing apart of the two sides of fault, and the slipping down of upper portion on lower; hence, they have been called tension or gravity faults. Reverse faults, by contrast, are called compression or THRUST faults; they often begin as overturned folds. If these stresses do produce their respective faults, then reverse faults should customarily have low dips, since, on approaching the perpendicular, friction would increase prohibitively. But, if tensional stress were relieved by a series of parallel faults, and one fault block were to drop below its neighbors, there would be a normal fault on one side of dropped block and a reverse fault on the other.

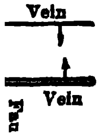

Fig 11. Two Veins, with Converging Dips, Normally Faulted

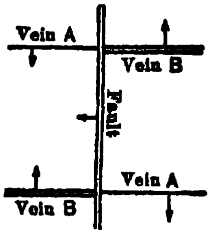

Fig 12. Two Veins, with Converging Dips, Dropped Below their Intersection by a Normal Fault

Compressive strains along the strike can easily develop normal faults by downward bulge of hanging wall and upward bulge of foot. Where comparatively short faults die out at each end, this explanation has weight. Again, assuming that in depth rocks are capable of viscous flow and transfer, pressure transmitted upward from such moving masses may cause faults from stresses wholly different from any previously mentioned. Where faults are inclined, fault blocks with the larger base would be relatively lifted, as compared with those having smaller base. Foot-walls would therefore rise relatively, causing normal faults (6, 7, 8, 10).

11. JOINTS, UNCONFORMITIES, OUTCROPS, EROSION

Joints are cracks which cross strata and masses, without producing dislocation of walls. Notwithstanding absence of dislocation, there may be difficulty in discriminating between joints and distributed faults of slight displacement, which produce sheeted structure.

All joints are due to easing of some kind of strain: as contractions in cooling of igneous rock, expansion of cold rock under the sun's heat, shrinkage from drying of water-soaked sediments, tensional strains at crests of anticlines or in outer layers in bottoms of synclines, and torsional stresses produced over wide areas by warping of earth's crust. As a result rocks break into polygonal columns of greater or less regularity. In joints produced by contraction of igneous magmas during consolidation, the long axes of the prisms are theoretically perpendicular to cooling surface. If the magma be homogeneous and transfer of heat uniform, regular hexagonal columns result, parted also across their axes by cup-shaped joints. Occasionally, as at Giant's Causeway, theoretical perfection is almost attained; usually, the columns are of all numbers of sides, from 3 to 8. Similar forms result from drying.

Strong heat of sun and weathering cause massive rocks to shell off in thin layers. Angular blocks produced by jointing may become rounded boulders. In granite quarries the SHEETING in great concentric curves, like a huge onion, has probably been caused either by contraction strains in cooling, or compression strains in earth's crust. Cracks which yawn upward at crests of anticlines, and gape downward in troughs of synclines, are common features of folds. In certain districts of flat sedimentary rocks (as in southern central New York), joints in two series, intersecting each other at nearly right angles (usually about 80°), run with remarkable regularity; probably due to torsional strains from warping. In areas of massive or metamorphic rocks, while a principal series can be traced, other joints show no regularity. Observed strikes may be plotted over a wide area, as lines intersecting at a common center like a clock-face, resulting in detection of prevailing strikes. The predominant joint is called a MASTER JOINT; the others, minor joints. Joints are of great practical importance in quarrying and in mining.

Unconformities. Tilted strata may subsequently be eroded, and buried under later sediments, with great discordance of dip; the lower strata being steeply inclined, the upper flat (Fig 13). A great time interval is thus indicated and an important break in the geological record. Unconformities are the best bases for division of geological time.

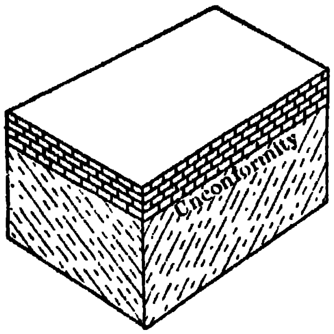

Fig 13. Unconformity of Manlius Limestone on Hudson River Ordovician Sandstone, Marking a Time Interval of nearly a Geol Period. Sandstones were Deposited Flat, then Tilted, Eroded, and Covered by Limestones, which were at first Flat. Near Rondout, N Y

Practically flat strata may be carved by erosion into gorges of narrow valleys; which, if again submerged, may be filled with new, flat sediments, showing no discordance of dip with older strata, but perhaps bringing sandstones sharply against limestones or other strata. This relation is a DISCONFORMITY (Fig 14). Should the sea, because of gradual submergence of shore, creep gradually upward and bring younger flat strata on top of much older ones, a SEDIMENTARY OVERLAP is formed.

Outcrops are portions of solid rock IN PLACE, projecting at surface. By observations upon them questions are solved regarding structure and stratigraphic relations. Regions without outcrops must be explored by trenches, pits, or bore-holes; in northern latitudes glacial drift is the chief obstacle; in southern, the products of rock weathering or decay. Heavy vegetation may increase difficulty.

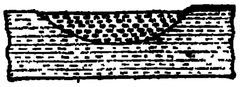

Fig 14. Disconformity, Vert Sec. Older Sandstones Eroded, and Resulting Valley Filled with Conglomerate, with no Discordance of Dip

Erosion, the wearing down of land and transfer of loose particles by water, wind, or ice, to places of deposition at lower altitudes, is in one sense destructive; in another, constructive, for sedimentary rocks are thereby composed.

Water erosion by streams, waves, or currents along shore lines, is the most important. Matter carried in suspension facilitates wear of rock masses exposed to moving grit. Of the same substance, larger particles require swifter currents for their removal than do the smaller, the surfaces of which are relatively greater compared to their masses. Small particles of high specific gravity may require as great velocity of current as large particles of low specific gravity As velocity decreases, sorting action takes place; the large and the heavy small particles sink first, small particles remaining in suspension, though presence of solutions of mineral salts or of acids facilitates clearing of fresh water emulsions. The transporting ability of a current increases with sixth power of velocity. Thus, if a current can move a 1-in cube of quartz, by doubling its velocity it can move a 4-in cube, or 64 cu in; because, twice as much water strikes the cube, with twice the velocity.

Competence of a stream refers to the maximum size of particle of given sp gr which, at a given velocity, the stream will move. Thus, a small, rapid stream can move a relatively large particle. Its competence is great, but total transported material will be small. Conversely, a large, slow-moving stream might carry in suspension a great quantity of small particles. Its competence is small, but its capacity is great. These principles are important in the development of placers; they also underlie the artificial concentration of ores.

Waves on a shore line batter cliffs, and with the ammunition provided by boulders do great execution during storms. In creeping across a subsiding shore they may ultimately level every eminence in their way. Off-shore currents are vehicles of transport, building up bars, spits, etc. In association with sedimentation by rivers, such currents wear away points and fill coastal bays.

Winds are specially effective in desert regions, the loose surface materials lacking protection of vegetation. Small particles as dust are carried by milder winds; while by storms even gravel may be swept along. The march of sand dunes is one of the results.

Glaciers are powerful agents in carrying away loosened pieces from cliffs, and grinding smaller particles from rocks on their sides and bottoms. Deposited products of glacial action are called MORAINES, with terminal, lateral, and ground moraines as varieties. The material is rarely sorted, so that very coarse and very fine are mingled. Unsorted glacial deposits are usually associated with others worked over by water.

12. SUMMARY OF STRATIGRAPHIC GEOLOGY

Definite periods of time are assignable for the formation of strata of earth's crust, and each period is characterized by presence of remains of distinctive organisms. During the 19th century, geologists succeeded in classifying according to geological age nearly all strata of earth's surface, however remote the region, provided properly preserved organic remains or fossils were present. Strata without fossils, or so metamorphosed as to destroy their fossils, were either classified by their relations to determined strata, or else proved insoluble problems. Recognizing the importance of uniformity of usage in time divisions and their corresponding strata, the International Geological Congress, Paris, 1900, adopted the following:

TIME	STRATA	TIME	STRATA
1. Era	No equivalent	4. Age	Stage
2. Period	System	5. Phase	Zone
3. Epoch	Series		

This table signifies that, during a period, strata constituting a system were formed; during the shorter epoch, a series, and so on. A system may embrace several series, each of which has stages, in turn divisible into zones. In the geological mapping of a district it is customary to work primarily on basis of periods-systems, and then under each to apply a local, geographical name to any stratum sufficiently persistent and well defined to be recognizable over an extensive area. The following table summarizes the generally accepted conclusions. For periods the older names are given, but it is now common to terminate periodic names in "ic"; thus, Carbonic for Carboniferous, etc.

Eras	Periods	Eras	Periods
Quaternary or Psychozoic	Recent Pleistocene, or Glacial	Paleozoic	Permian Carboniferous Devonian Silurian Ordovician Cambrian
Tertiary or Cenozoic	Pliocene Miocene Oligocene Eocene		
Mesozoic	Cretaceous Comanchean Jurassic Triassic	Pre-Cambrian or Archean	Keweenawan Huronian Laurentian Keewatin

Pre-Cambrian. Igneous rocks and metamorphic sediments predominate; including gneisses, schists, quartzites, slates, and marbles, with associated deep-seated and volcanic igneous rocks. In North America the most extensive exposures are in Canada, constituting a vast V-shaped area, with Hudson's Bay in the opening and the point at the Great Lakes. Underlying the entire continent, they also appear in backbones of the Appalachian and Rocky Mountains, and occasionally project elsewhere in small patches. Though almost devoid of fossil remains, sponges, algæ, and trails of moving organisms have in recent years been discovered in the Huronian, in Lake Superior region and Montana. Pre-Cambrian strata are very productive of metals, especially iron. KEEWATIN greenstones contain the gold veins at Porcupine, some of the Cobalt silver veins, and iron ore of Vermilion Range, Minn. LAURENTIAN consists of intrusive igneous rocks, poor in ore deposits. HURONIAN embraces a great series of metamorphosed sediments, with some igneous rocks, and yields the chief American iron ores in the Lake region. It has also most of the silver veins at

Cobalt, Ont. Keweenawan is largely a succession of basaltic rocks and minor sediments; it contains the copper mines of Keweenaw Point, Mich.

Paleozoic. Around the edges of pre-Cambrian areas are the earliest Paleozoic strata (unless from overlap later ones have crept inward over the earlier). The successive strata of the 6 periods are often marked off by unconformities, upturned by disturbances, and are sometimes missing in individual cases, where land conditions prevailed. In North America they are in greatest development in the U S, east of the Mississippi, and in states just west of it. In the Cordilleran region the areas are smaller and scattered. The Clinton iron ores appear in the east in the Silurian; the eastern coal supply comes from the Carboniferous; the eastern oil and gas are mainly in the Ordovician, Devonian, and Carboniferous.

Mesozoic strata are chief components of western half of North America; are of vast development in the Great Plains, the Cordillera, and Mexico. The western coals are chiefly in Cretaceous strata, but appear also in Eocene beds of next era. The mountain upheavals at close of Cretaceous, with attendant igneous outbreaks, are largely reponsible for the western ore deposits.

Cenozoic strata appear in the east in a coastal fringe. In the west they are represented by old land or lake deposits in the Great Plains, and marine strata along the Pacific. Because of the great development of mammals, the fossil remains are of great interest, especially in their bearings on doctrine of evolution.

Quaternary (sometimes called Psychozoic) is the era of man's especial development. It is marked by the continental ice sheet in its early portion in the north; in the south, by products of weathering and recent sediments. The strata of the closing Glacial or Pleistocene (Pleistocene is term especially used for regions south of glacial drift) pass gradually into coastal deposits now forming.

Note.—For full discussion of eras and periods, see Bibliog, numbers 17 to 22.

MINERAL DEPOSITS: ORES

13. INTRODUCTION, DEFINITIONS OF ORE

Mineral deposits include both ores and non-metallic minerals. In earlier years the metals were chiefly mined, but in recent time non-metallic minerals have greatly increased in relative importance. Metalliferous minerals only are included under the head of "ore deposits," non-metallics being treated separately.

Scientifically, the word "ore" comprehends all metal-bearing minerals which are commercial sources of the metals, percentages not being considered. Technically, an ore is a metal-bearing mineral, or aggregate of such minerals, mixed with barren matter, called "gangue," and capable of being mined at a profit. By contrast, where the element of profit is uncertain or impossible, the term "mineral deposit" may be used instead of "ore deposit." Thus, pay ore or commercial ore is contrasted with an orebody of uncertain yield. The richer part of an ore deposit is the "pay-streak" or "ore-shoot;" very rich parts, "bonanzas." The phrase "the ores" is sometimes employed by students of the microscopic characters of igneous rocks, to designate the group of minute minerals which first crystallize in the cooling of a molten magma. Magnetite is its most conspicuous member (25).

14. METALS IN THE EARTH'S CRUST

Ore deposits are portions of earth's crust enormously enriched with metals as compared with the rest. On basis of composition of the crust given in Sec 1, Art 1 (fuller details in *Bull* 491, U S Geol Surv, pp 27, 33), it is seen that among percentages down to a minimum of 0.03, a few common metals are named, *viz*: aluminum, 7.28; iron, 4.12; manganese, 0.08. In igneous rocks, considered alone, nickel, 0.023, and chromium, 0.033, are also found. Copper may reach 0.01%, but all others, lead, zinc, silver, gold, quicksilver, tin, etc, are expressed in very small decimals of 1%. An ore deposit, therefore, is a relatively enormous local concentration of metals, from a minimum of 4 times for low-grade aluminum ores, 7 times for low-grade iron ores, and 200 times for low-grade copper ores, to a concentration which, for the other metals, may reach thousands or hundreds of thousands. Ore deposits are largely produced by concentration by circulating waters in earth's crust.

15. CAVITIES IN ROCKS; GROUND-WATERS

Cavities in rocks. From the point of view of physics, the smallest cavities are those below capillaries, *i e*, below tubes 0.0002 mm diam, or tabular spaces 0.0001 mm across. In these, under ordinary conditions, adhesion prevents circulation. Capillaries range from the above dimensions to 0.5 mm for tubes and 0.25 mm for tabular spaces. In rocks these small cavities, called voids, appear as surviving and unfilled pores of crystals, contact spaces between minerals or grains, and cleavage cracks. They are expressed in tenths of

1% of the volume in dense rocks, up to 10% or more in porous sandstones. Cavities of larger size are found in pumice, amygdaloids, jointed rocks, faults, and caves.

Ground-waters, or waters which are below the earth's surface, are of 3 kinds: meteoric, connate, and magmatic. METEORIC water descends as rain and snow, in part soaking into the ground, and forming the standing body of water which requires pumping in mines, etc. CONNATE water is contained in sediments deposited beneath sea or lakes, having been carried down with the sediments as they were buried beneath later strata. MAGMATIC water is set free in the cooling and consolidation of molten masses of igneous rock, becoming manifest at volcanic vents and presumably in hot springs, which nearly always accompany expiring vulcanism.

Formerly, in discussing the formation of orebodies by underground circulation, only meteoric waters were considered. They were believed to descend to the general limit of cavities, to migrate extensively through small cavities in rocks; and, when heated from below and charged with ore and gangue, to return by larger channels towards the surface, forming veins and other orebodies. Connate waters were recognized in brines, often pumped to surface for salt. But, as experience in deep mines proved that meteoric water is almost always limited to the upper zone of about 1 000 ft, geologists have attributed more and more importance to magmatic waters to which the primary introduction of ore and gangue can be referred with fewer difficulties. This view is strengthened by the common association of ore deposits with intrusive igneous rocks, by study of contact zones and pegmatites, and by observations upon volcanic emissions. Apparently, magmatic waters or vapors or gases emerge from the igneous mass charged with the components of ores and gangue; but in subsequent circulation, they make take up more minerals, and bring all to a place of precipitation. The heat of an intrusive, igneous mass is a powerful agent in promoting underground circulations. It is more efficient than the normal increase of temperature with depth, or than natural head from high points of entrance and low points of emergence, the friction of small passages being considered (29).

16. MINERALS AND LOCALIZATION OF ORE DEPOSITS

Ore minerals are primary and secondary. The PRIMARY are those originally deposited in forming an orebody; the SECONDARY are produced by alteration of primary minerals under certain conditions. Except aluminum, iron, manganese, chromium, platinum and tin, all primary ore minerals are sulphides, arsenides, sulpharsenides, sulphantimonides, or similar compounds. Sulphides are of chief importance. Though secondary minerals are largely oxidized compounds, they also comprise a few very important sulphides.

The importance of the distinction lies in the following relations to the surface. Ground-waters stand at varying depths, depending on local rainfall, rock texture and local geological structure. Between ground-water level and the surface, is a zone called by Posepny the vadose zone, by Van Hise the zone of weathering, through which the oxidizing and dissolving rain waters freely descend. Within this vertical range, sulphides become oxidized to sulphates, and pass extensively into solution. Migrating downward, the solutions merge into the standing and protecting ground-waters, and often precipitate their dissolved metals in a zone of SECONDARY ENRICHMENT, at or near ground-water level. The reaction is especially important in copper mines.

Gangue minerals comprise quartz, calcite, fluorite, barite, rhodochrosite, rhodonite, and admixed minerals of the country rock. Decomposition or alteration under influence of thermal waters gives rise to much sericite, kaolinite, and related species.

Localization of ore deposits. Ore deposits resulting from processes outlined above are developed where circulating mineral-bearing solutions find favorable places to precipitate their contents. One method of classification is to arrange in a logical scheme the favorable geological places for this reaction. For the formation of some kinds of ore deposit, however, circulating solutions are not required. Ores may crystallize directly from molten magmas, and, either by sinking in the fluid mass because of higher specific gravity, or for some reason not well understood, may enrich the rock mass to the requirements of mining. Again, and in contrast with the reactions above indicated, moving waters in streams, or by wave action, may liberate and concentrate heavy minerals in sedimentary deposits, to the point of profitable mining. Again, in residual deposits, heavy and resistant minerals may be left behind in a concentrated condition by removal of products of weathering. In a few cases, chiefly iron ores, the processes of sedimentation, or associated precipitation, have given rise to bedded ore deposits. Experience shows, therefore, that it is difficult consistently to classify orebodies on any one of these subordinate principles. But, as compared with old-time schemes, based on shape, the broad principle of MODE OF ORIGIN has become increasingly important. In the following classification, the endeavor has been to pass from igneous phenomena, pure and simple, to surface reactions not connected with igneous phenomena, emphasizing especially the PLACE where orebodies originate.

Zonal distribution. Closer study of mining regions in the Cordilleran region of North America leads to following conclusions: (*a*) Ore deposition follows intrusions of igneous rocks, most frequently those related to granites or species intermediate between granites and diorites (as, granodiorites and quartz-monzonites). The ores are products of the cooling stages, precipitated in largest part from magmatic waters (30). (*b*) Ore and gangue minerals are distributed outwardly from the igneous center, in a series beginning with those requiring high temperatures and high pressures for their formation, and passing through varieties precipitated under diminishing temp and press until surface conditions are reached (31). Some persistent minerals, as pyrite, have a wide range of conditions. (*c*) It results that around an igneous source, both vertically and laterally, when the original magma produced several metals, zones characteristically containing certain ores may be recognized. In the igneous intrusive may be magmatic segregations (Art 17). Next come pegmatic dikes and contact zones; then, gold-bearing quartz veins related to pegmatites, dike-veins; then copper-bearing pyrite-quartz veins, passing into zinc-blende bearing phases in which zinc replaces copper, while pyrite persists. Farther out, galena replaces zinc-blende, and yields in succession to high-grade silver ores, gold tellurides, antimony ores, and others. Finally, gangue minerals alone survive (32). This principle is called the zonal distribution of metals, and in many districts has proved of great value as a guide to mine development.

17. CLASSIFICATION OF ORE DEPOSITS (37)

I. Primary magmatic origin.

(*a*) Masses produced by crystallization and segregation in cooling and solidifying igneous magmas: titaniferous and non-titaniferous magnetites, chromite, corundum, platinum, and probably sulphides of iron, nickel, and copper. A few dikes and sheets of igneous magnetite are known.

II. Deposited by emissions from cooling and solidifying magmas.

(*b*) Veins of nature of pegmatites, varying from the mineralogy of granite to fairly pure quartz; often with tourmaline, fluorite and minerals containing boron or fluorine; productive of tin, rare elements, and exceptionally gold, and intermediate in nature between dikes and veins; sometimes described as aqueo-igneous. (*c*) Contact deposits, produced from limestones by emissions from adjoining igneous magma, and consisting of lime-silicates, as: garnet, diopside, wollastonite, vesuvianite, epidote; also, magnetite, specular hematite, sulphides of iron, copper, and other metals.

III. Deposited by circulating ground-waters.

(*d*) Deposits in or along faults, with replacement and impregnation of the walls; often called "true fissure" veins. They vary from the filling of an open and clean-cut fissure, to impregnation and replacement of closely spaced faults of small individual displacement. (*e*) Saddle-reefs: precipitations of quartz or other minerals, at crest and between layers of an anticline, and extending with diminishing thickness for varying but usually moderate distances down its flanks. Inverted saddles appear in synclines. Apparently arching of the strata has aided precipitation. (*f*) Deposits in joints with greater or less replacement and impregnation of the walls; often called "gash veins," because limited to a single stratum or sheet. (*g*) Impregnations of volcanic agglomerates in the conduits of extinct explosive volcanoes. (*h*) Impregnations with greater or less replacement of permeable rocks, as: amygdaloids, volcanic tuffs and breccias, open-textured sandstones and conglomerates, autoclastics, etc. Supply conduit may be obscure. (*i*) Replacements of limestones, calcareous shales or other beds, which have yielded to circulating ground-waters. Supply conduit may be obscure.

IV. Deposited or concentrated by aid of surface waters.

(*j*) Surface precipitations, which may later be involved in stratified series. Bog iron ores. (*k*) Resistant or insoluble minerals, concentrated as a residuum by weathering and removal of the matrix. Residual deposits; Cuban brown hematites. (*l*) Placers or concentrations of heavy minerals in sands and gravels by action of moving water. Gold placers; stream tin.

18. IRON ORES

Four minerals are chiefly productive of iron: limonite (brown hematite, brown ore) $2\ Fe_2O_3 \cdot 3\ H_2O$, Fe 59.8%; siderite (carbonate, spathic ore) $FeCO_3$, Fe 48.3%; hematite (red and specular) Fe_2O_3, Fe 70.0%; magnetite (magnetic ore) $FeO \cdot Fe_2O_3$, Fe 72.4%.

Associated with limonite, but less common, are other ferric hydrates, as: turgite ($2\ Fe_2O_3 \cdot H_2O$); goethite ($Fe_2O_3 \cdot H_2O$). Hydrated silicates may also occur, as: chamoisite (hydrated ferrous aluminum silicate); thuringite (hydrated ferrous or ferric aluminum silicate); greenalite (hydrated ferrous silicate). Siderite may have its iron partly replaced by magnesium and calcium. With brown hematites, manganese minerals are not uncommon. Pyrite (FeS_2) may appear with all the ores, and, when largely freed of its sulphur, may yield a residue possible of utilisation for poor grades of iron. Pyrrhotite (Fe_7S_8) is frequent with magnetites. Ilmenite ($FeO \cdot TiO_2$) is mechanically mingled with many magnetites. Objectionable ingredients of iron ores are S and P; definite limits of these for merchantable grades of ore are variable, due to possible admixtures in furnace practice; in general, the less the better. In ores for acid bessemer pig, permissible phosphorus max is 0.001 part of the percentage of iron. Roughly, therefore, about 0.06% is max with richest ores.

Magnetites and specular hematites are the richest iron ores. In America lump magnetite ores have in the past exceeded 65% iron, but today practically only magnetically concentrated ore reaches this figure. Kiruna, Swedish Lapland, however, can furnish a great tonnage of this grade, even to American furnaces. Average of all iron ore mined in the U S in 1925 was not far from 50% iron. The grade will doubtless gradually decline. Alabama Clinton red hematites run 36 to 37%. Some crude ore is even lower. The principal local supply of continental Europe, from the minette ores, averages about 30%. The nearness of good fuels, markets, mixtures, etc, determine limiting percentages.

In the U S about four-fifths of the ore comes from Lake Superior region. Next in order are the red hematites of Alabama and Tennessee, the brown hematites and the magnetites of Appalachian belt. Individual mines in Wyoming, Colorado, and New Mexico have fed the iron and steel plant at Pueblo, Colo. Magnetites will be produced in time on the Pacific coast for a future industry to be located presumably in the Puget Sound region.

Lake Superior iron districts. In order of productiveness in the Lake Superior region are Minnesota, Michigan, and Wisconsin. Ontario has one productive range, and possibility of developing others. The ores of this region are all in pre-Cambrian strata:

Keweenawan: sandstones, basalt flows. Copper. Huronian. Upper, Middle and Lower: sedimentary and some igneous rocks. Iron ores in the sediments. Laurentian: granites. Keewatin: green schists, from ancient basic eruptives. Some sediments with iron ores.

As now mined the ores are chiefly soft, partially hydrated hematites, their percentage of water not reaching that of limonite. They have been produced by alteration of great beds of cherty carbonates of iron, of hydrated ferrous silicate, and of associated pyrite, under the general processes of weathering. Soft earthy masses of ore have thus resulted; of enormous volume, accessible, cheaply mined, and of relative purity as regards phosphorus and sulphur. They occupy synclinal basins, troughs produced by intersection of igneous dikes with each other or with impervious strata, or other minor places where circulating and oxidizing meteoric ground-waters have been temporarily obstructed in their flow. Besides soft ores there are lenticular bodies of hard specular hematite, produced by metamorphism of ancient soft-ore bodies; also great bodies of jaspery or siliceous iron-bearing strata, of 35% and above in iron, which, partly as concentrating ore, partly as low-grade lump ores, with the gradual exhaustion of better grades, will be available for a long time to come. The grade is well above that of present European ores. These ores originally formed beds precipitated at surface (Art 17, IV, *j*). They became bured in a stratified series, and afterward by weathering yielded residual deposits (Art 17, IV, *k*), some of which extend to great depths and are cases of secondary enrichment. Some have been metamorphosed to specular hematite, and even magnetite. In northeastern Minnesota gabbros occur with igneous titaniferous magnetites, not yet shown to be valuable (Art 17, I, *a*) (38).

Clinton red hematites are next in productiveness. They appear as beds of oölitic, often fossiliferous ore, associated with olive-green shales and subordinate limestones of the Clinton stage, at base of Silurian system. They outcrop in S E Wisconsin, western Ohio, central Kentucky, western New York, south of Lake Ontario, and farther east at town of Clinton (whence their name); in Pennsylvania, Virginia, eastern Tennessee, Georgia, and Alabama. Their greatest development is in Alabama, where they form an inner terrace, called Red Mountain, in the Birmingham anticlinal valley. Good coking coals and limestone are near, so that low-cost pig can be produced even from 35 and 40% ores. At outcrops the ores are siliceous; below ground-water level, they become basic. All are moderately high in phosphorus. They are probably oölitic beds, precipitated in shallow estuaries, fed by iron-bearing drainage (C. H. Smyth). Although utilized in Tennessee and Georgia, they are most important in Alabama. In time those in New York, Kentucky and Wisconsin are destined to be of greater moment than now.

Brown hematites ("brown ores") of the U S are produced chiefly along that portion of the Appalachian mountains formed by early Paleozoic strata, and just west of the earlier crystallines. They are products of weathering of ferruginous rocks, especially limestones. In almost all the mines they must be freed of ochers and clays by washing.

Magnetites occur in two chief types of deposits. The commoner is a lenticular or pod-shaped mass, in gneisses, parallel with the foliation. They appear widely in the ancient Appalachian crystallines, but are most productive in the Adirondacks. The second type appears in the contact zones (Art 17, II, *c*), produced by intrusive igneous rocks on limestones or limey shales. The greatest deposit of this type in the East is at Cornwall, Penn. The igneous rock is diabase and the limestone, Cambro-Ordovician. In the West many such deposits are known, in Utah (Iron Springs Dist), Nevada, California, and along the northwest coast.

In Europe, Germany, England, and France follow the U S in order of production of iron ores, the greatest single source being found in a series of Jurassic beds in and near Luxemburg, and in the northeast of England. The ores (called "minette") are of 30% or a little higher, and are brown

hematites, carbonates, and various silicates. Minor orebodies are in veins, of carbonates, and in beds of clay iron-stone and black-band. Spain ships from Bilbao great quantities of partially hydrated hematite, the weathered product of spathic ores in depth. Sweden is a heavy exporter of magnetites, especially from the igneous sheet of magnetite at Kiruna, Lapland. Many lenticular magnetites have been worked in middle Sweden. Great bodies of igneous magnetites exist in the Urals. Algiers ships important amounts of red, partly hydrated hematites.

Large orebodies have recently been developed in N E Cuba, where ancient serpentines have weathered for ages, leaving a residual soil, rich enough in iron to form ore. Great reserves of specular hematite, of ancient geological age, occur in eastern Brazil, state of Minas Geraes. With the opening of the Panama canal, iron ores reached American furnaces from Chile. In S E Newfoundland, at Wabana, extensive beds of red hematite have been developed in recent years (39).

19. COPPER ORES

The minerals in Table 4 constitute the common ores of copper:

Table 4. Copper Ores

Sulphides	% Cu	*Sulphates*	% Cu
Chalcopyrite, $CuFeS_2(Cu_2S \cdot Fe_2S_3)$	34.60	Chalcanthite, $CuSO_4 \cdot 5H_2O$	25.38
Bornite, $Cu_3FeS_3(2\,Cu_2S \cdot Fe_2S_3)$	55.50	Brochantite, $Cu_4(OH)_6SO_4$	56.10
Covellite, CuS	66.48	*Carbonates*	
Chalcocite, Cu_2S	79.80	Malachite, $CuCO_3 \cdot Cu(OH)_2$	57.27
Sulpharsenides and Sulphantimonides		Azurite, $2\,CuCO_3 \cdot Cu(OH)_2$	55.10
Enargite, $Cu_3AsS_4(3\,Cu_2S \cdot As_2S_5)$	48.40	*Silicate*	
Tetrahedrite, $Cu_8Sb_2S_7(4\,Cu_2S \cdot Sb_2S_3)$	52.06	Chrysocolla, $CuSiO_3 \cdot 2H_2O$	36.00
Oxides		*Oxychloride*	
Melaconite, CuO	78.86	Atacamite, $Cu_2Cl \cdot (OH)_3$	59.29
Cuprite, Cu_2O	88.80	*Native Metal*	
		Native copper, Cu	100.00

The distinction between primary and secondary minerals is more important with copper than with any other metal. Some copper minerals appear in both groups. PRIMARY: chalcopyrite, bornite, chalcocite, enargite, tetrahedrite (some native copper in Lake Superior mines). SECONDARY: chalcocite, covellite, melaconite, cuprite, chalcanthite, brochantite, malachite, azurite, chrysocolla, atacamite, and native copper. Possibly chalcopyrite and bornite are secondary in some cases. As a primary mineral lean copper-bearing pyrite is very important, especially in intrusive rocks. When oxidized by meteoric waters in the vadose zone (belt of weathering), all copper-bearing sulphides yield some form of sulphate. This soluble salt, in deposits in siliceous rocks, trickles downward until, in contact with some reducing agent, like pyrite, the copper is precipitated as chalcocite. This causes great concentration of copper, at or near ground-water level, termed SECONDARY ENRICHMENT. From bodies of copper-bearing sulphides, in regions of abundant rainfall, as at Ducktown, Tenn, an upper zone or GOSSAN of brown hematite results, which may form an iron ore. Below this, near ground-water level, a belt of rich chalcocite (black ore) appears, containing most of the copper once distributed throughout upper part of deposit. Still lower are unaltered, primary sulphides. In a comparatively arid region, when copper-bearing sulphides, usually in form of cupriferous pyrite, are disseminated in intrusive igneous rocks, or quartzites, or schists (which may be crushed or rendered open-textured along a zone of movement), descending waters of the vadose zone develop an upper leached belt, underlain by a chalcocite-bearing section of maximum richness; and below this is a belt of slight secondary enrichment. Thus have originated the disseminated copper ores, now being extensively mined in the southwest. If oxidizing reactions occur in open-textured tuffs, or contact lime silicates, chrysocolla often results, instead of chalcocite; if in presence of limestone, the blue and green carbonates and cuprite are characteristic products. In North America most of the copper produced comes from chalcocite. The region of Northern Rhodesia, with adjacent portions of Katanga, contains the largest copper-bearing area known.

Examples of copper deposits (letters in parentheses refer to Classification, Art 17).

A. Bodies of copper-bearing sulphides, chiefly chalcopyrite or lean, copper-bearing pyrite in igneous rocks (*a*). Chalcopyrite may be associated with a nickel-bearing sulphide, pentlandite, and with pyrrhotite, in basic intrusives (Sudbury, Ontario). Lean copper-bearing pyrite of igneous intrusive masses, usually monzonites, requires secondary enrichment for profitable operation (Bingham Canyon, Utah, and near Ely, Nevada).

B. Irregular masses of copper-bearing sulphides in contact zones (*c*) and associated with lime silicates. Secondary enrichment, incident to oxidation, may be necessary to increase percentage to mining requirements. Various minor forms of deposit may be associated. Bisbee and Morenci, Ariz, are best illustrations.

C. Veins along faults, with greater or less replacement and impregnation of the walls (*d*), as at Butte, Mont, where walls are granite. Innumerable other veins are known in all parts of world.

D. Lenticular or pod-shaped bodies of pyrite or pyrrhotite, with chalcopyrite (usually of later introduction). The lenses favor schists or slates, and lie parallel with the foliation. These rocks may be sheared eruptives, or may be sediments (Ducktown, Tenn, and many orebodies along Appalachians). Other examples appear in foot-hills of Sierra Nevadas, Cal. Rio Tinto, Spain, is one of the largest bodies yet discovered.

These orebodies were probably originally veins (*d*) parallel to structural planes of wall-rocks, and subsequently pinched into lenses by pressure. The type called "Kieslager" may be of sedimentary origin, or introduced as veins and pinched by pressure. Some have been considered igneous intrusives, as at Sulitelma, Norway, and Bodenmais, Bavaria.

E. Native copper in nodules, sheets, minute scales, and sometimes large branching masses, in amygdaloidal basalts, and associated conglomerates (*h*). Keweenaw Point, Michigan, is chief example. Introduction of the copper is a disputed subject, whether a product of expiring igneous activity, or of circulating meteoric and connate waters.

F. Impregnations of sedimentary rocks with sulphides or their oxidized products, often deposited on organic remains (*h*). Mansfeld, Germany, is best known example, where a black shale, with abundant organic remains, is impregnated with copper minerals for a width less than 1 ft, but over a great area. It is uncertain whether the copper was precipitated from Permian sea-water along with the sediments, or introduced by circulating ground-waters long after sediments were deposited. Triassic strata of the U S have many copper impregnations, mostly small.

The percentage of copper for successful mining depends on widely varying conditions. Native copper rock, on Keweenaw Point, Mich, yielding only 0.65% (13 lb per ton), has been treated successfully. The disseminated chalcocite of Bingham Canyon, Utah, has yielded average assays over 3 months' periods as low as 1%, with approx a seven-eighths recovery. Raw smelting ores, of slightly above 2% and with little aid from precious metals, have been worked at Ducktown, Tenn. In early days in western U S, ores of 10 to 20% were frequent in oxidized and enriched parts of deposits. Vast quantities of 10% ore are now reported from S E Congo State, Central Africa. To be valuable, all low-grade deposits must be of great size (40).

20. LEAD AND ZINC ORES

Lead. Following minerals constitute the common ores of lead: galena, PbS, 86.6% lead; anglesite, $PbSO_4$, 68.3%; cerussite, $PbCO_3$, 77.5%; pyromorphite, $3\,(PbO\cdot P_2O_5)\,PbCl_2$, 76.2% (much rarer than the others). Other compounds sometimes appear in small amount, as wulfenite, crocoite and vanadinite.

Galena is the chief primary lead ore, of which others are oxidation products. It is frequently associated with zinc blende and pyrite. All lead ores are commoner in limestones than with other wall rocks. Many lead ores carry silver in commercial amounts, especially in regions characteristically productive of precious metals. Gold is a rarer associate. The oxidized product of galena is oftener cerussite than anglesite. All oxidized ores are mingled with limonite in varying degree, and with silica and earthy minerals from alteration of wall rocks. Lead and zinc can best be discussed together.

Zinc. Following minerals constitute the common ores of zinc: sphalerite or zinc blende, ZnS, 67% zinc, hemimorphite (calamine), $2\,ZnO\cdot H_2O\cdot SiO_2$, 54.2%; smithsonite, $ZnCO_3$, 52.1%; willemite, $2\,ZnO\cdot SiO_2$, 58.6%; zincite, ZnO, 80.3%; franklinite, $(Fe,Mn,Zn)O(Fe,Mn)_2O_3$, variable, about 6.0%. Willemite, zincite and franklinite, exceptional in their occurrence in northern New Jersey, form a group by themselves.

Zinc blende is the almost universal primary mineral; calamine and smithsonite are its oxidation products. The latter two are often inseparably mixed, and together are known as "galmei" in Europe. "Dry-bone" is a local name in Mississippi Valley, the oxidation products suggesting old bones. (The significance of the names calamine and smithsonite in England is the exact reverse of the American meaning, smithsonite being used for the hydrated silicate.) The oxidized compounds are characteristic of the vadose zone. They may coat bedrock beneath a cap of residual products. The deposits are summarized from those with lead alone to those with zinc alone. Intimate mixtures of both ores afford one of the great metallurgical problems today. Neither lead nor zinc deposits have been found in immediate association with igneous rocks, such that a direct igneous origin could be ascribed to them. They reach their places of precipitation in solution.

Examples of lead and zinc deposits. (Letters in parentheses refer to Art 17.)

A. Disseminated and sometimes coalescing deposits of galena with associated sulphides, in sedimentary strata. The galena impregnates the older sediment; believed to have been introduced in solution, and to have replaced preëxisting minerals; source is conjectural (*h* and *i*). In S E Missouri, the chief American source of lead for lead alone, Cambrian limestones are impregnated.

Near Laurium, Greece, galena replaces limestones involved with mica schists. At Leadville, Colo, Carboniferous limestone has been replaced with silver-bearing galena, pyrite, manganese compounds and sometimes zinc blende, along under sides of sills of rhyolite-porphyry ("white porphyry"). Extensive oxidation developed carbonate ores for the early miners. Galena may yield to zinc blende in amount. In Belgium, Luxemburg, and near Aix-la-Chappelle, huge amounts of subordinate lead ores have been mined in Devonian and Carboniferous limestone along great faults. Zinc blende was doubtless the original mineral. In Silesia the zinc and lead ores are in Triassic limestones.

At Commern, Germany, knots of galena are disseminated in Triassic sandstone. In Cœur d'Alene district, Idaho, silver-bearing galena, with siderite, appears in great bodies in pre-Cambrian quartzite, along or near extensive faults. Zinc blende has been met in some mines; copper ores in a few others. Siderite seems to have first replaced the quartzite, and then yielded to galena. The reaction is much the same as with original limestones.

In S W Missouri zinc blende and subordinate galena impregnate breccias of chert, interbedded in Lower Carboniferous limestones.

B. Galena, zinc blende and associated sulphides in joints (" gash veins ") and related cavities (*f*). In S W Wisconsin and neighboring states of Upper Mississippi Valley the Ordovician " Galena " limestone has numerous vertical gash veins, with horizontal " runs " and inclined " pitches," containing galena, zinc blende, marcasite, and calcite.

C. Galena and zinc blende in fissure veins, often together, often separate, usually with other sulphides (*d*). Precious metals are frequently associated. Such deposits are world-wide, and in all kinds of wall-rocks.

D. Lenticular deposits containing willemite, franklinite, subordinate zincite and many lime silicates, are folded in pitching synclinal troughs in pre-Cambrian limestones. It is difficult to classify these deposits. Their zinc-bearing minerals are unique. The mineralogy suggests contact zones (*c*), but the actual metamorphosing igneous rock is not apparent.

21. SILVER AND GOLD ORES

Though deposits are known containing either gold or silver alone, these metals are generally associated and must be discussed together. Both are extensively obtained in connection with copper and lead. Lead ores are often called " wet ores," because metallic lead, freed in smelting, acts as a solvent for the precious metals, the distinctive ores of which are called " dry ores." Zinc desilverization for base bullion, electrolytic refining for copper, and the substitution of cyanidation for amalgamation, have greatly facilitated treatment of silver and gold ores.

Silver-bearing minerals: argentite ("silver glance"), Ag_2S, 87.1% silver; hessite, Ag_2Fe, 62.8%; proustite ("light ruby ore"), Ag_3S_3As or $3\,Ag_2S \cdot As_2S_3$, 65.5%; pyrargyrite ("dark ruby ore"), Ag_3S_3Sb, or $3\,Ag_2S \cdot Sb_2S_3$, 59.8%; stephanite ("brittle silver ore"), Ag_5S_4Sb or $5\,Ag_2S \cdot Sb_2S_3$, 68.5%; cerargyrite ("horn silver"), $AgCl$, 75.3%; native silver, Ag, 100%.

Galena almost always contains at least a trace of silver, which probably occurs as an isomorphous sulphide, but not appearing separately in polished plates. Silver is a component of certain varieties of tetrahedrite, and in this form is often found in copper ores.

Galena is probably a base for other copper minerals. Silver is sometimes found in zinc blende, but rarely in pyrite. Modern silver production is chiefly in connection with base metals. Cerargyrite and native silver are habitually secondary minerals, resulting from alteration in the vadose zone of other minerals mentioned above, or from silver-bearing, base-metal minerals. Argentite is sometimes secondary: it certainly is also primary. The others are generally primary.

Gold-bearing minerals: calaverite, $AuTe_2$, 44.5% gold; sylvanite (" graphic tellurium "), $(AuAg)\,Te_3$, variable; native gold, alloyed with silver, etc, variable. Gold most commonly occurs in quartz veins, both as native, and as scales and wires mechanically mixed in pyrite. It may be set free by oxidation and removal of the pyrite. It also accompanies mispickel, chalcopyrite, and rarely galena. In some of these minerals, when the ores are refractory, it may exist as an involved telluride, or as a bismuth compound (Richard Pearce). The tellurides of gold (a number of rare mixed tellurides of gold and other metals are not mentioned above) are primary minerals. On oxidizing and losing tellurium, they yield extremely fine particles, not readily panned and resisting amalgamation; called "rusty" gold. Gold, presumably as chloride, sometimes descends in solution from oxidized portions of veins containing manganese minerals, and is reprecipitated at or near water level. Presence of calcite may interfere with the reaction. The high sp gr and resistance of gold to natural solvents greatly favor the formation of placer deposits.

German writers sometimes classified precious metal deposits into an older series, in geological age, and a later series. The great silver-gold veins associated with mountain upheaval and igneous outbreaks, at close of the Cretaceous and in the opening Tertiary periods can thus be distinguished from older ones. Each group can then be subdivided on associated minerals, of which a series of subtypes can be established. Other writers have placed less emphasis on variations in time and mineralogy. Admitting some characteristic mineral associations, which might make possible finer subdivision, the following large types are permissible (see Classification, Art 17).

Predominant silver. A. Fissure veins, with distinctively silver minerals in quartz gangue, often amethystine and associated with manganese minerals and some calcite. Galena, zinc blende, pyrite and copper minerals, are very subordinate. Many great veins of Mexico, as at Pachuca, Real del Monte, and Guanajuato, exhibit these characters. The Butte silver veins are similar, but now, in instances, have developed copper in depth. In general, argentite is the chief source of silver (*d*).

B. Fissure veins yielding silver with little gold, in association with galena, zinc blende, copper minerals, and pyrite, in gangue of quartz, calcite, barite, fluorite, one or several (*d*). Veins of this mineralogy are world-wide in distribution.

C. Native silver and minor silver minerals, with arsenides of cobalt and nickel, in shrinkage cracks or fissures involving slight displacement (*d* and *f*). Cobalt, Ont., is best example, where veins are predominantly in Huronian conglomerate, associated with a diabase sill, which has some veins, and Keewatin green schists, which contain a few.

D. Impregnations of porous rocks, sandstones, tuffs, etc , with argentite, cerargyrite, and native silver; supply fissures obscure; some copper minerals may occur. (Silver Reef, Utah, Silver Cliff, Colo.)

E. Impregnations and replacements of crushed rocks along faults (silver-bearing galena in Cœur d'Alene, Idaho, Art 20, A).

F. Replacements of calcareous rocks with silver-bearing galena and associated sulphides. Leadville, Colo. (See Art 20, A, for other cases.)

Predominant gold. A. Fissure veins containing native gold, alone, or mechanically mixed in pyrite and much rarer base-metal sulphides, in quartz gangue. Gray, greasy-looking quartz seems to accompany best values. The common association of quartz with gold makes this type of world-wide distribution. Veins appear most frequently in schists, slates, or other metamorphic rocks, and in association with intrusive rocks, of which granite is commonest.

B. Impregnations and replacements of open-textured rocks with gold-bearing pyrite. The "banket" of gold-bearing conglomerates of Transvaal, the chief producers today, is the best example.

C. Saddle-reefs, or arch-like deposits of gold-bearing quartz at crests of anticlines (*e*) (Bendigo, Victoria, and gold reefs of Nova Scotia). Saddle-reefs may succeed one another in depth. Slates or slaty schists are common wall-rocks.

D. Veins carrying gold tellurides. At Cripple Creek, Colo, they are associated with an eroded Eocene volcano, often favoring neighborhood of minor dikes of phonolite and basaltic rocks, with which volcanic activity closed. Purple fluorite is a characteristic associate. In Boulder Co, Colo, veins are in gneisses; at Kalgoorlie, Western Australia, in amphibolites; in Hungary, altered andesitic rocks, called propylites. Once considered extremely rare, tellurides have been very productive in Cripple Creek and Kalgoorlie.

E. Lateral impregnations and replacements of calcareous shales, with tellurides along supply fissures, called verticals. Example, so-called "Potsdam" or "refractory ores," of the Black Hills, S Dak, the walls of which are of Cambrian age.

F. Contact zones, on the border of intrusive igneous rock and limestone, containing gold-bearing mispickel in lime silicates (Nickel Plate mine, B C). The usual contact zone of this type carries copper sulphides with a little gold (Art 19, B).

G. Placer deposits of gold-bearing gravels, which may be: residual, from weathering of rocks *in situ;* river gravels in active streams; river gravels in abandoned and often buried channels; alluvial fans; sea-beaches with active surf; sea-beaches now elevated and inland. Gold in streams favors places where current has been checked, as the inside of bends; junctions of tributaries; heads of quiet reaches. Gold favors gravel next the bedrock, or next a "false bedrock" of clay, but fine particles may be generally distributed in a thick vertical section. Magnetite, zircon, garnet, and various resistant, heavy minerals are characteristic associates, yielding "black sands" (42).

22. MINOR METALS

Aluminum is obtained today from bauxite, hydrous aluminum oxide, which is treated electrolytically in a bath of cryolite ($3\ NaF \cdot AlF_3$). Bauxite is developed by weathering of aluminous rocks, and may appear as a residual product. It may also be produced by solvent action of sulphuric acid, from oxidizing pyrite, upon aluminous rocks, such as shales. The resulting acid solution of aluminum sulphate may be neutralized by limestone, with precipitation of aluminum hydrate, which may then form concretionary masses. In America bauxite is largely produced in Georgia, where the last named reaction is believed to explain its occurrence. In Arkansas, it is associated with syenitic eruptives, to the alteration of which its formation is attributed. Cryolite is commercially obtained only on west coast of Greenland, where it constitutes a large, flat vein in gneiss. Siderite, galena, zinc blende, and a few other minerals are sparingly mingled with it.

Antimony is obtained from its sulphide, stibnite (Sb_2S_3); sometimes from the oxide, senarmontite (Sb_2O_3); and as an alloy from antimonial lead ores. Characteristic occurrence of stibnite is in quartzose veins, but less regular deposits in sandstone are recorded. The industry is small.

Arsenic is produced largely as a by-product in smelting arsenical lead, copper, gold or cobalt ores, chiefly enargite (Cu_3AsS_4). It is sold as oxide, but much more could be saved were there a better market for it.

Barium is chiefly consumed as the sulphate ($BaSO_4$). Barite characteristically appears in veins in limestones; is also a frequent gangue with lead and copper ores, regardless of nature of vein walls. Chief output in U S comes from deposits in Georgia, Missouri, and California.

Bismuth is a rare by-product in lead-silver refining. A few districts, as Leadville, Colo, and Cobalt, Canada, produce bismuth ore.

Cadmium is a minor associate of zinc, and whenever separated is a small by-product in zinc metallurgy, or in treatment of zinc-bearing lead ores. Greenockite (CdS) is the chief mineral.

Cæsium is a rare alkaline element of much the same associations as rubidium.

Cerium, with didymium, erbium, lanthanum, thorium, and yttrium, constitutes a group called the cerium group of rare earths. Their compounds, especially those of thorium, have incandescent properties when heated, for which purpose they are sought. They are obtained as phosphates in monazite and xenotime, and are characteristic of pegmatites. They may appear in normal granite. Being resistant and heavy, monazite and xenotime have accumulated in placers in the drainage of pegmatite and granite areas of the Carolinas; also on sea coast of Bahia, Brazil.

Chromium ($FeO \cdot Cr_2O_3$), sometimes ($(Fe \cdot Mg)O \cdot (Cr \cdot Al \cdot Fe)_2O_3$, is a characteristic associate of richly magnesian, basic igneous rocks, usually altered to serpentine. The chromite is believed to be a direct crystallization from molten magma. It forms irregular, sometimes large, distributed masses, and being extremely resistant may be freed and concentrated as a residual product in weathering. Commercial chromite should contain at least 40% Cr_2O_3. Rhodesia is a great producer of chromite ore.

Cobalt forms a variety of arsenides and sulphides, practically always in association with nickel. Linnæite (Co_3S_4), smaltite ($CoAs_2$), cobaltite ($CoAsS$), and the oxidized product erythrite or "cobalt bloom" ($Co_3As_2O_8 \cdot 8\ H_2O$). Cobalt has long been derived from the ores of Cobalt, Ont; Belgian Congo, Rhodesia, and French Morocco are also important producers.

Didymium (see Cerium).

Erbium (see Cerium).

Iridium (see Platinum).

Lanthanum (see Cerium).

Lithium is obtained from amblygonite $Li(AlF)PO_4$, lepidolite, the lithia-mica $LiK[Al(OH, F)_2]Al(SiO_3)_3$, with lithia ($Li_2O$) 2 to 5%; and spodumene ($LiO \cdot Al_2O_3 \cdot 4\ SiO_2$) with lithia 7.5%. Both are pegmatite minerals, occurring mainly in Black Hills, S Dak. The commercial importance of lithium has increased in recent years.

Magnesium is chiefly used as the earthy carbonate, magnesite, a refractory material. In Washington, magnesite lenses are found in metamorphosed dolomite. Magnesite also favors association with serpentines, in the alteration of which it is formed in veins in California. Russia, Austria and the U S have recently been the chief producers.

Manganese. The chief minerals are pyrolusite (MnO_2), psilomelane ($MnO_2 \cdot NH_2O$, plus K, Ba, etc), wad (an earthy Mn mineral), manganite ($Mn_3O_4 \cdot H_2O$), rhodochrosite ($MnCO_3$) and franklinite ($(FeZnMn)O \cdot (Fe\ Mn)_2O_3$. Russia, Gold Coast, India, Brazil and Cuba supply most of the manganese used in the U S. In geological relations of its ores, manganese is similar to the brown hematites (Art 6). The ores are usually residual products of weathering, and are found as nodules in clay or as masses on surface. They should be relatively low in phosphorus, for use in spiegeleisen, and not too high in silica (43).

Mercury has one chief ore, cinnabar (HgS_2), with which a little native mercury may be associated. Cinnabar appears in veins with quartz, calcite, altered wall-rock and bitumen. It may also impregnate porous beds, such as sandstones. In practice mercury is called quicksilver or "quick." In the U S, cinnabar is mined in Calif, Nev, Ark, and Texas.

Molybdenum is obtained from molybdenite (MoS_2). Wulfenite ($PbMoO_4$) has attracted some attention. The molybdenite deposits at Climax, Colo, are among the largest known in the world. The ore occurs in a large circular stock of granite. The bottom of the mineralization has not been determined.

Nickel has 3 varieties of ores: (*a*) sulphides and arsenides (millerite, NiS, niccolite, $NiAs$) and related minerals, all of small moment today; (*b*) pentlandite, ($(Fe\ Ni)S$, the nickel, iron and sulphur being each about one third. (Although nickel was formerly thought to replace iron in pyrrhotite, it is now considered to be in mechanically intermingled pentlandite); (*c*) a series of hydrated silicates of nickel and magnesium, somewhat analogous to serpentine in general composition and forming veins in serpentine, or produced in the alteration of very basic igneous rocks.

The nickel industry today is practically limited to 2 localities. At Sudbury, Ont, and vicinity, pentlandite with pyrrhotite and chalcopyrite are concentrated at bottom of a huge intrusive sheet, which varies from norite at the base, where the ores appear, to acid, micrographic granite at its upper surface. The sheet is folded into a huge basin, 40 miles across, and is buried in center beneath overlying sediments and volcanics. The ores favor embayments in the underlying older rocks, and one offsetting dike at the outer periphery. The underside of sheet dips inward at 60°, and is impregnated with nickel and copper ores up to widths of 100 or 150 ft. The gangue is self-fluxing. The ore bodies are generally classed under *a*, Art 17, but the 3 sulphides seem to have crystallized in serial order, and at times to have undergone some redeposition. The hydrated silicates of nickel are found, in workable richness, in the serpentinous district of New Caledonia. They constitute veins, and are the second but much smaller factor in the world's supply (44).

Osmium is a characteristic associate of platinum, in the placers of which its one source, iridosmine, is found, in scales or scaly nuggets and "colors."

Palladium is a characteristic associate of platinum in placers, and in the few cases where platinum has been discovered in copper ores. In latter case careful assays are necessary to avoid mistaking palladium for platinum.

Platinum appears in metallic grains and nuggets, more or less alloyed with iron, palladium, and rarer metals of the platinum group. It is characteristically associated with peridotites and pyroxenites, in which it is a direct crystallization from the original fused magma. Platinum is frequently intergrown with chromite. Aside from natural alloys, its one compound is sperrylite ($PtAs_2$), a minute associate of the Sudbury nickel-copper ores, and rarely elsewhere (45). Russia, Canada, Colombia and So Africa are the chief producers.

Potassium is treated as a saline (see Non-Metallic Minerals).

Radium is an extremely rare associate of the more abundant uranium, from the minerals of which it is separated (see Uranium).

Rhodium is a minor associate of platinum.

Rubidium is a rare alkaline element, associated in minute amounts with lithium in lepidolite and other lithium minerals.

Ruthenium is an extremely rare associate of platinum.

Sodium is treated as a saline (see Non-Metallic Minerals).

Strontium is obtained from the sulphate, celestite ($SrSO_4$), occurring like barite, but less abundant (see Barium).

Thorium (see Cerium). Thorianite is also found commercially in Ceylon and Australia.

Tin has one ore, cassiterite (SnO_2), and one rare sulphide, stannite. Cassiterite is almost always associated with granites and pegmatites, or veins closely akin to pegmatites. In weathering and erosion of these, being heavy and resistant, it is concentrated in placers as pebbles and finer particles, called stream tin. Cassiterite is obtained both by deep mining and placer working. It has been observed associated with rhyolites. Tin is also obtained in important quantities from Bolivian silver veins. Bolivia is now one of the largest producers of tin.

Titanium appears in the titaniferous magnetites, in which it has hitherto been a disadvantage to the iron. The nelsonite rocks of Virginia furnish titanium oxide in the form of rutile. Large amounts of ilmenite, $(FeTi)O_3$, are found in the sands of Travancore, India.

Tungsten, now an important metal in steel manufacture, is obtained from several tungstates, *viz*: wolframite, $(FeMn)WO_4$; huebnerite, $MnWO_4$; scheelite, $CaWO_4$. In the U S it is found chiefly in contact metamorphic deposits, where scheelite occurs associated with garnet and epidote, as at Mill City, Nev. The quartz veins at Atolia, Calif, have had an important history of scheelite production. The wolframite ores of China are extensively produced.

Uranium has gained great prominence as the associate of radium, but has also uses of its own. Pitchblende or uraninite, $(UPb_2)_3U_2O_2$, the earlier and still prized source, is a rare but characteristic mineral of pegmatites and related veins. A series of phosphates, torbernite, autunite, etc, have similar geological relations. Carnotite, a vanadate, $K_2O \cdot 2\ U_2O_3 \cdot V_2O_5 \cdot 3\ H_2O$, with 15 to 18% vanadium oxide, is found impregnating sandstones in western Colorado and eastern Utah. The uranium-bearing veins of Katanga, Belgian Congo, are an important source of radium. The Great Bear Lake district of Canada is also important.

Vanadium is a minor component of titaniferous iron ores, and of the uranium-bearing carnotite, and, in a series of vanadium sulphides and their oxidized derivatives, appears in asphaltite veins in Perú. Vanadium is also found in the carnotite ores of western Colo and Utah.

Yttrium (see Cerium).

Zirconium has one mineral, zircon ($ZrSiO_4$), an associate of granites and other feldspathic rocks and pegmatites, from which on weathering it is freed and concentrated in placers.

NON-METALLIC MINERALS

Here is included a miscellaneous series with no fundamental relations; hence, arranged alphabetically. The carbon series is the most important (46).

23. ABRASIVES; ASBESTOS; ASPHALT

Abrasives. Corundum and emery (emery is a mixture of corundum, spinel, magnetite and other hard and heavy minerals) are found in two principal geological relations: CORUNDUM crystallizes from rare igneous magmas containing excess of Al_2O_3 above requirements of ordinary rock-making minerals. Most of the world's supply of corundum comes from the Transvaal, where the mineral is found in syenite pegmatites. EMERY is commonly found at igneous contacts or where inclusions of aluminous sediments are involved and partly digested in igneous rocks. A vein or bed at Chester, Mass, containing emery in metamorphic rocks, is still different. GARNET, either in hornblende schist, as in the Adirondacks, or in mica schist, as at Reading, Conn, is a minor abrasive. Crushed, angular fragments of QUARTZ are used for sand-paper. DIATOMACEOUS EARTH and decomposed chert (TRIPOLI) are soft abrasives. WHETSTONES are made of gritty slates, which sometimes owe their "tooth" to minute garnets or other hard minerals; or of novaculite, a fine-grained siliceous rock in which the solution and removal of minute rhombs of calcite have left sharp-edged cavities. Coarse varieties are sandstones, or sandy schists, in which are set rutile, garnet, etc. GRINDSTONES are made of sandstones sufficiently friable not to wear smooth (50).

Asbestos of commerce, a variety of serpentine, called chrysotile, appears as veins with cross-fibers in some serpentine districts (most important is in southern Quebec). Poorer grades appear along slips in the serpentine and in the mass of the rock. Some believe the Canadian asbestos to be a deep-seated alteration product of basic igneous rocks; others, that it is developed from serpentine in fissures near intrusive dikes of aplite, a variety of granite (51).

Asphalt (see Carbon Minerals).

24. BUILDING STONE, CLAY, LIMES, CEMENTS

The granite industry is mainly developed along Atlantic seaboard; secondarily, in Wisconsin, Missouri, and California. Among igneous rocks, granite breaks best in the quarry. When of good grade, it is homogeneous in texture, though sometimes suffering from black inclusions, local coarse crystallisations, and development of gneissoid structure. SANDSTONES are widely quarried. The "brownstone" of eastern U S is a Triassic sandstone, from Longmeadow, Mass; Portland, Conn; Avon, N J; Hummelstown, near Harrisburg, Penn. "Bluestone," of Hudson River region, is a Devonian argillaceous sandstone, specially adapted to flagstones, curbing, sills, and lintels. Potsdam red sandstone or quartzite is Cambrian, quarried on western side of Adirondacks. A softer stone of nearly the same geological horizon is produced on south shore of Lake Superior. Medina pink sandstone of the Silurian is extensively obtained along the Erie Canal, between Rochester and Lockport, N Y. Cleveland or Ohio sandstone is a gray or pale-blue stone, of Mississippian (Lower Carboniferous) age, developed in outskirts of Cleveland. LIMESTONES. Preëminent is the Indiana or Bedford oölitic stone, of Mississippian (Lower Carboniferous) age, which outcrops in an extended N and S belt in S W Indiana. MARBLES, of Cambrian and Ordovician age, are extensively developed along the border of Western Vermont, Eastern Tennessee, and Georgia; of other age, in Colo. SLATES appear in S W Vermont and neighboring parts of N Y, and in the Lehigh Valley, Penn. They are in less degree produced in Virginia, the Lake Superior region, and Newfoundland. Wales is a famous source of slate and of skilled workers in slate. SERPENTINE is quarried in southeastern Pennsylvania and the neighboring parts of Maryland (52).

Clays belong to three general groups: (1) kaolin group, in which the chief mineral is kaolinite, $Al_2O_3 \cdot 2\,SiO_2 \cdot 2\,H_2O$; (2) montmorillonite group, in which the chief mineral in montmorillonite, $CaO \cdot MgO$, $Al_2O_3 \cdot 3\,SiO_2 \cdot nH_2O$; (3) alkali-bearing clay mineral group. Kaolin is chiefly of two kinds, residual, or transported, which are the finest sediments of still water. Residual clays are commonest south of the terminal moraine of Glacial epoch. They are impure and variable. Transported clays were extensively deposited by the floods which followed the melting of the continental glacier. They are very abundant in the valleys of the Connecticut and Hudson rivers, and are the basis of a great brick industry. Fireclay for refractory materials should be as free as possible from other ingredients than SiO_2, Al_2O_3, and H_2O. It is often found beneath coal seams. In these relations fireclays are mined in Pennsylvania, Maryland, Ohio, and at Cheltenham, Mo. Other fireclays of Cretaceous age are developed at Woodbridge and its neighborhood, N J, and near Golden, Colo (53). Clays of the montmorillonite group are extensively derived by the alteration of volcanic ash and find an important application in the purification of petroleum products.

Shales often possess properties which fit them for vitrified brick. They are then ground, moulded, and hard-burned. They are useful for pavements, especially where no good rock is available for macadam.

Limes and cements. For quicklime, calcium carbonate should be pure, free from coloring ingredients, such as iron compounds, and is preferred with little magnesium carbonate. Silica and alumina together develop hydraulic properties, and injure "fat" limes. Kilns are widespread and, for local use, any reasonably pure limestone answers. Rockland, Me, is the principal American producing district. As limestones contain increasing amounts of alumina and silica, they develop hydraulic properties when burned, and in varieties of special excellence afford natural rock cement. The crude stone is called a "water-lime." Although important in former years, the natural cements have given way to "Portland" cement, which is an artificial mixture of limestone and clay or shale, entirely under control of the chemist, and being therefore more uniform in properties. In Portland cement magnesia is kept very low, not over 2 or 3%. The Lehigh Valley, Penn, is chief center of manufacture in U S, but plants are widely distributed (54).

25. THE CARBON MINERALS

These embrace Coals and their relatives, and the Petroleum series, including Natural Gas, Maltha, Asphalt, and Asphaltites.

Coals and their relatives are vegetable remains so preserved in sedimentary strata as to become progressively enriched in carbon. They begin as some form of woody tissue, perhaps also in part spores, algæ, and resins; under conditions of retarded oxidation they pass toward a theoretical limit of nearly pure carbon, and finally to mineral ash. Cellulose, the principal original contributor, is $C_6H_{10}O_5$ (approx, C 50%, H 6%, and O 44%), but there was always also a little N, S, and mineral matter in original deposit. If vegetable tissue accumulates under a protecting layer of water, oxidation is retarded and relative enrichment in carbon ensues. On subsidence of the land, or, in case of lakes and swamps, as result of heavy floods, sediments bury the accumulated vegetable tissue. The complete process comprises several stages. PEAT is still brown; a visible aggregate of stems, leaves, etc; high in O and H and relatively low in C. LIGNITE is firmer, often black, but has a brown streak, and usually still shows evidence of vegetable tissue; has less O and H than peat and relatively more C. Sub-bituminous coals or black lignites are a stage beyond typical lignite, but are not typically bituminous. BITUMINOUS COALS (Sec 35) are black, solider, lower in O, higher in C, and at times possess coking properties. SEMI-BITUMINOUS and SEMI-ANTHRACITE mark passages to ANTHRACITE (Sec 34) in which the C is greatly enriched and the coal hard and firm. Still further stages toward graphite are known.

Table 5. Characteristic Chemical Composition of Coal Series

Cellulose	Peat	Lignite	Bituminous	Anthracite
C 50	59	69.0	82.0	95.0
H 6	6	5.5	4.5	2.5
O 43	33	25.0	13.0	2.5
N 1	2	0.5	0.5	trace

Sulphur is also present in varying percentages, up to several units, and mineral ash never fails.

Coals are analyzed commercially in 2 ways, proximate and elementary. In PROXIMATE ANALYSIS, moisture, volatile matter, fixed carbon, ash and sulphur are usually determined. Sample is dried, weighed, ignited until flames cease or for a standard time over a standard Bunsen burner, weighed, ignited again to consume the carbon; after which residue is weighed for ash. Sulphur is determined in a separate sample. This analysis shows if the coal is high or low in water; is high or low in volatiles; has a long or short flame; cokes or not; is high or low in ash; is sulphurous or not. These are the most important points regarding a fuel. Dividing the percentage of fixed carbon by the percentage of volatiles gives the "fuel ratio," characteristic for each particular coal. Anthracites give high, and richly bituminous coals low ratios. Ratios vary from less than 1, to about 30. ELEMENTARY ANALYSIS of a dried sample gives the C, H, O, N, S, and ash. It affords a better idea of the heat units in the coal, a matter of growing importance each year, but does not indicate coking properties nor volatiles. It is known that the O in coals is already combined with C or H, and is as inert as ash, besides reducing the available C and H. Since H has a high calorific value, the necessary proportion to yield H_2O with the O present is often called combined hydrogen; the excess, disposable hydrogen. Relatively high values of the latter are esteemed.

Table 6. Characteristic Proximate Analyses

	Moisture	Volatiles	Fixed carbon	Ash	Sulphur
Peat	20.22	52.31	24.52	2.95	....
Lignite	17.75	37.85	37.40	6.20	0.80
Sub-bituminous	13.43	37.15	45.57	3.85	....
Bituminous	1.26	30.11	59.62	8.23	0.78
Semi-bituminous	1.23	15 47	73.51	9.09	0.70
Semi-anthracite	1.29	8.10	83.35	6.23	1.03
Anthracite	4.12	3.08	86.38	5.92	0.50

Table 7. Characteristic Elementary Analyses

	Moisture	C	H	O	N	S	Ash
Peat (air dried)	13.60	40.78	5.55	30.95	1.40	0.58	20.74
Lignite	22.63	54.91	6.39	32.59	1.02	0.59	4.50
Sub-bituminous	11.05	59.08	5.37	21.52	1.33	1.73	10.97
Bituminous	3.36	68.69	4.84	11.49	1.54	1.01	12.43
Semi-bituminous	1.53	82.87	4.76	4.99	1.68	0.65	5.05
Anthracite	1.97	91.40	2.81	1.83	0.21	0.71	3.04

Heat units are expressed as British thermal units (B t u), or as French (calories). High ash or high-oxygen coals give low thermal values. The usual range is as follows, the peat being exceptionally good (Sussex Co, N J):

Peat	Lignite		Bituminous coal		Anthracite	
High	Low	High	Low	High	Low	High
8 260	7 204	10 143	10 242	13 790	12 047	14 686

Moisture in coal is a serious drawback, and varies so much in unprotected samples, especially of lignites and sub-bituminous coals, that the sample, as soon as cut in the mine, should be put into an air-tight glass jar, and analysed as soon as possible after top is unscrewed.

Classification. Many attempts have been made to classify coals, but for eastern coals the scheme suggested by H. D. Rogers, State Geologist of Penn, about 1855, is still widely current:

Bituminous	Volatiles, greater than 18
Semi-bituminous	" 18 to 12
Semi-anthracite	" 12 to 8
Anthracite	" less than 8

More recent schemes are those of: M. R. Campbell, based on $C + H$ ratio, as shown by elementary analysis; F. G. Grout, who employs ratios based on sum of volatiles and fixed carbon of a proximate analysis, and the elementary carbon of ultimate analysis; and D. B. Dowling, who employs what he calls the split-volatile ratio. All these give greater attention to western lignites and sub-bituminous coals, which in earlier years were practically unknown. Elaborate classifications are unimportant commercially. The B t u's and the physical and coking properties are the essentials.

Geological associates of coal seams are almost always shales and sandstones. They often have a fireclay floor; are seldom associated with limestones. A seam may be broken up into benches by a " parting " of shale, called " slate " by miners. A parting may increase in thickness and separate a seam into 2 distinct seams. Seams may be cut out by old drainage channels, either contemporaneous with the old swamp, or later and long after coal was formed. Pot-holes and channels in Carboniferous coals were developed even in the Glacial epoch and filled with gravel. Coal seams may be pinched by the upward bulge of a relatively plastic clay floor, and may have cracks filled with clay gouge.

Coal seams are subject to faults and folds; are very often in synclines (" basins "), left disconnected by erosion of intervening anticlines. Folds may be violent, as in middle anthracite fields of Penn, and in Belgian and French areas. Coal seams are of all thicknesses from a fraction of an inch to many feet. The thickest single seam, reasonably free from thick partings, recorded in America, is at Adaville, Western Wyoming, with 86 ft of clean coal (except for one parting of 1 in of sandstone). A thickness of 1 ft is ordinarily considered the minimum of workability.

With increase of ash (20% ash is the usual commercial maximum) coals pass into " bony " coals, then into " bone " and into bituminous shale or slate. Foreign matter may be minutely interstratified with thin layers of relatively pure coal; or be invisibly mingled. If the layers are sufficiently coarse, crushing and washing may greatly reduce the ash (Sec 34 and 35). In a cross-section of a good seam can be recognized: bright lustrous " glance " coal and dull, lusterless " splint " coal. The proportions vary; one variety may be in great excess. There is a third variety, porous, tender, and often showing plant structure, called " mother of coal " or " mineral charcoal." It affords an unfortunate place of precipitation for gypsum, pyrite, and other undesirables. The sulphur in coal is partly in pyrite, when half passes off in burning; partly in gypsum, when all passes into the ash; and partly in sulphurous hydrocarbons. In coking or other combustion, roughly one-half the sulphur passes off.

In geological age coal ranges practically from Carboniferous period through Tertiary. Anthracite is even reported in remote pre-Cambrian strata of Finland, but no seams of importance are yet known older than Carboniferous The oldest seam in America is in the Pocono sandstone series, of the Mississippian (Lower Carboniferous) strata of S W Virginia (Altona and elsewhere). The really important coals begin with the Pennsylvanian. In eastern half of North America, they range up into the Permian and even Triassic (in Va and N C). In the western U S, coals range from early Cretaceous to Pliocene. The Laramie of Cretaceous and Eocene Tertiary are most productive. The later coals are often lignitic, especially if in relatively undisturbed strata (55).

Petroleum series. Coals are residual accumulations; petroleums are evolved, and move from their sources elsewhere for storage. The petroleum series embraces gases, liquids, and solids. The chemistry is very complex, but most of the members belong to the marsh-gas or paraffine series of compounds, C_nH_{2n+2}. Up to C_4H_{10} they are gases at ordinary temperatures: from $C_{20}H_{42}$ up they are solids. The gases are called natural gas; the liquids, petroleum; the thick, black, tarry liquids, maltha; the solids at ordinary temperatures, of tough leathery character, asphalt; the brittle, coal-like substances, asphaltite; the natural paraffines, ozocerite. Shales impregnated with bituminous matter are called oil shales. They may be rich in paraffines. (See Sec 44.)

Natural gases are chiefly CH_4, but have some higher members, with a little of the olefine series C_nH_{2n}, more or less of H_2S, N, O, CO_2, and others rarer.

Petroleums include the liquids at ordinary temperatures. Some are of low sp gr, some high. These characters are expressed in degrees Beaumé, a scale in which 10° Beaumé is sp gr 1. Others are calculated by the formula: (140 ÷ sp gr) − 130. Light petroleums range from 35° B up; the heavy drop below 20° B. Lighter oils give higher percentages of illuminants and are the most valuable. Heavy oils have an asphalt base. Some oils contain sulphur compounds. Malthas are much rarer than petroleums, and have different uses; asphalts are employed for paving; asphaltites for varnishes, etc.

Origin of petroleums. There are two radically different views: the inorganic (now discarded) and the organic. There is some support for the theory attributing hydrocarbons to igneous sources, but most geologists favor the organic explanations. These assume original plant or animal matter in the sediments, by decomposition in the rock (T. S. Hunt); or distillation from internal heat (J. S. Newberry); or, the modern view, by bacterial decomposition while freshly deposited, the hydrocarbons being later squeezed out of the shales and mud-rocks, by pressure of overlying accumulations, into porous beds for storage. The latter genesis certainly applies to CH_4, but has not been proved for oils.

Storage in the rocks is better understood. The most extensive pools are found under low anticlinal folds, in which an impervious shale rests upon a porous sandstone or limestone, so as to imprison the gas and oil; which, from some source of the hydrocarbons rise through the heavier ground-waters and are finally caught beneath the crest. Theoretically, and sometimes actually, there is an uppermost layer of gas, a layer beneath of oil, and a bottom layer of water or connate brine. Usually either gas or oil rests on brine. Other deposits favor lenticular or pod-like bodies of sandstone in shales, apparently old sand-bars, or similar accumulations. Prospecting is usually guided in recent years by the anticlinal view. The axes of anticlines rise and fall, and pools are thus non-continuous along their trend. A very gentle anticline or even a slight monocline may suffice. Pools sometimes seem to lie to one side of the observed anticlinial crest (Sec 44).

Geologically, the oldest gases and oils are tapped from Ordovician (or Lower Silurian) strata, of which the Trenton limestone is very productive in Ohio and Indiana. Higher in the Paleozoic, the Silurian (or Upper Silurian), Devonian and Carboniferous strata are all productive in the Eastern States. A sandstone at base of the Coal Measures (Carboniferous) is very productive in Illinois, Kansas, and Oklahoma. Cretaceous sandstones carry oil in Wyoming; and Cretaceous limestones are the apparent source of Mexican petroleum, even though tapped from overlying Tertiary beds. Various Tertiary horizons yield oils in different parts of the world, but the Miocene is especially rich. In America are the following fields: Appalachian; Lima-Indiana (western Ohio and Indiana); Illinois; Mid-Continental, in Kansas, Oklahoma and northern Texas; Gulf, in Louisiana and Texas; Mexican, in the coastal plain or tierra caliente, west of Tampico and farther south; and California. There are many smaller areas in Colorado, Wyoming, Alberta, and Alaska. Trinidad is productive, also Venezuela. Abroad, Rumania, Baku on the Caspian Sea, Dutch East Indies, and Japan are the chief producers, but some oil has also been found in Germany (56).

Maltha is a rather unusual product, but appears at times where oils with an asphaltic base rise to surface and lose their more volatile constituents. Maltha may impregnate porous sandstone.

Asphalt, a further stage in the process, may accumulate in pools, or impregnate porous sandstones or limestones. Sometimes oils have risen in fissures and have changed with loss of volatiles to brittle substances, suggesting coal. Illustrations: albertite, of N B; grahamite, of West Va; uintaite and wurtzilite, of Utah. Oils with a paraffine base have left behind the natural paraffine, ozocerite, in fissures in sandstone (57).

Graphite is the final metamorphic stage of all carbon minerals. It appears sometimes in pegmatite veins, but more often impregnates sandstones, schists, and crystalline limestones, from which it may be separated by concentrating the light components (58).

26. MISCELLANEOUS NON-METALLIC MINERALS

Gems are objects of mining, but the geological relations are very diverse. Diamonds seem to be original crystallizations in very basic igneous rocks, in South Africa and in western Arkansas. They are elsewhere obtained from placer deposits. Sapphires may be in contact zones, or components of an igneous dike, as at Yogo, Mont. Beryls are pegmatite minerals, but the variety emerald may be in contact zones. Turquoise appears in small veinlets in various rocks, where copper salts have circulated. No brief summary can include more than a few of the widely contrasted associations (59).

Graphite (see Carbon Minerals).

Gums (see Carbon Minerals).

Gypsum (see Salines).

Mica, in commercial quantities, occurs as a constituent of coarsely crystallized pegmatites; both muscovite (white) and phlogopite (amber) are utilized, the former produced mainly in India and N Carolina the latter in Ontario and Quebec provinces, Canada. Market requirements are: (*a*) minimum size of rectangular trimmed sheet, 2 sq in (larger sizes bring higher prices). Demand for pulverized mica is amply supplied by trimmings from sheet-mica mines. (*b*) Softness; the softer the mica the better adapted it is for electric commutator insulation. (*c*) Freedom from inclusions, which are generally iron minerals and diminish insulating properties. (*d*) Flexibility. Value of a given mica can be ascertained only by submitting samples to a dealer. Electrical manufacturers are the largest consumers.

Limes (see Building Stone).

Natural Gas (see Carbon minerals).

Ozocerite (see Carbon Minerals).

Paints (mineral paints, pigments), or the bases for them, are sometimes the objects of mining. Practically all are minerals of iron. Limonite, deposits containing iron carbonate, and red hematite, are all utilized. The crude product is usually calcined to insure uniformity of color or shade. Fine clays stained with limonite yield ochers. Barite and even refuse slate are ground for "fillers."

Petroleum (see Carbon Minerals).

Phosphates are dug or quarried for fertilizers. They are of 2 kinds: (*a*) Crystalline apatite, which generally appears on borders of igneous intrusive rocks and is especially associated with pre-Cambrian limestones, along the Ottawa River in Ontario and Quebec. Apatite in different geological relations is obtained as tailings in magnetic concentration of richly phosphatic magnetites, at Mineville, N Y. (*b*) Earthy phosphates, such as fossil bones, coprolites, and replacements of $CaCO_3$ in limestones by phosphate of lime.

Along the seacoast of South Carolina, Tertiary beds have long been dug for fossil phosphates and replaced limestone nodules. More recent discoveries of Florida rock phosphates, and of pebble phosphates in deltas in the drainage of rock-phosphate areas, have afforded very low-cost product. In the Peace River, Fla, is done much dredging and concentration similar to that in placer gold deposits. Beds of rock phosphate in sedimentary series have been still more recently discovered and utilized in Tennessee. Other beds have been discovered by prospectors in N E Utah, but have been withdrawn from location by the Federal Government. These phosphates form interstratified beds, probably produced by reaction upon limestone of phosphoric acid from organic remains. Guano, formed by the droppings of wild-fowl in regions of slight rainfall, is now practically exhausted (60).

Resins (fossil) (see Carbon Minerals).

Salines. When circulating ground-waters have traversed rocks containing alkali salts, and have afterwards been impounded and evaporated to dryness, or when bodies of sea water are isolated and evaporated, the dissolved salts are precipitated in the inverse order of solubility. From sea water, gypsum precipitates first, then common salt, and then rarely the less abundant potassium salts. In general, potassium-bearing final mother-liquors seem to have escaped, or else their very soluble precipitates were removed in next inrush of salt water.

From isolated bodies of the ocean, cut off perhaps by a barrier cast up during a storm, relatively thin beds of salt and their associates have been derived. Thick beds of hundreds of feet in section are difficult to explain in this way. A substitute explanation is the "Bar Theory" of Ochsenius. A deep estuary is assumed to be isolated by a broad bar from the open sea. Evaporation on the bar leads to the passage down inner side of bar, of heavy concentrated brine, until salt is deposited in the estuary's depths. Thick beds may also be precipitated in salt lakes, in deep depressions without outlet, yet so situated as to be fed by salt-bearing streams. Great Salt Lake is an illustion. Salt deposits at Petite Anse, Louisiana, and elsewhere along Gulf of Mexico, appear in columnar or chimney-like form, crossing sedimentary strata as great cylindrical masses, above which are domes or mounds, and around which the beds turn up. These are best explained by uprising salt springs and the expansive force of growing crystals, which may have thrust the strata aside and upward. Important beds of potassium salts occur in the Stassfurt region, western Germany, and large deposits have been found in the Permian rocks of New Mexico and Texas. Beds of Na_2SO_4 are not infrequent in arid regions, and less often waters or even beds charged with Na_2CO_3 and sodium and calcium borates, likewise occur in a few districts (as southern California

and western Nevada), where local drainage contains these rare salts. The soils of the northern Chilean desert have become charged with sodium nitrate; also in a few other arid localities (61)

Borax is obtained, by chemical treatment, mainly from 2 minerals: boracite, occurring in fumaroles in northern Italy, and in dry-lake deposits in many desert regions of the world; and colemanite (borate of lime) occurring as beaded saline deposits in southern California. More recently, Kernite ($Na_2B_4O_7 \cdot 4H_2O$), has been found in great quantities in tabular deposits in the Mojave desert region of Calif.

Sulphur. In native state, sulphur is found in 2 types of deposit: (*a*) In or near volcanic craters, expiring or largely dormant. Emitted as vapor, sulphur condenses on walls of cavities and impregnates porous tuffs and breccias. It is possible, but not highly probable, that SO_2 and H_2S when mingled hot react to deposit sulphur. (*b*) In association with gypsum in sedimentary strata, as in Sicily, Louisiana, and Texas. The sulphur was formerly believed to result from reduction of gypsum ($CaSO_4 \cdot 2\ H_2O$), by organic matter in circulating ground-waters. There is at present a disposition to refer it to minute organisms now known to secrete elementary sulphur, and to favor its precipitation amid deposits of decaying organic matter, at bottom of certain bodies of water. Gypsum is a universal associate (62). The sulphur deposits in Louisiana and Texas occur with limestone, in the capping above salt domes.

BIBLIOGRAPHY

Rocks and their Minerals All good treatises on geology have chapters on rocks

1. Harker, A. Petrology for Students. Longmans, Green & Co, London and N Y. Revised ed. (Based on microscopic study)
2. Kemp, J. F. Handbook of Rocks. 5th ed. D. Van Nostrand Co, N Y
3. Pirsson, L. V. Rocks and Rock Minerals. John Wiley & Sons, Inc, N Y. Iddings, J. P. Igneous Rocks. 2 vol. John Wiley & Sons, Inc, N Y, 1913
4. Alling, H. L. Interpretative Petrology of the Igneous Rocks. McGraw-Hill, 1936
5. Grout, F. F. Petrography and Petrology. McGraw-Hill, 1932

Faults Current textbooks on ore deposits, mining and geology, usually have a chapter on faults

6. Church, J. A. Cause of Faulting. *Trans* A I M E, Vol 21, p 782

Note.—Numbers in parentheses in text refer to Bibliography at end of this section.

This section deals only with open-cut excavation, embankment and dredging. For earthwork in tunnels, shafts or caissons, see Sec 6, 7, 8. Mechanical details, methods of work and equipment are given only to the extent that their usefulness to the project may be judged. Horse-drawn vehicles for moving earth have been largely replaced by mechanical equipment; for data on this subject, see Art 5 of the Second Edition; also, Sec 27.

EARTH EXCAVATION

1. ECONOMICS

Factors in economical handling of earth: (1) organization and management; (2) effic of workmen; (3) type, condition and interchangeability of equipment; (4) lost time; (5) weather conditions. Wet or freezing weather adds to costs of handling and transport; freezing may convert loose earth into a solid mass, and thawing, into sloppy mud. Liberal allowances should always be made for LOST TIME.

Management. LABOR-UNION RESTRICTIONS. Examples: a truck driver can do no other work, an oiler is paid for double time if he must wait until a power shovel is idle after 5 P M; these and similar regulations add greatly to costs and must be provided for in estimates (For extent of unionization, see *Eng News Record*, Jan 24, 1937, p 943). Coordination between loading, transport and dumping is essential to effic. Much small-scale work must still be done by hand or minor equipment, at relatively high unit cost. It is important that sizes of shovels are economically correct, that picks are sharp, and that rest periods are coordinated with work of equipment units.

Costkeeping. Much equipment used in earth moving is utilized also for moving rock, handling concrete, etc. The cost of equipment should be apportioned to its several uses.

Comparative cost data of other jobs should be used cautiously; allowances should be made for date, locality, length of haul, horse or motor equipment, labor conditions and unionization, delays due to rock, structures or traffic, and the character of material. Soils differ greatly in wt, cohesiveness, capacity for holding water, natural slope under quiescent loads, and final slope under moving loads.

Lost time. Construction may be discontinued in winter, only because it costs more. Rain and mud, next to winter idleness, are the chief causes of lost time, due to storms and waiting for ground to dry. Water-soaked soil hampers work by increasing weights to be handled, and hindering movement of men and machinery.

Saturation affects soils differently; sand and gravel give a firmer footing when wet; clayey soils, gumbo and alluvial silt become mud. Drainage should be provided to divert surface water from workings, or dispose quickly of that which enters. Employ machines capable of traveling over soft ground; provide equipment that can operate say a third of the time in rainfall, or in water-soaked material.

Machinery maintenance. Failure of any one machine may mean stoppage of others. One man should be in sole charge of maintenance. With a dozen or more machines, he should have a special repair and blacksmith shop, welding equipment and all necessary tools and spare parts; for small tools, duplicates should be kept on hand. In the Culebra cut of Panama Canal, machine shops mounted on cars were highly profitable in keeping a large fleet of steam shovels in repair. Inspection of machinery, oiling and other routine servicing may well be done at lunch time, between shifts, or at night; if not done in working hours, unions demand payment for overtime. Motor trucks may be required to report regularly to gasolene stations having water, compressed air, oil and tires. For less mobile machines, as power shovels and cableways, supplies should be delivered by trucks on regular trips. Road maintenance is especially important now that rubber tires are widely used. Roads should be kept well surfaced (19).

Economics of power shovels (1). In earthwork handled by machinery the following principles are fundamental: (*a*) the shorter the time required to fill dipper and the longer the arc of swing to dumping point, the more important is size of dipper or bucket, width of cutting edge, and ability to fill it properly; (*b*) effort should be made to increase both number and size of bucket loads; (*c*) OPERATING CYCLE comprises: loading time, swinging and dumping time, time to return bucket to loading point. Time losses can be reduced by moving trucks or cars forward during cycle of dipper or bucket operation; (*d*) height of lift should be minimized. In bucket-crane work, the shortest feasible length of boom should be used, with minimum arc of swing; (*e*) if digging is hard, blasting is done whenever its cost is less than that which would be due to delays to shovel and hauling equipment, plus extra repairs to shovel; (*f*) every organization should determine its output multiplier, which depends upon management of work, placing, handling and upkeep of equipment, balance maintained between the types of equipment used, effic and coordination of personnel.

Choice of equipment. No definite rule applies. Equipment for doing work at lowest cost depends upon: investment for capac sought; labor and operating cost; facility of instructing operating men; adaptability to future work (ignored if equipment will not survive the job). To minimize loading cost, use self-loading machines where soil conditions permit. Self-loaders cannot be operated in rocky or sticky soil, in soils with stumps and roots, or below water line. Scarifying certain hard soils (Art 4) prior to loading may be required, especially for large self-loading scrapers (2). For data on DEPRECIATION OF EQUIPMENT, see *Contractors & Engineers Monthly*, July, 1931.

Time losses of power-shovels. Studies by Keystone Driller Co list as UNAVOIDABLE LOSSES: checking grade, moving, blasting, broken cable, mechanical trouble, stumps and roots, frozen material; as AVOIDABLE LOSSES: insufficient supply and inefficient operation of hauling units, inefficient operator, refueling.

2. SOIL PHYSICS AND MECHANICS

Recent studies (3–6) are of value respecting: (*a*) slopes for unsheeted excavations; (*b*) closeness to which excavation can be carried to a building; (*c*) distance or width of berm between working face and spoil bank; (*d*) water required for backfilling; (*e*) degree of compacting and settlement to be expected in rolled earth embankments; (*f*) suitability of material for hydraulic fill dams; (*g*) design of sheeted trenches. "Soil mechanics in present stage of development can be more a liability than an asset to an engineer, unless he has initiative and opportunity to keep abreast of latest developments by personal contact" (6).

Classification of soils by U S Bur Public Roads is based on plasticity, moisture equivalent, grain size, shrinkage and swell.

Aver increase of vol of earth when first loosened: clean sand and gravel, 14%; loam, loamy sand or gravel, 20%; dense clay and dense mixtures of gravel and clay, 35%; unusually dense gravel and clay, as from river beds, 50%.

Voids. If hard spherical grains are thoroughly compacted, the voids amount to 26%; if massed as loosely as possible, the voids are 48%. When measured loose, pit sand or gravel has 35 to 40% voids. Sand of uniform size has 45% voids, measured loose, but only 36% when watered and rammed. Uniform pebbles have 44% voids measured loose; 39% when watered and rammed. Clay allowed to settle in water has 50 to 79% voids; measured loose in the ordinary state, the voids are about 50% (1).

Table 1. Voids in Different Soils

(D. C. Henny)

Soil	Percentage of voids		
	Loose	Compact	Wet-rammed
Surface (organic)	59	49	44
Fine subsoil	54	43	45
Gravel	42	37	34
Coarse subsoil	55	49	46

Quicksand is a hydraulic condition of granular material, where there is sufficient movement of ground water through it to lift the particles, so that they tend to flow upon one another. Fine-grained sand becomes "quicksand" much more readily than a coarse sand.

Table 2. Average Weights of Soils

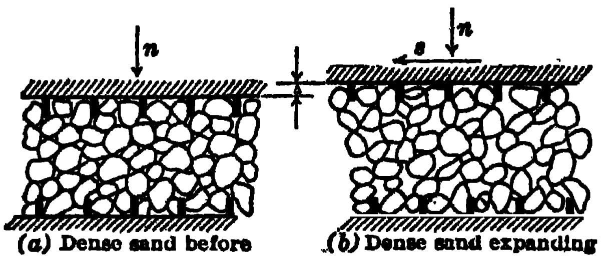
Soil	Condition	Lb per cu ft	Lb per cu yd	Soil	Condition	Lb per cu ft	Lb per cu yd
Sand	Wet	122	3 294	Clay	Loose, dry	70	1 890
Sand	Dry	100	2 700	Clay	In place	116	3 132
Sand	Packed	110	2 970	Clay	Compressed	130	3 510
Gravel	Wet	125	3 375	Clayey earth	Rolled dry	110	2 970
Gravel	Dry	112	3 024	Mud	....	112	3 024

Angle of repose. The face of a mass of earth when exposed for a time to the elements assumes a NATURAL SLOPE, the angle of which with the horizontal is called the ANGLE OF REPOSE. Values in Table 3 are average; in cohesive materials, they may change markedly when the water level against a saturated slope is rapidly lowered (7). Slopes may slough due to seepage toward an open cut, and may change when height and wt of bank become great enough to displace underlying materials.

Table 3. Slopes and Angles of Repose

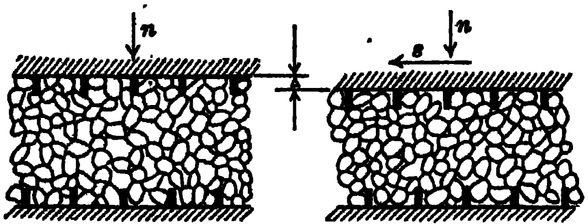
Kind of earth	Slope of repose	Angle of repose	Kind of earth	Slope of repose	Angle of repose
Sand, clean, loose	1.5 : 1	34°	Clay, wet	3.5 : 1	16°
Sand and clay, loose	1.33 : 1	37°	Rock, hard (riprap)	1 : 1	45°
Sand, wet	2.5 : 1	22°	Sand, clay, gravel (suction-dredged)	2 : 1	26°
Gravel, clean, loose	1.33 : 1	37°	River mud (suction-dredged)	3 : 1	18°
Gravel and clay, loose	1.33 : 1	37°	Gravel and sand on shores, exposed to waves	7.5 : 1	7.5°
Clay, dry, loose	1.33 : 1	37°			
Clay, dry, natural	1 : 1	45°			

Stability of cohesionless materials (6). There is a rather wide range of uncertain behavior between the loose unstable and the compact stable state. **SHEARING RESISTANCE OF SOILS**, important in all problems of stability, is influenced largely by water content (Fig 1, 2). In general, it depends upon combined effect of cohesion and internal friction, the cohesive resistance being independent of any applied pressure. Tests to measure shear resistance may be made by the Krey shearing box, obtaining values for cohesion and angle of internal friction (8).



(a) Dense sand before shearing

(b) Dense sand expanding during shear



(c) Loose sand or fine grained soil before shearing

(d) Loose sand or fine grained soil compressing during shear

Fig 1. Effect of Shear on Volume of Sand, Shown by Grain Rearrangement

Landslides and slips are often due to geological causes, such as unfavorable strata with moist surfaces. Conditions leading to landslides: (1) cuts in tilted strata on downdipping side of sandstone, limestone and solid shale beds; nearly vert face left in cut in shale or sandstone, from which material is precipitated by frost action, or slippage on interbedded seams of water-softened clay; (2) accumulations on hillsides of clay silt from decomposed rocks which become fluid when wet; (3) beds of plastic clay not far below surface; (4) plastic clay coatings formed on slopes beneath detritus by wetting and softening of shales. Water lubricates surfaces and increases wt of materials. A homogeneous soil may slide when geometric shape of the mass becomes unstable, as when a trench reaches a certain depth. For each angle of slope there is a max height where part of the mass slides along a surface, which is always curved, never plane (5).

Slips in embankments resemble landslides. The principal soil properties governing safety of embankments are: shearing resistance; coef of permeability; difference in consistency between undisturbed and remolded states; and extent of stratification and fissures, which influence creation of hydrostatic pressure (6). Compaction is aimed to control shearing resistance, stratification and permeability (Art 9).

Corrective measures against landslides. Ordinarily, removal of the shifting material is too costly. Good drainage is first preventive. Landslides have been halted by draining away the water; more effective than piling, blasting or rock-facing slopes (9, 11). From 1931 to 1934, slides and slips of embankments caused 3 000 deaths in 13 major disasters, and cost millions of dollars (13).

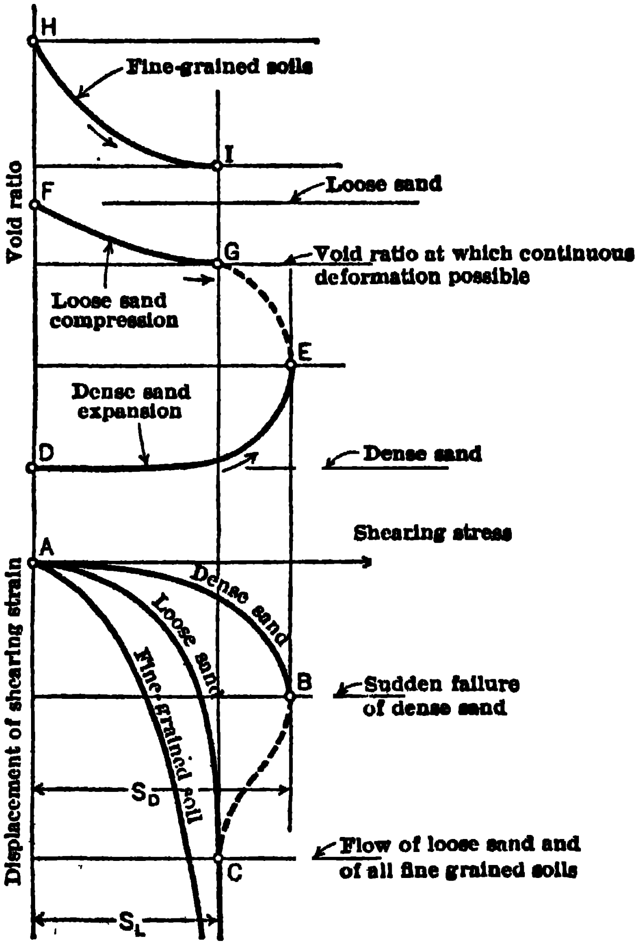


Fig 2. Displacement and Volume Change, as Functions of Shearing Stress of Sands

Shrinkage of embankments has long been a subject of discussion, due to lack of experimental data and of an accepted meaning of the term. Shrinkage may be expressed as the relation of: vol of fresh fill to that of the same fill after settlement; or, as the vol of an excavation to that of the settled fill made from it. A cu yd of earth measured in place will occupy less space ultimately in compacted embankment. The usual allowance for shrinkage, 8–12%, does not apply to gumbo, cemented gravel, or materials from beds of streams, all of which are dense, and their shrinkage can be determined only by actual measurement. Investigations by "Bur of Valuation," of Interstate Commerce Comm, indicate that 9.1% is a minimum, and 14.4% is a closer final aver. These figures were modified by a Comm of the "Railroad Presidents' Conference" which, on basis of 12 million cu yd of earth embankment, found an aver of 10.4% initial shrinkage (Table 4), and, after complete settlement, 14.4% (see *Eng News-Rec*, Mch 10, 1921, p 434).

Table 4. Shrinkage of Earth in R R Fills, as Determined by Measurement and by the Rule of "Bur of Valuation," Interstate Commerce Comm (18)

Railway	State	Material	Shrinkage by measurement, %	Shrinkage by the rule, %	Method of construction	Vol. of excavation, cu yd
Ill Cent	Ill	Dune sand, fine and dry	8.81	9.1	A	256 408
Nor & West	....	Light clay, considerable sand, some mica	8.8–9.7	9.1	C, D	124 059
Cent Vt	R I	Fine, dry sand	7.77	9.1	A	96 767
Nor & West	....	Some quicksand	10.3	9.1	C, D	77 120
So Pac	Ore	Silt and coarse gravel, bottom of large fill	10.3	9.1	B, C, D	64 160
Nor & West	....	60% dry sand	6.1	9.1	C, D	44 360
So Pac	Ore	Clayey silt, gravelly in spots	10.1	9.1	B	31 660
So Pac	Ore	Cemented material, clayey, mostly cuts; 2.5% rock in fill	15.1	8.6	E	26 781
So Pac	Ore	Borrow-pit earth, very clayey	1.8	9.1	B	11 016
So Pac	Ore	Clayey silt	11.1	8.7	A, C	9 648
So Pac	Ore	Very clayey	3.5	9.1	C, D	5 572
Cent Vt	R I	Stiff blue clay	12.27	9.1	A	3 047

A. Unloaded from trestle. B. Teams and scrapers. C. Steam shovels. D. Dump wagons. E. Carts and horse-drawn cars, dumped from sides and ends of fills.

3. EARTH-MOVING EQUIPMENT (17)

Operations: (1) loosening surface; (2) loading; (3) transport and dumping; sometimes (4) compacting. FOR LOOSENING hard ground: scarifiers, rippers, rooters, dipper shovels, backhoes and skimmers, pneumatic spades, dredges, steam jets, explosives, and hydraulic sluicing. FOR LOADING: mechanical shovels with clamshell or dragline dippers, push shovels, backhoes, elevating graders, cableways, belt conveyers. FOR TRANSPORT: wheelbarrows, carts, trucks, cars, graders and scrapers, cableways, conveyers, hydraulic sluicing. FOR COMPACTING: rollers, vibrators and drainage operations.

Hand labor and horse-drawn vehicles have been generally superseded by mechanical equipment, except for minor operations. For large-scale work, the trend is toward complete mechanization. Cars and trucks are usually mounted on low-press pneumatic tires, involving more attention to haulage roads. Power scrapers are more used on short-haul work, and their radius may be extended. Diesel is supplanting gasolene power for all except very small units (17).

Hand work. Few soils can be shoveled without picking or plowing. Light blasting is often advantageous.

Table 5. Rates of Picking, Cu Yd per Hour

Stiff clay or cemented gravel	1.4
Strong heavy soils	2.5
Loam	4
Light sandy soils	6

Picking is costly. Table 5 shows fair aver duty per man-hr (19).

A man shoveling 1.4 cu yd per hr of the loosened material mentioned in Table 7 can handle only about half that amount if he does his own picking. Advantage of cheaper means of loosening is obvious.

Plowing is satisfactory for preceding shovel or smaller scraper work. Table 6 shows fair aver duty of horse-drawn plows.

Table 6. Rates of Plowing

Soil	Labor	Cu yd per hr
Loam	1 driver, 1 holder, 2 horses	50
Gravel and loam	1 " 1 " 2 "	35
Fairly tough clay	1 " 1 " 2 "	25
Very hard soil	1 " 1 " 4-6 "	15-20
Ordinary soil	2 men on plow beam of rooter plow 1 driver, 6 horses, on gang plow	40

Wheelbarrows, of wood, steel or aluminum alloy, generally have steel wheels, sometimes pneumatic tires; the latter, with large-diam wheels, reduce traction on soft ground. Loads are 2-2.5 cu ft. The lightest barrows weigh 35 lb, empty; the larger, over 90 lb. The man holds $^1/_5$ to $^1/_3$ of the load (17).

Carts. One-horse, 2-wheeled, dump carts hold 0.3-0.5 cu yd. On ordinary road loads seldom exceed 0.4 cu yd (place measure). With hauls of 300 ft or less, 1 driver can attend 2 carts by taking one to the dump while the other is being loaded. COST OF CART WORK per cu yd = $^1/_{20}$ hr wages of team, driver and helper on plow; + $^2/_3$ hr wages of labor shoveling; + $^1/_4$ hr wages of cart horse and driver for "lost time"; + $^1/_{20}$ hr wages of cart horse and driver for each 100 ft of haul.

Wagons. Horse-drawn, bottom-dump wagons have nominal capac of 1-2.5 cu yd. Speed of travel per min (not including delays and rests): poor roads, 130 ft; fair dirt roads, 175 ft; best roads, 220 ft.

Table 7. Loading by Shoveling

(*a*) 10 miles, Erie Canal. (*b*) 10 000 cu yd bank measurement. (*c*) 20 000 cu yd in embankment. (*d*) A rush job. (*e*) Spaded out and handled with forks.

Railroad cars. Air-dump cars must discharge their loads quickly, with as small air press and consumption as possible, and leave dumped material so that the cars can be righted and backed promptly, with minimum labor for track shifting and incidental work at dump. Car should be simple in design, rugged in construction, with few operating parts, all easily accessible (19).

Industrial railways are for extensive hauling over a long fixed route, as for R R construction, highways, dams, tunnels, aqueducts, large ditches and canals. Greater flexibility is obtained by use of locomotives, though grades of over a few per cent seriously limit wt of cars hauled. **Track gage** is usually 18, 24 or 36 in; some 42 in. Rails weigh 8-20 lb per yd, and are in 20, 30 or 33-ft lengths. Second-hand rails and ties often serve for short job. Portability of track is important where there is much shifting and relaying. Light track is economical, in which ties and rails are assembled in lengths of 15-20 or even 30 ft, that can be carried by 2 or 3 men; with curved sections, switches and turntables, and joints readily fastened and unfastened. Units can be laid on firm ground with little if any grading. Ties may be of wood, but steel saves shifting time (19).

Track grades. If a locomotive alone can operate on 8% grade, it will haul a train of its own wt on only a 4% grade. Hence, practicable grades are determined by the relation (grade % × wt loco) + (wt loco + wt of loaded train). Under favorable track conditions, the operation of locomotives may approach theoret fric coef, but a little water or grease on rails seriously reduce its tractive power (see Sec 11).

Tractors (see Sec 27) are mounted on caterpillars or rubber tires; draw-bar pull, up to 22 000 lb in first gear. Rubber tracks, claimed to be good for 5 000 miles, are offered in place of metal. Principal tractors (1939): International, Caterpillar, Cletrac and Allis Chalmers. Horsepower, 22–96; the smaller sizes have gas or Diesel drives; the larger, Diesel only. Wt, 5 000 to over 30 000 lb, but unit ground loads for crawler-traction are limited to 6 lb per sq in. Draw-bar pull varies with speed, grade and ground conditions. Load should not exceed 75% of max draw-bar pull of tractor in second gear (2). Allis Chalmers, Model I-U, is a fast, powerful wheel tractor for hauling and road building at low cost. Speeds, $2^1/_3$–25 miles per hr. OPERATING COSTS. Studies of Dept of Agriculture, Cornell Univ (1935), on about 70 machines, of 16–30 brake h p, showed costs from 25¢ to $1.12 per hr; aver 50–70¢ (19).

Motor trucks for earthwork are power-dumping. Nominal capac, 1.5–18 cu yd. The rear end may have wheels or caterpillar traction.

Dump trucks. Speeds were formerly kept down by governors to about 15 miles per hr, but are now generally unrestricted. Wt, 11 000–14 500 lb; h p, 75–100. Recent special types ("dumptors" and "iron mules") have a short wheel-base, making possible quick turns within 15 ft; driver sits behind body and has unobstructed view to rear for reverse running; speed, 10–13 miles per hr in high gear and 3.5–4 in low, in both forward and reverse gear (19). POWER. Steam has been mostly replaced by gasolene and Diesel engines. Diesels have higher first cost and more complicated mechanism, but use cheaper fuel and $^1/_2$–$^1/_3$ the quantity required by gasolene machines. Elec operation is sometimes employed for large-scale work.

Crawler wagons, developed since 1920, are desirable in soft, wet ground, where soil is sticky. They roll and smooth the road surface, instead of cutting it into ruts, as is done by motor trucks. As many variable factors affect wagon operation, cost estimates must be conservative. Skill of operators of the loading machines, and the wide variations in character of the material excavated, directly affect yardage output. For crawlers hauled by tractors, costs are: 5-cu yd wagon, 45¢ per hr; 10 to 13-cu yd wagon, 69¢ per hr, excluding deprec (2).

Pneumatic-tired, bottom-dump wagons, of 20, 25 or 30-cu yd capac, will haul greater distances, at lower cost, than crawlers or other equipment, providing scale of work justifies the investment, and road surfaces are good, with grades less than 5%. A Cletrac No 80 tractor, with 25-yd wagon, will haul an aver of about 72 cu yd per hr to a distance of 2 000 ft, the rate of work being affected by size of shovel, skill of operator, extent of swing, vert lift, and soil conditions. A 25-yd wagon costs about $8 750 f o b; cost of operation, about 84¢ per hr, including deprec (2). Two wagons are sometimes hauled in tandem.

Scrapers drawn by tractors can dig economically to depth of 24 in and transport several hundred ft, provided ground has been cleared and grubbed (Art 4) and is free of boulders. There are many forms: as wheeled and carryall scrapers, bulldozers, trailbuilders, self-loading wheelers. Limit of haul, 200 to about 1 400 ft (2) (see also Sec 27).

Graders have a cutting blade between front and rear wheels. Capac, 1–12 cu yd. They may be pulled by tractors of 15–80 h p, or propelled by their own power (usually about 50 h p). Mounted on 4 steel wheels, or 4, 6 or 8 rubber-tired wheels. Blade or moldboard, 7–16 ft long, 12 ft being usual, with a height of about 18 in, is adjustable in height and tip. Wt, from 1 400 lb for towed graders, to 17 000 lb for power machines. Speeds of power graders, usually 2 miles per hr in low gear, 19 miles in high gear, with two intermediate gears and reverse (2).

Bulldozers are tractor scrapers with a very strong blade, arranged to be lifted 3–3.5 ft, and lowered 5–6 ft below ground level. Wt, 3 500–6 000 lb. Capac when loaded for shoving, 2–4 cu yd; h p, 30–70. Speeds, 120–240 ft per min. After depositing load, return is made with blade raised, at about 240 ft per min. Cost, $750–$1 825, f o b. The blade is movable only up and down. "TRAILBUILDER" blade can be angled horiz, vert or moved up and down (2). Cost, $900–$2 750.

Carryall scrapers, on pneumatic tires, pick up loads singly or in tandem, and travel at high-gear speeds. They are operated by a power-control unit, which obtains power from tractor drive shaft and transmits it by cable to the working parts. Single carryall scrapers require 2 drums; cable from one drum raises or lowers bowl in loading and unloading, the other operates front apron and tailgate in unloading and spreading. For tandem operation, a 4-drum unit is needed (2). LE TOURNEAU CARRYALL is mounted on large pneumatic tires, and has Timken bearings. Alloy steels of great strength and resiliency are used, minimizing the wt. Capac is large because: (*a*) the expanding bowl carries the soil back into the bucket during loading, so that the tractor can put more effort into cutting;

(*b*) entire wt of body can be applied to the cutting edge; (*c*) front apron, tailgate and telescoping bucket facilitate loading; (*d*) the operator can instantaneously adjust cutting depth, or raise the blade to avoid stumps or rocks, or avoid stalling motor in deep cuts.

Self-loading, single-unit scraper will load seamed rocky material without blasting. It is adapted to hauls of 500–2 000 ft. Sizes, 5, 6, 10 and 12 cu yd when heaped. Cost, $2 400 for 5-yd size to $5 225 for 12 yd, f o b.

Self-loading wheel scrapers are adapted to longer hauls than ordinary scrapers; up to 200–1 000 ft. Capac is small, 1.5 and 2 cu yd. They are hauled singly, in tandem, or, under favorable conditions, in threes. Cost, $800–$1 150, f o b (2).

Fresno scraper, the oldest type of wheel scraper, was formerly drawn by horses, now usually by tractors. Capac, 0.75–3.5 cu yd. Cost (1938), $130–$450.

Spreaders. Western spreader car is hauled on 36-in track by locomotive. Designed for spreading material dumped from R R cars. Body and frame are of wood, strongly braced and ironed; trucks, of I-beams. It has steel-faced oak wings or blades, 15.5 ft long, with removable cutting edges, and will spread 7 ft from outside of rail. Long wheelbase of Model U carryall, with split-second cable control, gives great accuracy in spreading.

Belt conveyers (see Sec 27 for details of construction and applications). For earth work they are important as accessories to dredges, trench excavators and elevating graders.

Power shovels (Fig 3) were first mounted on crawlers instead of R R trucks in 1911. In 1939 practically all except those for R R service have crawler mountings, which exert bearing press on ground of only 0.72–1.08 ton per sq ft, and require no auxiliary mats. DIPPERS usually have capac of 2–3.8 cu yd; occasionally up to 15 yd. Manganese steel is largely used for lips and dipper teeth. By welding to the teeth hard wearing surfaces of stellite, or an alloy of cobalt, chromium and tungsten, life is increased more than ten times. BUCKETS are self-filling (clamshell or orangepeel); or hand filled (turnover or bottom-dump). The orangepeel may exert more digging force and is heavier than the clamshell. Capac, 0.5–3 cu yd; corresponding weights 2 000 and 7 000 lb. Clamshells of 16.5 cu yd have been built. Turn-over buckets hold 0.5–1.5 cu yd; shape, cylindrical or cubical. Exact placing of material is impossible with them. Bottom-dump buckets are of 1–3 cu yd; seldom used. Dredge buckets can be used with any type of engine having 2 drums. Advantage of orangepeel or clamshell bucket on a crane over a dipper shovel is that there is practically no limit to digging depth; whereas the depth for dipper shovel is limited (Fig 3).

Excavators with booms. Most power shovels with dippers smaller than 2.5 yd have interchangeable booms, so that with delay of a few hours they can be converted in the field to plunger shovel, a backhoe, dragline, or clamshell. Plungers are lighter than dippers of same capac and hence have greater cycle speed. Dipper shovels fill buckets by a "crowding" (pushing) motion; backhoes (backdiggers, pullscoops, ditchers), by pulling toward the machine, the bucket being thrust forward by an auxiliary handle. Skimmers, plungers and scoops fill bucket by pulling it away from shovel under the boom by a cable, and carry load to dumping point by raising and swinging the boom. Operations are more restricted than those of a dipper shovel. See Sec 27.

Table 8. Operating Speeds, in Seconds, of Dipper Shovel

	Loading	Swinging	Dumping	Returning	Total
Maximum..	16	7.5	5.75	7.25	36.5
Average....	9.6	6.0	2.4	6.2	24.2
Minimum ..	7	5.25	2	5.5	19.75

Minimum may be expected in poorly blasted rock and max in dry earth (21).

Table 9. Digging Radius of Revolving Shovel, 24-ft Boom; 14-ft Dipper Handle; Caterpillar Tread; 1 yd Dipper (Fig 3)

Boom angle with horiz, deg	Height of dump, dipper door open A	Radius of dump C	Digging radius D	Radius floor level cut E	Center rotation to point to boom G
45	14′ 2″	23′ 6″	26′ 11″	19′ 9″	21′ 11″
55	17′ 2″	21′ 3″	25′ 3″	16′ 7″	18′ 9″

Clamshells and orangepeels, suspended from a crane, fill the buckets solely by dead wt

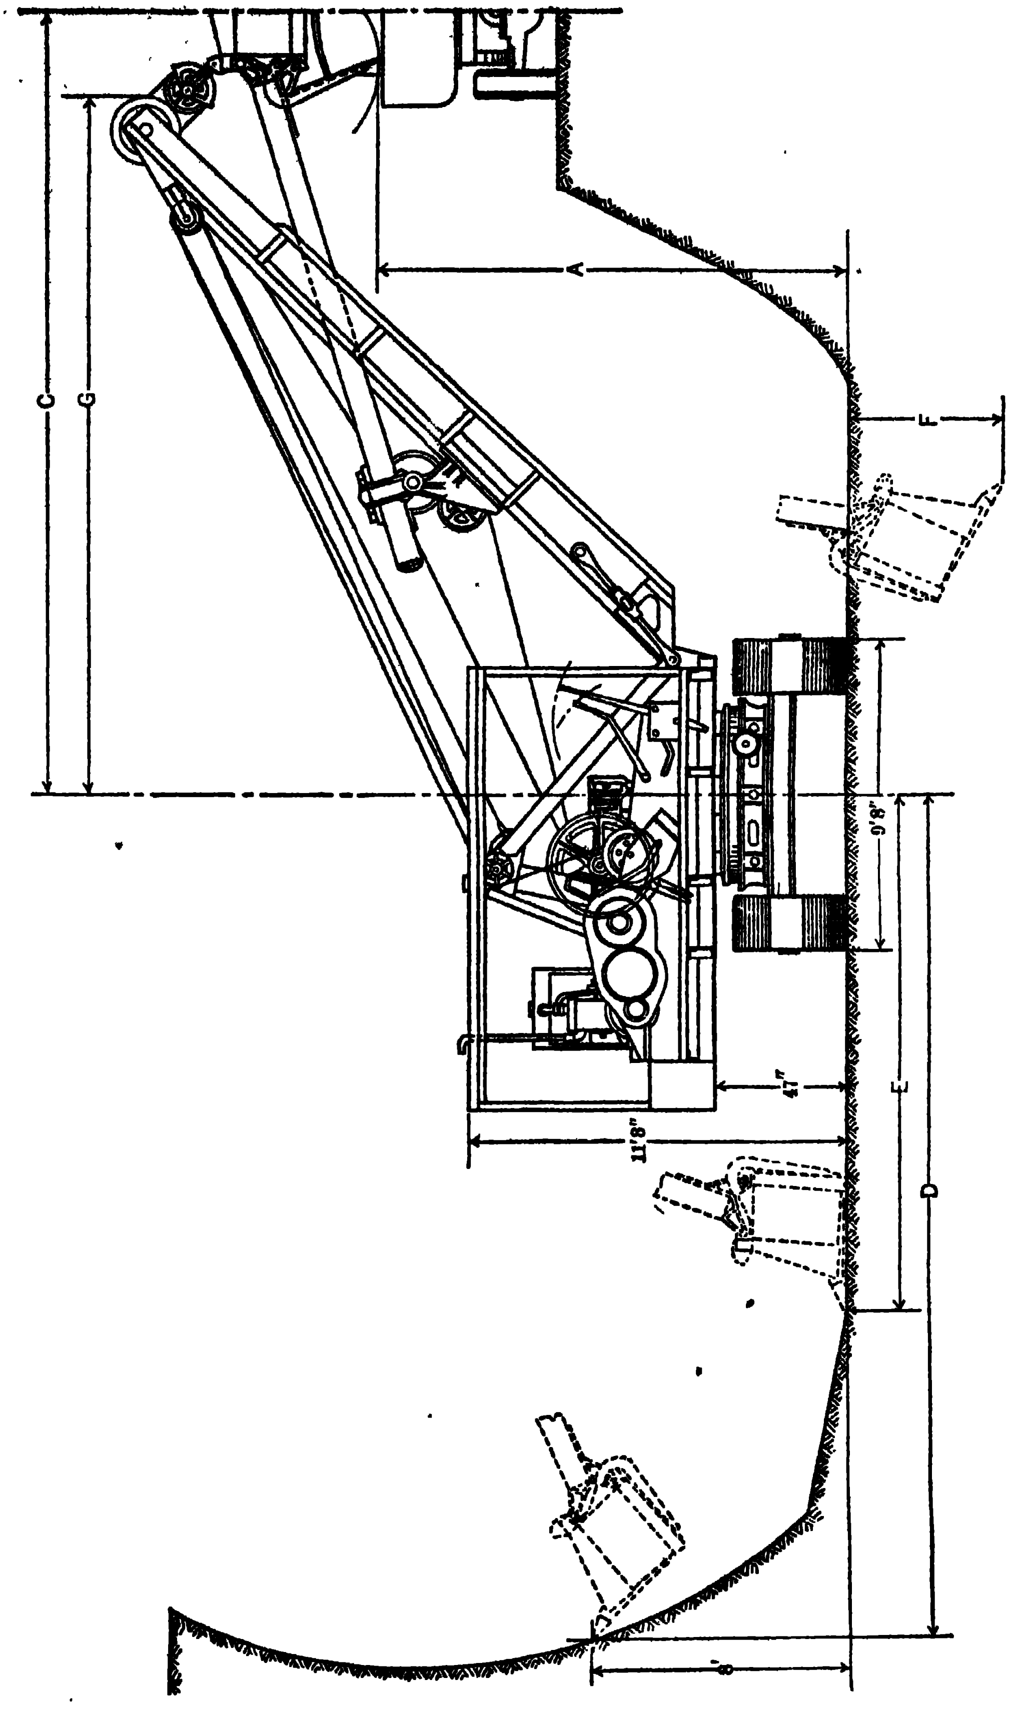

Fig 3. Power-shovel with Dipper

and impact; dragline fills by the pulling motion of cables toward the machine. Modern equipment is designed for quick change from clamshell to dragline.

Push shovels can dig compact soil, where draglines, clamshells and orangepeels would be uneconomical. Their "crowding" motion is of first importance. "HILL-BILLY" (Insley Mfg Co, Indianapolis) will work on steep hillsides. BACK-HOE (pullscoop, or trench hoe) is an inward-arc digging bucket, carried by a handle pivoted on a boom, and dumps by raising handle until contents discharge by gravity. It is used for excavation below grade; especially adapted to trenching. Capac, 0.75–2 cu yd. Will dig to depth of 25 ft, but can be swung horiz like a shovel for excavating level areas. It can cut through hard slate, shale, blasted rock, or a foot of frozen soil.

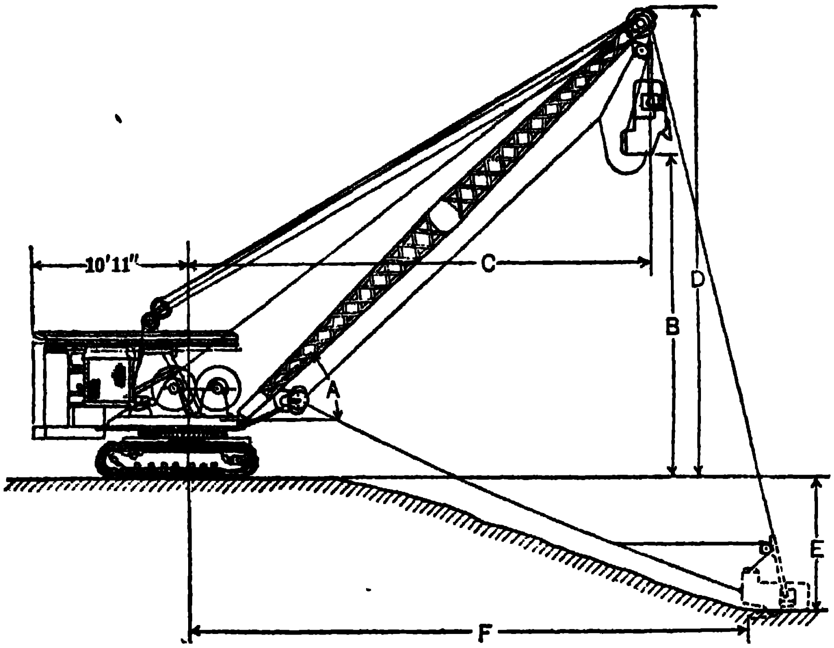

Fig 4. Erie Dragline Scraper

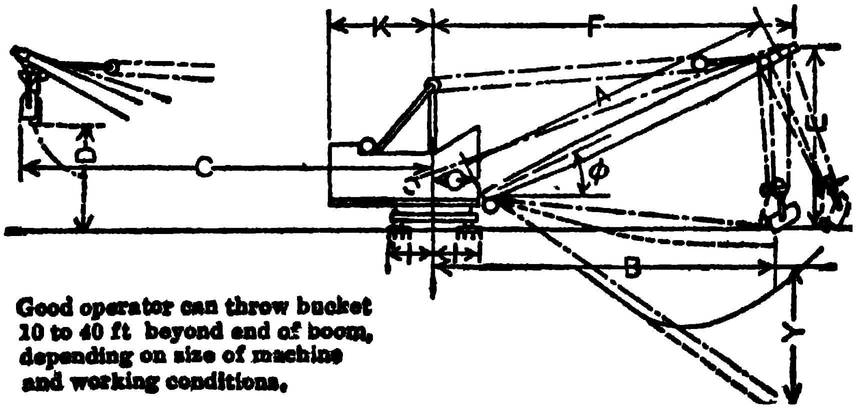
A (angle of boom)	20°	30°	40°	50°
B (clearange lift of 3/4 yd bucket)	11′ 10″	19′ 5″	26′ 2″	32′ 0′
C (radius of boom)	46′ 7″	43′ 4″	38′ 9″	33′ 3′
D (height boom)	19′ 8″	27′ 2″	34′ 0″	39′ 10′
E (approx. depth below grade)	20′ 0″	20′ 0″	20′ 0″	20′ 0′
F (approx digging radius)	54′ 7″	51′ 4″	48′ 9″	43′ 3′

Dragline scraper (17) is widely used, but cannot dig accurately to grade. The bucket is operated from a crane boom, and its digging radius is considerably greater than boom length (Fig 4, 5). There are several types of scoop, and, as they are lighter than clamshells, less power is required. Advantages: (*a*) the wide reach of a long boom; (*b*) reduces amount of labor and equipment by combining digging, elevating and conveying in a single



Good operator can throw bucket 10 to 40 ft beyond end of boom, depending on size of machine and working conditions.

Fig 5. Possible Reach of a Large Dragline

machine controlled by one operator; (*c*) small lifting force needed while bucket is filling, power for loading being applied in a nearly straight line from winding drum; (*d*) nearly all the engine power is available for cutting through obstructions while filling the bucket. Range of digging with 0.75-yd bucket is about 14 ft horiz and 17 ft vert; dumping height, about 18 ft. Booms up to 160 ft have been used. Draglines are especially useful for moving soils say 500 ft, with a tower excavator, or belt or other conveyer, close behind. Under aver conditions, a 150-ft boom dragline can excavate and place for 10¢ per cu yd on 300-ft max movements; for 500 ft, 14¢. With belt conveyer, cost is a little more to excavate and place, but less to haul. Cable replacement is a large item of expense; may be 50–80% of total; careful handling is essential. Plow-steel cable, 6 × 19 Lang lay (see Sec 12) is recommended. Drum diam is 400–500 times that of individual wires.

Table 10. Dimensions of Dragline Scrapers

(Averages from catalogs of well-known mfrs) Trautwine, 1937 Ed

Capac, cu yd	0.5	0.75	1	1.25	2.5	5	10

Rotating speed, rev per min	5.25	3.5	3.5	2.25	....	....	0.85

Trenching machines are of wheel or ladder type, the buckets in both revolving towards the machine. Buckets deliver to belt conveyer, discharging on one side of trench. Depth of trench for bucket-wheel machines is 8–12 ft max; width, 12 in up. Speed in ordinary soil is claimed by makers as 1.25–4 ft of trench per min; in exceptional cases, 5 ft; partly frozen ground may slow it to 0.5 ft. Depth of trench for ladder trenches is 12–20 ft; width, same as for bucket-wheel machines. Trenching machines are especially suitable for widths to 4 ft (see Art 5).

Cableways for trenching are strung over line of trench, handling a number of buckets loaded by men in trench. Formerly much used, and are still useful for deep digging, and where excavated material cannot be stored alongside.

Elevating grader (17) is a combination of plow and belt or bucket conveyer, on frame carried by wheels or caterpillars. Plow cuts a furrow about 1 ft wide, and 6–7 in deep. Moldboard delivers material onto lower end of a small conveyer or elevator of changeable inclination, 14–25 ft long, belt being usually 42 or 48 in wide. Conveyer is at right angles to direction of motion, extending to right or left, and upward for loading wagons moving alongside and keeping pace with it. The machine may be hauled by tractor, and conveyer operated either by separate power unit, making belt speed control easier, or by a "power-take-off" from wheels or tractor, which is simpler and lighter (for details, see Sec 27).

4. METHODS OF EXCAVATION

(For dredging, embankments, trenching, ditching and hydraulic handling, see Art 7–9)

Clearing, grubbing and stripping. CLEARING is the cutting of trees (generally leaving 2.5-ft stumps) and their disposal, together with brush. Pulling stumps and roots is termed GRUBBING. STRIPPING is the shallow excavation and removal of top-soil containing organic matter; where backfilling follows laying of pipes, etc, top-soil may be stored nearby for use as dressing on barren backfill. Clearing and grubbing are especially necessary where graders and scrapers are to be used. Roots and small brush interfere with all machines except power shovels and dragline excavators, which do their own grubbing. Cost of grubbing is difficult to estimate, as local conditions are extremely variable.

Methods of grubbing: (*a*) by tractors and bulldozers; (*b*) burning, blasting and pulling stumps; (*c*) by scarifiers. Grubbing by hand is uneconomical, but still practiced. In cold regions, if large roots are cut in fall, winter frosts may heave stumps and lessen work of removal. If standing trees are pulled over after partial grubbing, their wt in falling will break roots difficult to reach, and lift stump out of hole.

Blasting stumps (16): (*a*) expose tap root to depth of say 18 in and bore a hole in it with wood auger, more than half through; split a dynamite cartridge, pack well into the hole, and tamp with moist clay; (*b*) place 2 or more cartridges at least 2 ft below surface of ground, and close against the tap root. To place a heavy charge for a large stump, the bottom of the hole alongside the stump may be enlarged by "springing" it with a light charge of one-quarter cartridge. For more than one hole, a blasting machine should be used to explode all simultaneously. A charge under middle of a stump having large lateral roots may merely split the stump. For large stumps, charges are often placed under each heavy root. Single charges under small stumps should be placed considerably below the butt, so that the cushion of earth will distribute the force, and prevent splitting the stump. Fresh, fibrous-rooted stumps are harder to blast than those that are decayed or have tap roots. For sound stumps, charges of 40% dynamite are given in Table 11; for green stumps, multiply these by 1.5–2; for decayed stumps, use less than shown.

Table 11. Dynamite Required to Blast Stumps

Diam of stump, in.....	12	18	24	30	36	48	60	72
40% dynamite, lb.....	0.56	0.75	1.12	1.50	2.25	3.75	5.25	8.25

For western fir, pine and cedar stumps, in firm deep soil, use 1.5 lb of Judson (contractor's powder) per ft diam of stump, up to 4 ft; for larger diam, 2–2.5 lb per ft; in gravel or loose ground, 2.5–3.5 lb per ft. For stumps 8 ft or more in diam, the charge of Judson powder in lb = diam of stump, ft.

Burning stumps. Soil is dug away, partly exposing largest roots. Brush and logs are piled about stump, and kept burning until it and larger roots are consumed. This method is good for rotten stumps, difficult to blast or pull. CHAR-PIT method consists in placing brush or kindling around stump and covering all with clay and sod, leaving small openings for admission of air; stumps should first be split, by exploding dynamite in ship-auger hole in center of stump. A portable gasolene engine and blower are useful in burning large stumps, and may be more economical than grubbing or blasting.

Pulling stumps is done by hand, or horse-drawn machines, but chiefly by tractors. Though slower, pulling may be cheaper for a single stump than grubbing or blasting. Pulling is facilitated if stump is first shattered with small blast. Small trees, singly or in groups, can be torn out by tractors; such trees should not be cut, as it is more difficult to make fast to small stumps.

Disposal of stumps in cut-over forest land costs as much as grubbing. It is best to blast first, using only enough powder to shatter stumps and loosen their hold, and then pull and collect them with a winding engine; 1 200–1 500 ft of rope will reach all stumps on 5 acres at one set-up. Rope is carried over a gin pole, about which stumps are piled and then burned. Brush land may be cleared by heavy, tractor-hauled plows, but considerable hand labor is necessary to gather and remove debris.

Loosening. Efficiency is gained by blasting frozen crust, particularly in dragline work, and it is generally best to "dig in," and have a good working face before frost comes. For winter blasting, non-freezing explosives are essential. It is economical to loosen heavy soils by scarifiers (see below); their use ahead of scraper shortens loading time. On aver hauls, one tractor and scarifier can keep ahead of 2 or 3 tractor and scraper units (2).

Scarifiers have a series of vert teeth, side by side on a bar; may be used instead of blade of grader or attached to rear of a road roller. Types: RIPPER is useful for breaking hard-surfaced roads and general surface work, in conjunction with large scrapers. ROOTER resembles a harrow with 3 to 9 teeth, and digs to depth of 2 ft. It is mounted on 2 wheels, 2–3 ft diam, and pulled by tractor. Wt, 2 500–8 000 lb. Valuable in preparing hard ground for graders, dislodging stumps, or breaking up concrete; they frequently obviate blasting frozen ground (2).

Loosening by explosives. Hardpan is economically loosened by charges of low-grade dynamite, or Judson (contractor's) powder. Holes, except in high banks, should be at 45° to the vert. Horiz holes in face of a bank are effective. For details of chamber and coyote-hole blasting, see Sec 5.

Thawing frozen ground may be done by burning gasolene or coal oil, or by use of lime, steam jets, or wood fires. Ground frozen too hard to be excavated by a trench machine, can be softened by spreading small pieces of lime along the line of proposed trench, covering them with manure or straw, and pouring on hot water to slack the lime and liberate the heat. Clay, frozen so hard to depth of 34 in that stones embedded in it could be sheared off without loosening them, has been thawed by jetting holes with a $^1/_2$-in pipe connected by hose to a boiler. In each hole was inserted a $^1/_2$-in capped pipe, with 4 $^1/_8$-in holes bored in it, and steam forced in to thaw out the surrounding ground (10).

Hot water thawing is more economical than steam for working frozen gold-bearing gravels. In the Yukon district, Alaska, a 30-hp pump, with 4-in intake and 3-in discharge, delivered water at

40 lb press through a 1-in nozzle; 6 000 gal of water were used over and over. The water was kept at a temp of 150° Fah by discharging the pump exhaust into the suction sump. In 10 hr this thawed and broke down 175 cu yd gravel (see also Sec 10). Cold water has also been used.

Bank blasting. In hard, cemented material, dynamite is better than black powder; in soft ground, the latter is more economical. With very high banks the bottom should be blown out and the top allowed to drop. Charges should be placed so that the line of least resistance is horiz. With banks 50 to 150 ft high in cemented gravel, the length of main drift should generally equal $^2/_3$ the height of bank. Cross drifts are driven parallel to the bank face, their length depending on length of face to be blasted. Powder charge for aver conditions is about 0.4 lb per cu yd of ground. (For further details, see Sec 5.)

Blasting at the property of the Milton Mining and Water Co, Sweetland, Cal, during 3 years, required an aver of 0.382 lb Judson powder per cu yd. The top gravel had been washed off, leaving banks (usually hard and cemented for 50 ft, but soft above) from 50 to 150 ft high. In some parts, 8.3 to 8.5 cu yd were shattered per lb of powder.

In soils difficult to pick, blasting may be economical. Excavate by picks until a face is formed, and make vert 1.5 to 2.25-in holes in a line back of the face with pointed bar, churn drill, or auger. Depth of holes should be a little less than the height of bank, distance between them being 1.5 times line of least resistance (Sec 5, Art 5). In the formula $B = CR^3$, B = charge in oz, and R = line of least resistance in ft; the "rock coeff" C should be determined by trial. For loam, conglomerates, and ordinary soil, using 30% dynamite, C is usually nearly 0.6. Holes in frozen ground should be "chambered" (Sec 4, Art 8).

Loading. Elevating graders and power shovels, with dipper or backhoe equipment, are favored for large-scale work. For earth cuts the tractor-wheeled scrapers are used. Elevating grader will load for about 5¢ and power shovel for 7¢ per cu yd, not including waiting time of hauling equipment. Cost of spreading, watering and rolling is about 7¢; of hauling, 0.75¢ per cu yd in place, not including road maintenance. The dragline scraper is always economical for excavating large, shallow areas.

Influence of depth of cut on power-shovel costs (23). Unit cost of excavating with dipper shovel in shallow cuts may be 2 or 3 times more than for medium depths. Output is greatest in cuts between 4 and 12 ft deep, where full dipper loads can be taken by each crowding and hoisting movement. Latest type of plunger shovel also works best at depths of 4–12 ft, but has an advantage in working speed, because the boom and scoop assembly, size for size, weighs nearly 6 000 lb less than standard boom and dipper. Time studies indicate 10–14% faster work than dipper shovel. For depths exceeding 12 ft, it is generally best to resort to benching. Power-shovel delays on 51 highway operations: hauling equipment, 9.9%; moving shovel and repairs, 18.6%; weather, 14.9%; misc, 20.2%. Effect of material on time for loading dipper: good earth, 5.6 sec; earth and some rock, cemented material, 8.4 sec; poorly-blasted rock, 10.3–16.7 sec.

Following figures are for work of Bucyrus steam shovels under favorable conditions. No. 20-B, loading blue clay and sand into trucks, 93.5 cu yd per hr; road grading, overcasting, digging clay, roots, stumps and rocks, 50 yd per hr; road work in solid limestone, poorly blasted, 34 yd per hr. No. 30-B on road work, loading earth, rock and some shale, 130 cu yd per hr; partly loading in cars, partly overcasting, clay and laminated limestone, 70 yd per hr. Loading in wagons, very stiff clay, 60 yd per hr.

On R R grading in West Va (22), 4 Lorain gasolene crawler shovels with 1.25-cu yd dipper, loaded trains of four 4-cu yd dump cars in 3 min, dumping at height of 17–18 ft. Output per 10-hr shift, 1 000–3 000 cu yd; distance hauled on each side of cut, about 1 000 ft. Much of excavation was in rock or hard shale, requiring blasting.

Power-shovel costs for general grading: $^5/_8$-cu yd dipper, 23.3¢ per yd; $^7/_8$-cu yd dipper, 17.7–19.2¢ per cu yd.

Selection of hauling equipment. For short hauls and large-scale work, the combined excavating, hauling and placing unit, like the elevating grader and dragline scraper, are desirable. For long hauls, bottom or side-dump crawler wagons, and especially tractor-drawn pneumatic-tired wagons holding 3–25 cu yd, are economical. New developments are the 24-cu yd wagon, mounted on 16 large low-press tires, and the pneumatic-tire tractor unit, with trailer wagon. They are speedy, but require solid roads; can not run on very wet earth surfaces (17). Apply to makers for tables of economic hauls for the different machines.

Elevating grader. If soil is free from rocks and stumps, a motor-driven, 48-in grader, pulled by a Cletrac tractor, will load on aver a 7-cu yd wagon per min, where the plow can work to its full depth and loading is done without turning; or a 10–13 yd wagon in 1.5–2 min (2).

Fresno scraper (sliding), in absence of ledge rock or boulders larger than scraper opening, will haul more dirt per dollar invested and at lower cost than any other excavator, within a distance of 200–300 ft, and is widely used for removing overburden, stripping, and cutting down grades. The 0.75-yd size can handle 15 cu yd per hr on 200-ft haul, at about 39¢ per yd; a 3.5-yd Fresno will handle 70 cu yd 200 ft at about 13.5¢ per cu yd, all including deprec (2).

Bulldozer, in leveling dumps or moving dirt on short hauls, is a closer competitor of the Fresno, within the same distances, and is useful for similar work. Hard material must first be loosened. Experiment determines best speed to avoid spilling. They are effective for scraping down slopes as steep as 35%; and, if gear is right, they can back up the grade for next load. On 200-ft haul, capac is 13–40 cu yd firm dirt per hr, at cost of 20–47¢ per yd for bulldozer and Cletrac motor, including deprec. These figures are conservative for good soil and level grades; capac increases on down grades, and decreases on up grades (2).

Observations in 1934 indicate that aver load transported from cut to fill under ordinary conditions varies with length and shape of blade, and grade and character of soil. Loads on the 4 bulldozers in Table 12 often fluctuated as much as 100%; smallest loads, about 2 cu yd, largest 4 cu yd (16). Recent improvements, permitting independent vert movements of either end of bulldozer and also lateral movement, make it easier to keep excavation in proper condition, and to shape slopes at proper angle.

NOTE.—Scrapers 1 to 5 were on same job; and 1, 5, 6 and 7 were of same make, but working under different conditions. Scraper No 7 worked in winter, when materials were wet and sticky. For such soils, crawler wagons are preferable.

Cost of excavation by self-loading wheeled scrapers, hauled by tractor, is 13–18¢ per cu yd, including deprec, but exclusive of hand labor. Tandem scrapers have been largely replaced by single units of greater capac (2). They are especially adapted to cut-and-fill work on hauls of less than 2 000 ft.

Cableways (17) are suitable for large-scale work. Except where movable towers are used, irregular topography, swamps and bodies of water are no obstacles. They require no earthwork, no bridges, and their operation is unaffected by weather. On some recent gov't projects, single loads of 15 tons or more have been handled. For design and details of construction, see Sec 26.

5. TRENCHING AND DITCHING

Hand labor is still used for small-scale jobs. Cost depends on character of soil, number of boulders or other obstructions, presence of water, and depth and (somewhat) on the width of trench. In trenches over 4 ft deep, some soil must be shoveled twice: first, to surface; then, as spoil pile grows, back from edge of trench. In trenches 6–12 ft deep, soil must first be thrown to a staging about halfway up, thence to surface and finally, back from edge. For depths of 12–18 ft, the soil must be handled 4 times. Timbering of deep trenches slows up rate of work.

Trenching machine, resembling a very small chain-bucket dredge, can operate satisfactorily in narrow trenches, where soil is free from large stones; always leaving vert walls, and therefore applicable only to stable, dry soils (24).

Power shovels for trenching (with dipper, plunger, backhoe, or clamshell) are supported on timbers spanning the trench (Fig 6). As their wt comes directly on the banks, they can not be used in soft ground unless the walls are sheeted and braced. The shovel must usually be stopped while the trench is being sheeted, and the consequent delays materially decrease the output. Trenching machines, though not subject to this delay, cannot dig in such difficult soil as power shovels.

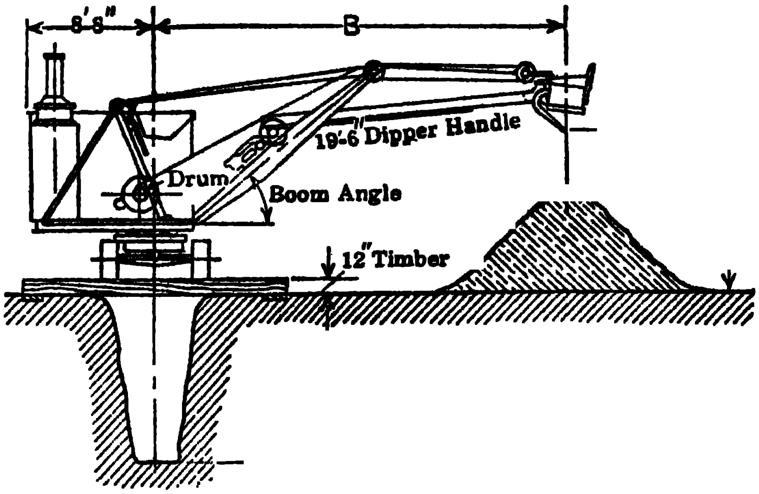

Fig 6. Trenching with Power Shovel

Dragline can dig trenches and ditches to depth of about 20 ft, and to any width greater than about 30 in; best adapted to wider work. Sloping banks are readily made, thus eliminating need of shoring and bracing. In soft, wet soils, as when the ground-water level is very near the surface, draglines can operate at about the same cost as in dryer ground. In wide ditching, it is far cheaper to use dragline and slope the banks, than to use trenching machine or clamshell, and shore the sides; added cost of moving a larger vol of earth to obviate need for shoring or bracing is negligible. Under bad soil conditions the dragline can deposit the spoil far enough from edge of trench to insure stability, which can not be done by trenching machine (24).

Trench sheeting. All deep trenches left open more than say a day should be sheeted. In fluid sands, cross bracing follows theory. In other soils, many practical shorers place heaviest braces near top rather than at bottom; for, if a wedge starts to slide from surface its center of thrust is $^1/_3$ depth below surface.

Cableways (Sec 26) can be used to advantage for trenches 6 ft and wider. A cableway on 30-ft towers, 300 to 400 ft apart, handling 1-cu yd tub at a time, is good in either soft digging or rock, as no part of the machine is carried on the side banks. Tubs can be loaded at any point and swung as much as 10 ft to the side. Engine and 1 tower stand on a car or rails; the other tower stands on the ground, and must be lowered for removal to a new position but can be readily shifted as work advances. Outfit, weighing about 19 tons, can be loaded on 1 R R car.

Backfilling is generally done by bulldozers or backhoes. Cost depends on: condition of soil (whether frozen, wet, packed, or dry); means employed; amount of tamping required. When back-filling and tamping are done by hand, work per man-hr is 1–3 cu yd, aver 1.5 cu yd; most compact tamping (clay excepted) is obtained by casting soil into water; for thorough dry tamping on large-scale work, use power tampers.

Ditching by explosives, if properly done, will excavate and spread the material over a distance, and is economical in dry or wet ground, or soil under water. The flow of water is depended upon to clean out the bottom. In stiff clay or hardpan, holes should be 26 in apart, in loose mucky soil, 30 in apart, and are punched or bored to within 6 in of desired depth of ditch. Strongly sodded soil is cut with a spade along side lines. For methods of charging and firing dynamite, see Sec 4, 5. Holes are best blasted simultaneously with a magneto; or placed 18 to 24 in apart and exploded by concussion from a middle hole, detonated by fuse and cap; 20% dynamite is ordinarily used, or 40% in stiff, tenacious soil. For soils soft at top, hard at bottom, use 40% dynamite in bottom of charge and 20% above.

6. STRIPPING (37–40)

For stripping and other opencut work economic methods are of utmost importance. More effective excavating machinery is now making opencut mining possible where underground methods only were formerly feasible.

Elevating grader for coal stripping in Kansas (33). Overburden, 16.5 ft aver depth, was removed in strips 60–75 ft wide, alternate strips 40 ft wide being temporarily left untouched. One side of cut was kept vert; the other sloped 1 : 2. Intervening strips were excavated after the coal first stripped was mined, and as much as possible of the material from them filled into adjoining excavations. Equipment: elevating grader and tractor, and 8 3-horse, 1.5-cu yd dump wagons. Crew: engineer, steersman for tractor, machine man, 8 drivers, dumpman, man and team for water wagon, and stableman. Duty: 750–800 cu yd per 9-hr day.

Stripping by draglines. In Florida phosphate mines (49), the booms were at first 136 ft long, with 8-yd buckets, using Diesel engines. Since 1920, boom length has been increased to 168 ft, with 10-yd buckets, electrically operated. In excavations about 210 ft wide, each machine handles 600 cu yd per hr; three 8-hr shifts, 3 men per shift. Hydraulic mining (Art 7) of the phosphate pebbles follows close behind draglines, so that, by hauling back to starting point, the draglines place material from second cut in mined out area of first cut. In Mich, 1914–15, 1 200 000 cu yd of overburden 60–100 ft deep, were stripped from an iron deposit. Two draglines loaded 206 000 cu yd into cars in 1 month (38). For data on large strippings in Penn anthracite district, see Bib (42) and Sec 10.

7. HYDRAULIC EXCAVATION

This method originated in California for excavating gold-bearing gravels. For HYDRAULIC MINING, piping, "giants" (monitors), and ground sluices, see Sec 10. Hydraulic methods are here considered only for moving material in ordinary excavation, as for hydraulic-fill dams, embankments, and grading (33).

Hydraulicking is essentially a loosening operation, attacking the material on a nearly vert face, with high-press hydraulic nozzles, and is obviously suitable only where earth is moved downgrade. Ample water supply, either gravity or pumped, is essential. Centrifugal pumps (Sec 40) are generally used. For gravity supply the head may be several hundred ft. A head of 80–100 ft may remove the material, but 200–600 ft heads are often needed for effic cutting. Quantity of water is determined by head, size of nozzle and rate of work. Water delivered by hydraulic giants is approx:

Diam of nozzle, in.................	1	3	6	9
Flow under 200-ft head, cu ft per min	33	250	1 500	2 700

One 8-in nozzle, using 3 600 cu ft per min, has excavated 800 cu yd per hr; but, a number of small nozzles are sometimes more effective than a single large one. Sluices for transporting mixture of water and earth usually require a grade of 4%. Proportion of solids that water will carry is from 6 to 20%; aver, 11–12% (Sec 10).

Stripping by sluicing and hydraulicking (35). Fig 7 shows layout for an ore deposit in Mesabi district, Minn. Overburden was sluiced into a nearby river so long as the difference in elevation permitted. Afterward, a hydraulic giant undercut the overburden, washing it through a rough sluiceway to sump, whence a centrifugal sand pump delivered it 1 000 ft through 12-in pipe to river (Fig 7). Giant was supplied by pumps of 3 500 gal per min rated capac, pumping through 1 500 ft of 12-in pipe. The centrifugal pump (capac 5 000 gal) required care to keep it at proper speed to deal with sump inflow. Overburden, of unconsolidated glacial drift, washed easily and work was done cheaply. In another case (35), from 3 to 6 ft of loam, sand and gravel were washed off a shale deposit by 2 giants, with normal water press of 115 lb. Crew: engineer, fireman, and 2 men on the giants. Aver duty, 2 000 cu yd per 10 hr. Cost, 2¢ per cu yd.

Hydraulic-fill dams. With enough water, a sufficiently high working face and grade to convey mixed earth and water, dams can be built more cheaply (and as well) by hydraulicking than by ordinary methods of embankment with rolling and tamping. Water is delivered by pump or gravity to a HYDRAULIC GIANT or MONITOR; press at nozzle, 75–300 lb per sq in; veloc, 100 to 200 ft per sec; vol 8–20 cu ft per sec. When water is scarce waste may be led to sump or clarifying basin, and used again. Soil, after being loosened by monitor, is carried by sluices to pipes or flumes and thence to dam. Bank from which earth is washed must be at higher elevation than crest of dam, grade to dam being at least 2% for fine materials, and 6 to 8% for coarse, heavy stuff. Design and construction of hydraulic-fill dams should be under expert supervision (52). There have been conspicuous failures.

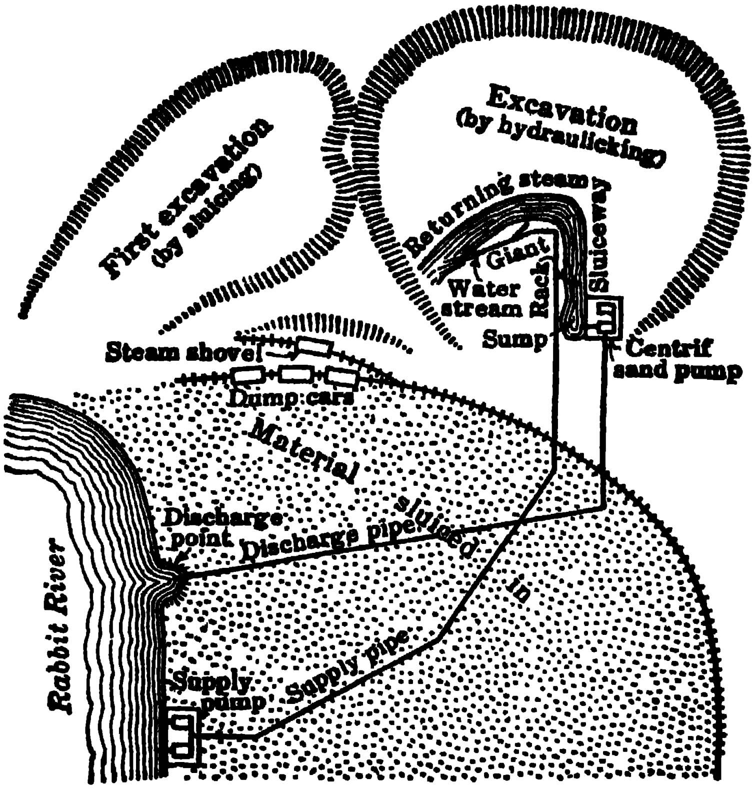

Fig 7. Layout for Hydraulic Stripping (35)

Northern Pacific R R embankment. A number of trestles were filled by the hydraulic method. In 8 cases, where there was a gravity supply of water, the cost was 4.79¢ per cu yd. In one case, pumping was necessary, making a cost of 13.5¢, which included clearing of dense forest growth.

8. DREDGING

Dredging is required to deepen waterways for navigation or flood control, and to procure sub-aqueous material for land filling and levees. It is done by a floating equipment, except on narrow channels, where draglines or walking dredges are used. Mud, silt and sand are easiest materials to excavate, but, if mingled with much water, repetition of work is sometimes needed; or, with disproportionately large quantities of water, subsequent separation may be troublesome. Sand, silt and gravels are easy to dredge; sticky clays will adhere to buckets, and may clog suction orifice or pipe line; indurated clays or hardpans may have to be blasted before dredging (17).

Depth and width of cut determine type of dredge. Distance of transport of dredged material is important, often requiring long pipe-lines, or use of scows and tugs. Sometimes material must be rehandled at an intermediate point. Permanence of work is a controlling factor. Isolated jobs may justify use of any available dredge that can do the work, even if poorly suited to it. But, in general, the plant should be closely adapted to work in hand, and have high operating effic (19).

Types of dredges: dipper; grapple or grab-bucket; ladder or bucket-elevator; hydraulic or suction. Those having bunkers or hoppers for carrying dredged material are "hopper dredges" (35).

Dipper dredge is essentially a power shovel mounted on a scow. There are 3 classes: for drainage and irrigation ditches; for deep water and harbor improvements; and for canal work. Ditching dredges are small, with narrow hulls and telescopic bank spuds; canal dredges have narrow hulls and side floats; deep-water dredges, for depths to 50 ft, are generally of large size, with spuds operated by independent engines. Wooden hulls are common, but steel hulls are now favored (Sec 10).

Grapple dredge is a floating derrick, with clamshell, orangepeel, or other type of grab bucket. It serves for very deep water or in confined places. The largest have 6-yd buckets, 225-ft booms and can dump 400 ft from digging point. Under suitable conditions they are very economical, requiring only a lever man, oiler and fireman per shift. Digging depth is limited only by length of wire rope on hoisting drums; but, in depth, the bucket may not settle and take its load at the exact place desired; the bottom is therefore usually very uneven. Grapple dredge is not good for hard material, unless previously broken. Clamshell bucket is most useful in soft ground, stiff mud, sand and gravel. Orangepeel buckets are adapted to dredging boulders and blasted rock (19).

Ladder dredge (widely used for gold placer mining, Sec 10), is good in sand and gravel, if not too fine; will handle indurated clays, shales, and even soft or broken rock and hard pan, when depth is too great for dipper dredge. It cuts its own flotation (19).

Hydraulic or suction dredge is a scow, carrying a centrifugal pump with a suction pipe reaching to the bottom to be excavated, and a discharge pipe to place of deposit. Usually powered by Diesel-elec engines, or straight Diesels. In all except the easiest materials, a revolving cutter at mouth of the suction pipe is required for loosening the soil. Special advantage of this dredge is its ability to convey excavated material long distances. It is largely used for sand, silt, mud and clay, in open water. Gravel and small stones may be dredged with aid of the revolving cutter, and a large dredge will handle stumps, loose rock and other debris. The discharge pipe is often supported on pontoons; flexible joints, with a small amount of movement at each, allow the dredge to move freely. Pipe lines 10 000 ft long have been used for embankment work. BOTTOM-DISCHARGE GATES are important for the land section of pipelines. The heavy material (coarse sand and stones) rolling along bottom of pipe, can be discharged through small gates without disturbing the main flow. This coarse stuff will stand at relatively steep slopes, forming dikes, behind which liquid filling is deposited (47).

Hydraulic dredging for a million-yd fill (42). 100 000 cu yd of sand per month pumped by 15-in centrifugal pump, to fill a 65-acre site to depth of 6-16 ft. Aver proportion of solids to water, 12.5%; max, 27%. Max length of discharge pipe, about 5 000 ft; no booster pump; total lift was close to dredge through a steeply-inclined section of pipe on trestle to point of discharge. This arrangement minimized formation of "plugs" in pipe line, and facilitated their removal; nearly all stoppages cleared in less than 40 min. Dredging for Chesapeake and Delaware Canal involved excavation of over 16 000 000 cu yd of earth (48). Deepest cut, about 95 ft, nearly all by suction dredges, with revolving cutter heads. Most of the spoil was lifted 80-95 ft.

9. EMBANKMENTS AND DAMS

(See Art 7 for hydraulic-fill dams)

Railroad embankments are generally made by filling from old trestles. A ditching machine, with 16-yd dump cars may be used for jobs to 5 000 cu yd; steam shovel for larger work. Shrinkage is usually 12% when fill is placed by wagons; to 15% when dumped from cars. Embankments are often compacted by wetting, harrowing, and rolling in thin layers. Unstable material beneath embankments may be removed by blasting, to hasten settlement (see du Pont Co's circular on this subject).

Embankment placed hydraulically (41). In 160 days, 821 000 cu yd of fine sand were placed by a suction dredge with cutting head, pumping through 24-in pipe. Pump, operated by two 500-hp elec motors, gave discharge veloc of 12-15 ft per sec; volume at times reached 1 000 cu yd per hr. Total runoff of sand from embankment was about 250 000 cu yd, adding 30% to vol handled. Length of discharge pipe was 4 000 ft, working from dredge alone; booster pump used for an additional 9 000 ft; an exceptionally long distance. Pipe carried on pontoons was No 7 gage, riveted, with slip joints; No 10 gage elsewhere.

Compacting earth-fill dams (14). For sand and silt, rolling is usually better than tamping. Best moisture content is just below saturation; layer thickness; 12 in; best rolling equipment, a heavy crawler tractor, followed by a "sheepsfoot" tamper (2), or a disk roller; 6-8 passes of the tractor over a layer produce desired density.

Vibrating machines, sometimes used, are expensive (*Eng News-Record*, July 23, 1936). For a recent (1937) Western dam, a central impervious core was built in 6-in layers, sprinkled to maintain moisture content at about 16%. Core compacted by 12 or more passes of "sheepsfoot" roller, giving a press of 250 lb per sq in.

Change in volume by compacting. On an earth dam, where a mixture of earth and gravel was hauled in wagons and sprinkled and rolled in 6-in layers, it was found that material weighing 116.5 lb per cu ft in its natural bank, weighed only 79.6 lb per cu ft as dumped loosely by wagons; that is, it swelled 46%; after consolidation by rolling in thin layers, it weighed 133 lb per cu ft, a shrinkage of 12%. An exception to the general proposition that earth can be compacted to less than its original volume is dry clay, particularly when taken from deep pits; it absorbs moisture from the air, and occupies more space in embankment than in its original bed (33).

EXPLOSIVES

1. CHEMISTRY OF EXPLOSIVES

Underlying principles. The power of an explosive to do work depends upon the facts: (*a*) that a small volume of explosive is capable, under certain conditions, of changing into a large volume of gas at high temperature, and (*b*) that this change takes place almost instantaneously, resulting in the development of great expansive force at the moment of detonation. In the case of black blasting powder, a mixture of sulphur, charcoal and sodium or potassium nitrate, the nitrate supplies oxygen for combustion of the sulphur and charcoal. The decomposition of black powder, once started, therefore proceeds without need of oxygen from the air. The case is somewhat different with nitroglycerin, a compound of carbon, hydrogen, and nitrogen, which is explosive in itself without requiring admixture with other substances. When detonated, it is decomposed into CO_2, nitrogen, and water, which at the high temperature of explosion occupies at atmospheric pressure about 1 000 times the volume of the original nitroglycerin.

Ingredients and their properties. The common ingredients of high explosives are given in Table 1. The term "explosive base" in column 3 covers, besides compounds explosive in themselves, certain compounds which are not explosive alone, but become so when sensitized by some such substance as nitroglycerin.

Note. Throughout this section, nitroglycerin will generally be designated by N G, and other ingredients of explosives by their chemical symbols.

Reactions. When carbon burns in presence of an excess of oxygen CO_2 is formed; if there be insufficient oxygen for complete combustion, CO also is formed. When carbon in lumps burns in air, combustion is slow; but if in form of dust the reaction is very rapid, and may result in explosion. The ingredients of black blasting powder (S, charcoal and niter) are finely ground, and thoroughly incorporated, to bring all parts of the combustibles into close contact with the oxidizing ingredient, thus favoring rapid and complete combustion.

When black powder explodes, the reaction is:

$20\,KNO_3 +$	$30\,C +$	$10\,S =$	$6\,K_2CO_3 +$	$K_2SO_4 +$	$3\,K_2S_3 +$	$14\,CO_2 +$	$10\,CO +$	$10\,N_2$
Potass nitrate	Charcoal	Sulphur	Potass carbonate	Potass sulphate	Potass trisulphide	Carbon dioxide	Carbon monoxide	Nitrogen
Solid	Solid	Solid	Solid	Solid	Solid	Gas	Gas	Gas

The explosion is accompanied by evolution of heat, which expands the gases to a very large volume, resulting in high pressure.

When nitroglycerin explodes, the reaction is:

$4\,C_3H_5(NO_3)_3 =$	$12\,CO_2 +$	$10\,H_2O +$	$6\,N_2 +$	O_2
N G	Carbon dioxide	Water	Nitrogen	Oxygen
Liquid	Gas	Vapor	Gas	Gas

The intense rapidity of this change is illustrated by the fact that, if a pipe 5 miles long were filled with N G, and a blasting cap were detonated at one end, the entire column would be converted into gas within about one second.

Dynamite consists essentially of a mixture of $NaNO_3$, wood meal, and N G. The $NaNO_3$ may be replaced by KNO_3, the wood meal by flour or sawdust, and even a portion of the N G by other organic compounds or by NH_4NO_3. The solid ingredients are not so finely divided as those of black powder, nor so thoroughly incorporated; hence, the mixture would not burn so rapidly except for the N G, the extremely rapid explosion of which so accelerates combustion of the other ingredients that the whole mixture explodes much faster than black powder. Taking a dynamite of the composition: N G, 40%; $NaNO_3$, 46%; wood meal, 14%; and assuming that wood meal has same ultimate composition as pure cellulose $(C_6H_{10}O_5)_x$, the reaction of explosion is:

$$2\,C_3H_5(NO_3)_3 + 6\,NaNO_3 + C_6H_{10}O_5 = 9\,CO_2 + 6\,N_2 + 10\,H_2O + 2\,O_2 + 3\,Na_2CO_3.$$

Table 1. Ingredients of High Explosives

Ingredient	Chem symbol	Function	Remarks
Nitroglycerin	$C_3H_5(NO_3)_3$	Explosive base	Liquid, highly explosive
Tetranitro-di-glycerin	$C_6H_{10}N_4O_{13}$	Explosive base	Viscous liquid, highly explosive, practically non-freezing
Ethylene glycol dinitrate	$C_2H_4(NO_3)_2$	Explosive base, and to reduce freezing point	Liquid, highly explosive, somewhat volatile, non-freezing
Nitrocellulose (guncotton)	$(C_6H_7(NO_3)_3O_2)_x$	Explosive base and gelatinizing agent	Solid, highly inflammable, and explosive when dry
Nitrostarch	$(C_6H_7(NO_3)_3O_2)_x$	Explosive base	White powder, highly inflammable and explosive when dry
Organic nitro-compounds		Explosive base, but used primarily to reduce freezing point	Some solid, others liquid; the higher nitro-compounds explosive, the lower non-explosive in themselves
Ammonium nitrate	NH_4NO_3	Explosive bases and oxygen carriers	Solid, difficultly explosive alone, very soluble in water
Potassium chlorate	$KClO_3$		Soluble in water, highly explosive when mixed with combustible matter
Potassium perchlorate	$KClO_4$		Difficultly soluble in water, highly explosive when mixed with combustible matter
Liquid oxygen		Highly volatile	Carbonaceous matter in contact becomes highly inflammable. Most sensitive when absorbed by lampblack
Sodium nitrate	$NaNO_3$	Oxygen carrier	Soluble in water, not explosive alone, deliquescent
Potassium nitrate	KNO_3	Oxygen carrier	Soluble in water, not explosive alone, not deliquescent
Wood pulp		Absorbent and combustible	Best combustible absorbent; in highest grades equal to kieselguhr in absorbent capacity
Wood meal		Absorbent and combustible	Fairly high absorbent capacity
Ground coal		Combustible	
Charcoal		Combustible	
Flour		Combustible	
Sulphur	S	Combustible	
Chalk	$CaCO_3$	Antacid	
Zinc oxide	ZnO	Antacid	
Kieselguhr	SiO_2	Absorbent	Has no value except as absorbent

Gaseous products of explosion. When explosives detonate, they usually form a mixture of solid, liquid, and gaseous products. The solid products may include sodium or potassium carbonate, sodium or potassium sulphate or sulphite, where sulphur is present in the explosive, and calcium carbonate, etc. Nearly all explosives, except black powder, form large quantities of water, becoming vapor at moment of detonation. Smoke consists of the solid products in a finely divided state. Gaseous products are of most importance to the miner, since they determine character of fumes after a blast, and provide the ruptive force. (For products of different explosives, see Sec 23, Mine Air.)

With the Bichel pressure gage (1) it is possible to detonate an explosive in a closed chamber, to withdraw a sample of the gases formed by the explosion, and to determine their composition. The gases produced by a 40% straight gelatin under these conditions have approximately the following composition, as determined experimentally: CO_2, 57%; N_2, 42%; O_2, 1%. Fumes given off by any explosive fired in a vacuum do not correspond with those fired under strong confinement. The material blasted may greatly change the character of fumes, either by entering into the reaction, or by exercising a cooling effect on the explosion. Presence of water or high humidity also may alter the fumes produced. The composition of the gases varies with different explosives. In some cases there is a small amount of free O_2, as in example cited above; in others, no free O_2 but varying amounts of CO and H_2. CO is poisonous, and serious or even fatal consequences may result from the use of explosives which produce large amounts of this gas in places where ventilation is poor. See Table 2.

Table 2. Fumes, Special Gelatin 60%

Tested in Bichel Bomb; no confinement other than bomb itself. Total gas = 5.35 cu ft per lb.

	By %	Cu ft per lb	Cu ft per 1 1/4″ × 8″ cartridge		By %	Cu ft per lb	Cu ft per 1 1/4″ × 8″ cartridge
CO_2	47.1%	2.52	1.23	CH_4	0.7%	0.04	0.02
CO	1.5	0.08	0.04	H_2S	1.2	trace	trace
O_2	nil	nil	nil	NO_2	nil	nil	nil
H_2	3.6	0.19	0.10	N_2	45.9	2.46	1.20
						5.35	2.62

Some states have passed regulations requiring makers of explosives to mark their containers according to the fume class, which refers to amount of poisonous gas (CO and H_2S) in cu ft per 1¼″ × 8″ cartridge, when tested according to standard procedure of U S Bur of Mines. Fume Class 1, less than 0.16 cu ft; Fume Class 2, 0.16 to 0.33 cu ft; Fume Class 3, 0.33 to 0.67 cu ft.

Fume Class 1 includes: Straight Gelatins, 20% to 60%; Ammonia Gelatins, 30% to 75%; Ammonia Semi-gelatins (less than 128 cartridges).

Fume Class 2 includes: Permissible gelatins and Semi-gelatins; Ammonia Dynamites, 15% to 60%; Low-density Ammonia Dynamites (not dipped); Class A Ammonia Permissibles; Straight Dynamites, 10% to 30%.

Fume Class 3 includes: Low-density Ammonia Dynamites (dipped); Class B Ammonia Permissibles.

Explosives complying with the requirements of Fume Class 1 may be used in underground workings free from combustible gases and/or combustible dust without specific application by the operator to the Industrial Accident Commission. The Commission also provides that the explosive: (1) has not deteriorated by prolonged or improper storage; (2) is properly charged and stemmed with non-combustible stemming; (3) does not have a burden so heavy that it will be liable to blow out; (4) is not overloaded; and (5) that the mine is properly ventilated.

Before blasting, men must be removed to a safe distance from the face, and shall not return until the poisonous gases have been cleared. Explosives complying with the requirements of Fume Classes 2 and 3 shall not be used underground unless the operator has made specific application to, and shown to the satisfaction of, Industrial Accident Commission that ventilation is adequate.

Character of fumes from an explosive is affected by conditions under which explosive is used. When dynamite BURNS instead of detonating the fumes are entirely different from those formed by detonation, and contain large amounts of oxides of nitrogen and CO, both poisonous. Burning of dynamite in a drill-hole may result from improper mode of charging; for example, if the fuse be passed through a cartridge, the dynamite may be ignited by side-spit of fire from fuse. Blown-out shots are apt to produce noxious fumes; well-tamped shots are least apt to yield them. When dynamite is so charged that maximum amount of useful work is done, the fumes are least harmful.

Ammonia gelatins, straight gelatins and semi-gelatins give the least vol of noxious fumes per lb of explosive. The ammonia dynamites are next in order and the straight dynamites are the worst All of these give off much worse fumes when fired unconfined than when tamped with adequate stemming.

2. HIGH EXPLOSIVES

General classification of explosives. There are two general classes: (*a*) the different types of black blasting powder, and (*b*) high explosives. Black powder is a mixture of combustible and oxidizing ingredients, no one of which is explosive alone; high explosives always contain an ingredient which is explosive in itself, at least when sensitized by proper means. Because of this difference in composition, high explosive detonates with much greater rapidity than black powder; hence, the great rending and shattering effect of high explosive, even when unconfined. It is a common idea that high explosives " shoot down," while black powder " shoots up." This fallacy arises from the fact that the slow black powder, when exploded unconfined on top of a rock or other object, does no damage to the rock, but dissipates into the air; while the quicker high explosive, under same conditions may break the rock beneath it, even without confinement other than that of the atmosphere. All explosives exert equal pressure in all directions.

Table 3. Classification of High Explosives

Principal types		Essential ingredients
1. Straight dynamite		Nitroglycerin, sodium nitrate, and wood pulp or other combustible material
2. Ammonia dynamite		Like 1, with addition of ammonium nitrate
3. Straight gelatin		Nitroglycerin, nitrocotton, sodium nitrate, and wood pulp or other combustible material
4. Ammonia gelatin		Like 3, with addition of ammonium nitrate
5. Blasting gelatin		Nitroglycerin and nitrocotton
6. Granulated dynamite		Sodium nitrate, sulphur, and coal, sensitised by nitroglycerin
7. Special explosives for coal mines	Gelatin permissibles. Used in very wet work, especially for "lifters" where coal is cut at roof	Similar to 3 and 4, containing ammonium chloride and sodium chloride to reduce the temp of detonation
	Ammonium nitrate class	High percentage of ammonium nitrate, with low percentages of nitroglycerin and wood pulp
8. Explosives not containing nitroglycerin	Ammonium nitrate class	Ammonium nitrate, with small amount of organic nitro-compounds
	Nitrostarch class	Nitrostarch, sodium nitrate, ammonium nitrate and combustible material
	Chlorate class	Potassium chlorate or perchlorate, with organic substances
9. Liquid-oxygen explosives		Liquid oxygen and finely divided carbon

Note. Low-freezing modifications of nearly all dynamites and gelatins are also on the market. They have same essential composition as the above, with additional ingredients which cause them to remain unfrozen for a long time at temp far below freezing point of other N G explosives.

Properties. The different types of high explosives (Table 3) vary widely in their properties. Some are exceedingly quick, others relatively slow, still others intermediate in quickness. They also vary in density, from the heavy gelatins to some of the coal-mine powders, which are very light. High explosives are graded according to their strength compared with straight dynamite, the only type in which the grade strength corresponds to actual percentage of nitroglycerin contained in the explosive. The other types make up their strength by use of nitro-substitution compounds, explosive salts and guncotton.

Straight dynamite containing only N G, $NaNO_3$, wood meal, and an antacid (Table 1), is taken as the standard for determining strengths of all types of dynamite. It is more or less pulpy, easily crumbled when wrapper is removed, obtainable in different strengths up to 60%, very quick, fairly waterproof, and the most sensitive of the dynamites. A 50-lb case contains 100 1¼ by 8-in sticks. Straight dynamites are suitable for work requiring strength and quickness, where water conditions are not too severe; not recommended where ventilation is poor. High explosives made from tetranitro-diglycerol have a freezing point of −35° F.

Ammonia dynamites have explosive base consisting of N G and NH_4NO_3. They are of same strengths as straight dynamites, but slightly slower and less sensitive; are not easily ignited by flame, and, hence, not liable to be lighted by side-spit of fuse. Because of the solubility of NH_4NO_3 in water, they require more care in wet work than straight dynamites.

Straight gelatins are distinguished by plasticity, high density, imperviousness to water, and comparative freedom of their explosion products from noxious fumes; good for wet work, or where ventilation is poor and where a " permissible explosive " is unnecessary. They contain guncotton dissolved in N G, making a jelly which coats the soluble ingredients, and imparts to latter its own characteristics.

Ammonia gelatins are somewhat similar to the straight gelatins in plasticity, density and fumes, but they do not stand water quite so well.

Blasting gelatin is a tough, elastic, jelly-like mass which, except for 1% of antacid, consists entirely of N G and nitro-cotton. It is the strongest and most water-resisting of all explosives.

When loaded to fill drill-hole completely it is excellent for hard rock, especially where large holes can not be drilled. Owing to its elasticity it is difficult to make it fill the holes completely; whence, a loss of efficiency. Best results are obtained if explosive is charged with wrappers on; it can then be pressed in to fill the hole, without so much tendency to spring back and leave unfilled spaces. When soft and plastic, blasting gelatin is no more dangerous than other explosives, but when frozen it should be handled very carefully. It is dangerous to break frozen sticks of blasting gelatin. Use of a proportion of ethylene glycol with the glycerin, nitrated, makes a satisfactory low-freezing Blasting Gelatin.

Granular dynamites are mixtures of $NaNO_3$ and combustible dope in form of hard grains, with a small percentage of N G. They are free running, especially the lowest grade, known as R R P, containing 5% N G, which is in grains nearly corresponding in size to FF blasting powder. R R P dynamite is usually packed in paraffined bags, containing 12 1/2 lb. Granular dynamites are slowest of all dynamites, approaching black powder more nearly than other high explosives; not well adapted for wet work, but resist water better than black powder; especially useful for stripping work in sprung holes and for loosening sand and earth.

Trinitrotoluene (TNT) is a brownish, yellow powder, the higher grades melting at about 80° C. It is chiefly used as a military explosive, occasionally as a freezing-point depressant in commercial explosives. TNT is about as strong as 50% Straight Dynamite, but, owing to very great oxygen deficiency, its explosion produces so much CO that it can not be used underground where ventilation is poor.

Picric acid has been used as an explosive. It acts somewhat like TNT, but is uncertain in its behavior and has the added disadvantage of staining everything with which it comes in contact a bright yellow. Neither TNT nor picric acid stands water very well.

Coal mining explosives. Permissible explosives, formerly called short-flame or safety explosives, should be used in mines containing dangerous amounts of inflammable gas or dust. They have been used in the U S since 1902, when 11 300 lb were sold. In 1913, 27 685 771 lb of permissibles were sold; in 1936, 47 859 019 lb; in 1943, 90 845 344 lb.

" Permissibles." At the Pittsburgh testing station of U S Bureau of Mines, coal-mining explosives are tested to determine whether they meet definite requirements for safety in " fiery " mines. Those which pass the prescribed physical and chemical tests are classed as "permissible" explosives (27), lists of which are published at intervals.

The tests include firing " blown-out " shots into explosive mixtures of gas and air, coal dust and air, or gas and dust with air, in a steel gallery. Explosives which do not cause ignition of such mixtures, and are also satisfactory as to chemical composition, stability, sensitiveness, and volume of poisonous gases evolved, are considered " permissible," when used under prescribed conditions. These explosives are recommended by U S Bureau of Mines for use in collieries, and in some states are required by law for dangerous mines. Bureau of Mines bulletins describe methods of testing, results, and fees for testing explosives (21, 27, 30, 43).

Classification of permissible explosives in the U S: (*a*) ammonium-nitrate explosives, containing NH_4NO_3 as chief ingredient, are insensitive to shock, free from liability to ignition from side-spit of fuse, and produce small amount of noxious fumes; (*b*) hydrated explosives (now obsolete), in which the desired reduction of temperature results chiefly from water of crystallization of salts included in their composition; (*c*) explosives of the organic-nitrate (other than N G class) include nitrostarch explosives; (*d*) nitroglycerin class comprises those containing N G which are not included in the other classes, and are now obsolete, the gelatin permissibles being far superior as to water resistance and freedom from fumes. In each class are explosives of widely varying properties, and the selection of a suitable " permissible " depends largely upon local conditions (24, 27, 43).

High explosives not containing N G usually contain no liquid ingredient which can freeze, a decided advantage in cold climates. They are usually lacking in plasticity, are often somewhat dusty, and have the disadvantages of low density, low strength, and low sensitiveness. They can not be used indiscriminately instead of N G explosives, but are useful for special purposes.

Low-freezing explosives, made from tetra-nitro-di-glycerin and ethylene glycol dinitrate, are similar in properties to other nitroglycerin explosives, but will resist freezing at temperatures considerably below the freezing point of nitroglycerin and may remain unfrozen for days or weeks at temperatures as low as −35° F. They are much superior to dynamites, having the freezing point lowered by the addition of nitro-aromatic compounds and have practically done away with the necessity of thawing explosives anywhere in the United States.

Liquid-oxygen explosives have not been successful in underground work in the U S, although used in the iron mines in Lorraine. They are also used extensively in coal stripping in the Middle West, where large blasts are made in the overburden. They are fired with electric blasting caps, or Primacord. Great care must be taken in their use, as the oxygen causes the grass or other combustible material around the operation to become extremely inflammable. Their principal advantage is cheapness; disadvantages are that they must be fired in a relatively short time after the cartridges of finely divided carbon, lamp black or gas black are dipped in the liquid oxygen, and strength of the cartridges is extremely variable. They are more sensitive to impact than any other commercial high explosive.

They are fired with either fuse or electric blasting cap, but care must be taken that the liquid oxygen does not run down the fuse, as it is liable to explode prematurely. They have been used with some success in very large cartridges in well drill-holes for quarrying, and in Lorraine, France, in the iron mines, largely owing to the fact that for a time they escaped the government tax on explosives (14, 15). Chlorate of potash or sodium with a liquid nitro-aromatic ("Rack-a-Rock") is still used in some parts of the world. It has to be prepared immediately before using and it becomes unstable with age.

Testing high explosives. While laboratory tests, however elaborate, can not entirely replace practical field tests, in determining relative value of different explosives for any particular work, they can aid in selection, if carried out with suitable apparatus and by competent persons. No single apparatus or test is sufficient, since the practical value of an explosive depends upon many factors. Some of the more important factors, determinable in a well-equipped laboratory, are: STRENGTH: determined in the ballistic mortar (5, 10) or in the Druckmesser. QUICKNESS, or velocity of detonation: determined by the Bichel (1) or the Dautriche method (10). STRENGTH AND QUICKNESS combined: determined by the Trausl lead block test (2). (Note. For a discussion of the Druckmesser, Trausl, and ballistic mortar tests, with comparison of results, see Rep Eighth International Cong Applied Chem, N Y, Vol 25, p 217) SAFETY in gaseous and dusty mines: determined by means of a testing gallery, as at the testing plant of the U S Bureau of Mines, Pittsburgh (63). OTHER FACTORS are: propagating power, density, resistance to water, resistance to freezing, stability, and sensitiveness to impact. Density of high explosives is generally expressed in number of 1 1/4 by 8-in cartridges per 50-lb case. Fig 1 and Table 4 show the relation.

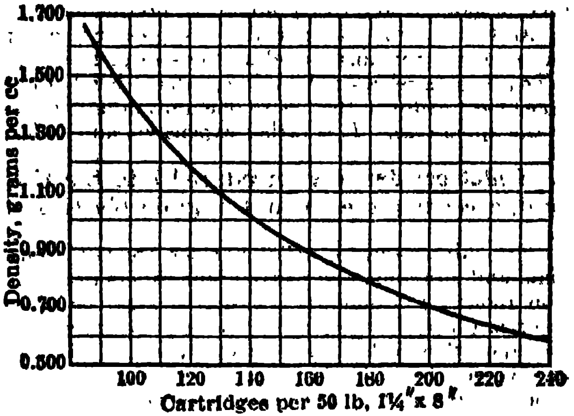

Fig 1. Stick Count of Cartridges vs Density

Table 4. Approximate Number Cartridges per 50-lb Case

Size of ctge, in	Straight dynamite	Ammonia dynamite	35% gelatin	60% gelatin	Semi-gelatin (high density)	Semi-gelatin (low density)
7/8 × 8	205	220	167	178	204	234
1 × 8	155	167	132	142	156	178
1 1/8 × 8	127	137	111	118	130	148
1 1/4 × 8	102	110	89	96	105	120
1 1/2 × 8	75	79	59	63	75	86
2 × 8	42	45	34	37	42	48

3. BLACK BLASTING POWDER

"A" blasting powder (saltpeter) is made from KNO_3, charcoal, and sulphur, in the approximate proportions of 75, 15, and 10. It is used mainly in quarrying, for blasting hard dimension stone, and for work in damp climates.

"B" blasting powder (soda) is made from $NaNO_3$, charcoal, and sulphur, in the approximate proportions of 72, 16, and 12. Because of its lower cost "B" powder is more commonly used than "A" powder, and is sufficiently strong for most of the purposes for which black powders are used. Owing to deliquescent property of soda niter, "B" powder is less desirable for use in damp climates, and for long transportation or storage.

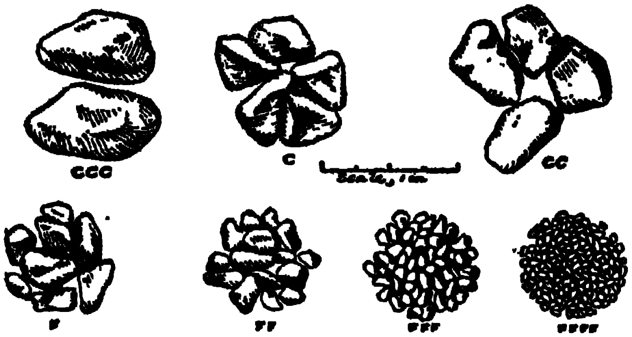

Fig 2. Standard Sizes of Black Powder Grains

Important properties. Black powder is not made in different strengths like dynamite, but varies in quickness, depending upon size of grain. Classes "A" and "B" are of different granulations. For "A" powder the common sizes are C, F, FF, and FFF; for "B" powder, CCC, CC, C, F, FF, FFF, FFFF. The CCC grains, representing largest size and rarely used, are about $^1/_2$ in diameter; FFFF grains, the smallest, are about $^1/_{16}$ in diameter. Fig 2 shows the sizes to scale.

The finer granulations are quicker than the coarser, and are used for blasting rock, coking coal, etc; the coarser granulations are slow and are used for other coals, shale and earthwork, or wherever it is desirable to heave out the material in large pieces, instead of shattering it (see Art 9). Blasting powder is either glazed (polished) or unglazed. Glazed powder is brighter, and more free-running than unglazed, and is more generally used. Glazing does not increase effic and produces more smoke. The sp gr of black powder varies from 1.5 to 1.9, usually about 1.8. High sp gr results from compressing the powder to smaller bulk, with consequent reduction of air-spaces in the grain. Black powder is unaffected by cold, but has little resistance to water, since niter is readily soluble.

Cardox depends for its action on rupture of the disk at one end of a steel cylinder, filled with liquid CO_2 and containing a heating agent somewhat similar to Thermite. This gasifies the liquid CO_2, breaks the disk and emits gas at end of the cylinder at bottom of the borehole. Cardox is used in gaseous and dusty mines for producing lump coal.

Airdox. Air from a portable compressor is pumped into a steel cylinder having a double-acting valve, which remains closed at the end of the cylinder as long as press is applied inside cylinder. When press is released the valve opens at head of cylinder, releasing the air. Airdox has the advantage over Cardox in that, with one unit, different pressures can be applied to the coal without change in the apparatus. It is rather expensive, and so far has had limited application.

Pellet powder was introduced into the U S in 1928, and in 1943, 26 607 900 lb were used, exceeding the amount of grain blasting powder by about one-third.

The advantages of pellet powder are numerous. Being made in cylinders of 1 $^1/_4$ to 2 $^1/_2$ in diam and 2 in long, and packed four pellets in a paper wrapper, each pellet having an axial perforation about $^3/_8$ in diam, it is easier to gage the amount of explosive needed for a certain shot than when grain powder is poured into a previously made paper tube. As the cartridges are protected by paper, there is less danger from sparks falling into the explosive, and the cartridges being packed in a wooden box, like dynamite, there is much less danger from handling, and the hazard of driving a pick into the steel keg of black powder is eliminated. Pellet powder can be used in somewhat wet holes, provided the charge is fired immediately after tamping. It is best fired by an electric squib, safety fuse or a miner's squib.

Composition of Explosives Listed in Table 5

"*Hi-Velocity*" *Blasting gelatin* is a modification of Blasting gelatin, by which the explosive reaches its maximum velocity at once, regardless of the water pressure under which it is used. Not suitable for close work underground.

Du Pont "*Extra*" has high ammonia content and low nitroglycerin, excellent fumes, but a very slow, heaving action; 135 to 170 cartridges, 1 $^1/_4$ in by 8 in, per 50-lb case.

"*Gelex*" *No 2* is a low density, high ammonia, semi-gelatin, having a cartridge count of about 120; is fairly plastic, sticks well in uppers, and is one of the best explosives for close work; also one of the most economical.

"*Red Cross*" *blasting* is a free running, granular high explosive, especially designed for sprung-holes, although successful in certain kinds of work where there is little moisture.

"*Gelobel C*" a permissible of the semi-gelatin type; resists water well and has good fumes. Much used for rock work in gaseous and dusty mines and for producing lump coal where hard-rock bands are encountered.

"*Monobel*" is a permissible made in 5 grades, designated by letters A, B, C, D and E, running from 135 to 205, 1 $^1/_4$ in by 8 in, cartridges per 50-lb case. They have much lower velocities than the Duobels, and with the latter comprise a series of permissibles adapted to every type of coal mining where the work is dry.

Table 5. Brands of Explosives and Uses to Which They Are Adapted

Class of work			Explosive recommended
Artesian wells			Hi-velocity 80% blasting gelatin
Boulders	Block-holes		Du Pont Extra D-H
	Mud-caps		Hi-velocity gelatin 40%
	Snake-holes		Gelatin 40–60%
Clay mining	Open-pit	Wet	Gelex 2
		Dry	Pellet powder Red Cross blasting
	Underground	Wet	Gelex 2
		Dry	Pellet powder
Coal mining	Non-gaseous		Pellet powder
	Gaseous	Wet	Gelobel C
		Dry	Monobel or Duobel Lump Coal C
Concrete and masonry			Red Cross 40%
Foundation excavations			Special gelatin 30–40%
Gullies			Red Cross blasting 2
Gypsum mining	Open-pit		Gelex 2
	Underground		Du Pont Extra E-1, G-1
Ice blasting			Gelatin 40%
Log jams			Straight 40–60%
Limestone mining	Hand-loaded		Du Pont Extra D-E
	Machine-loaded		Du Pont Extra C-1 to F-1
Open-pit mining	Sprung holes	Wet	Gelatin 30%
		Dry	Red Cross blasting
	Airhammer holes		Gelex 2
	Well-drill holes		Gelatin and Du Pont Extras
Ore mines			Gelex 1 and 2
Quarries	Coyote tunnels		Nitramon
	Block-holes		Du Pont Extra D-H
	Air-hammer holes	Sprung	Red Cross Blasting
		Not sprung	Du Pont Extra
	Well-drill holes		Nitramon
Salamanders			Blasting gelatin
Salt mining			LV Du Pont Extra
Scrapping old machy			Straight 40-60%
Shaft sinking			Du Pont gelatin 40–60%
Stripping	Well drills		Nitramon
	Hammer drills	Wet	Gelatin 40%
		Dry	Red Cross Extra
	Horizontal holes		Red Cross blasting 2-4
Springing			Straight 40–60%
Sprung-holes			Red Cross blasting 2-3-5
Submarine blasting			Hi-velocity gelatin Straight 60%
Tunneling and drifting			Gelatin, Du Pont or Special 40-60%

"*Duobel*" is the name of high-velocity permissibles, lettered from A to G and running from 135 cartridges, 1 1/4 in by 8 in, per 50-lb case for Duobel A, to 250 for Duobel G.

"*Lump Coal*" *C* is a new permissible having medium density and extremely low velocity. At present made only in cartridges 1 1/2 and 2 in diam. It runs 118, 1 1/2 in by 8 in, cartridges per 50-lb case.

"*Red Cross*" *Extra* dynamite is an ammonia dynamite of high density, averaging 102 to 106 cartridges, 1 1/4 in by 8 in, per 50-lb case. Strengths are from 15 to 60% and suited to a wide variety of work.

"*Special*" *gelatin* is an ammonia gelatin similar in most respects to du Pont gelatin, but not quite so water resisting and not adapted for very wet work, like submarine blasting. Its fumes are considered slightly better than straight du Pont gelatin; not quite so dense as the latter.

"*Seismograph Hi-Velocity*" and "*Seismogel*" are specially designed and packaged to meet the demands of seismic prospecting, for which see Sec 10-A, Art 4 and Tables XV–XIX.

Straight dynamite consists of N G, nitrate of soda, wood pulp and a small amount of chalk. It is the only explosive at present in which the grade corresponds to actual percentage of N G. Has very poor fumes and should not be used underground. Very quick in its action and especially adapted for propagation shooting of ditches.

Du Pont "Extras" D-1, E-1, F-1 and G-1 are of considerably lower velocity than the regular du Pont Extras, but in other respects are similar.

"*Nitramon*" is a new blasting agent, not of itself explosive; that is, it is so insensitive that it can not be detonated by a blasting cap or impact of a rifle bullet. Requires a special primer to explode it. It is put up in tin cans from 4 in to 8 in diam, and 21 in to 24 in long, the 21-in being the length of the 8-in diam can. Has been used very successfully in quarry work, well-drill holes and tunnels, and, when used with Primacord, is the safest blasting agent now known.

Blasting gelatin consists of N G and nitrocotton only, and is the strongest explosive known. Used where greatest strength is required, regardless of expense.

4. TRANSPORT OF EXPLOSIVES AND BLASTING SUPPLIES

Transport by rail. A shipper of explosives should be familiar with local ordinances, state and federal laws, and the regulations of the Interstate Commerce Commission. By Act of Congress, March 4, 1909, effective Jan 1, 1910, and as amended March 4, 1921, the Interstate Commerce Commission has power to regulate interstate transport of explosives. These regulations specify that explosives to be shipped by rail must pass certain tests for stability and sensitiveness, that containers shall stand specified tests for strength, and that cases and contents be packed in a prescribed way. Nearly all makers of explosives doing RR business pack their products to comply with the regulations. Copies of regulations are obtainable from Bureau of Explosives (17, 33).

Explosives which can not be shipped by rail include: 1. Liquid nitroglycerin. 2. Dynamite containing over 60% N G (except gelatins); see Table 2, No 3, 4, and 5. 3. Dynamite having an unsatisfactory absorbent, or showing signs of leakage of N G. 4. Nitro-cellulose in a dry condition, in quantities over 10 lb, in one outside package. 5. Dry fulminates in bulk.

The matter of forbidden explosives is of interest to the user mainly in connection with condition of his stock, in case of reshipment, then item 3 above becomes important. Dynamite stored for a great length of time, or under adverse temperature conditions, may exude N G, and become unfit for rail transport. With proper storage, reasonably rapid movement of stock, and care to use old stocks first, this condition should not arise. If necessary to ship by rail explosives not acceptable under Interstate Commerce Commission regulations, these explosives may be repacked only when authorized by Bureau of Explosives. No explosives in broken or damaged packages should be offered for rail shipment. The aforementioned Act of Congress makes it a criminal offense to ship explosives on common carriers carrying passengers for hire, or to offer for shipment any explosive under deceptive markings.

Explosives which must not be shipped together. The Bureau of Explosives publishes a chart showing the explosives and other inflammable articles which must not be shipped together. A specially important regulation is that blasting caps must not be shipped or stored with high explosives.

Condition of cars. R R cars in which explosives are shipped must be carefully inspected, and must comply with certain specifications. They must also be certified and placarded in uniform manner, as well as loaded and braced in a specified way.

Carload shipments. The Interstate Commerce Commission regulations permit shipment in one car of not more than 70 000 lb gross weight of explosives. The minimum quantity taken at carload prices varies with different railroads and in different parts of the country, ranging from 17 500 to 40 000 lb. Consignee must remove shipment of explosives from carriers' property within 48 hr after notice of arrival at destination; many railroads allow only 24 h.

Shipment by boat. Navigation laws must be complied with, also all local regulations as to authorized docks and quantities which may be unloaded. Regulations prohibiting transport of caps with dynamite apply whether the vessel is under Interstate Commerce Commission jurisdiction or not; but it is permissible on large vessels, in certain cases, to carry caps in special compartments, entirely separate from the cargo of high explosives and at safe distance therefrom.

Shipment by wagons or trucks. Special care should be taken that vehicles used for transport of explosives are in good condition and preferably provided with springs, free from excess grease and oil, and that any exposed metal on the inside of vehicle is protected, to prevent its coming in contact with the explosives. Never overload vehicles. Put no metal or metal tools in the bed or body of vehicle carrying explosives See that explosives transported in open-body vehicles are well covered, to protect them from sun and weather.

5. SHIPPING CONTAINERS

Black blasting powder for general use is shipped in kegs of two sizes, known as kegs and half-kegs, containing 25 and 12 1/2 lb of powder, or in 5-lb cans usually packed 20 in a box. Much of the black powder for anthracite coal fields is packed in paper cartridges or "skins," of 12 1/2 lb of powder. Two "skins" (25 lb of powder) are packed together in a long can. Approx gross weights of packages of black powder are:

25-lb keg with contents, 27 1/4 lb, 12 1/2-lb keg with contents, 12 3/4 lb, 20 5-lb cans, with contents and shipping box, 135 lb, 25-lb can, with contents in two cartridges, 29 lb.

High explosives are contained in cylindrical cartridges, about 8 in long by 7/8 to 2 in diameter. Cartridges are usually packed in wooden boxes or cases, 25 or 50 lb to the case.

Table 6. Distances for Magazines, American Practice (16)

Blasting and electric blasting caps		Other explosives		Inhabited buildings barricaded * (Feet)	Public railway, barricaded * (Feet)	Public highway, barricaded * (Feet)

		90 000	95 000	1 790	1 075	540
		95 000	100 000	1 815	1 090	545
		100 000	125 000	1 835	1 100	550

Note Distances for 125 000 to 225 000 lb from inhabited bldgs, 1 900–2 095 ft; from R Rs, 1 140–1 260 ft, from highways, 570–630 ft, The full schedule prescribes distances for quantities up to 500 000 lb

---

* Barricaded, as here used, signifies that the building containing explosives is screened from other buildings, railways, or from highways by either natural or artificial barriers *Where such barriers do not exist, the distances should be doubled.*

Character of cases, as to strength, thickness of wood and construction, is regulated by Interstate Commerce Commission. The number of cartridges of each size in a 50-lb case is fairly regular for any given kind of dynamite. (See Table 4.)

Approx wt per cu in: Gelatin (straight and Ammonia), 0.97 oz; Dynamite (straight, ammonia, and granulated), 0.85 oz; Colliery powders, 0.63 oz. (*Note.* There are some exceptions; also a few explosives, such as the low granulated dynamites, which are packed in 12 1/2-lb paper bags, 4 bags to a case.)

Blasting supplies. Caps are packed in tin boxes, containing 100 caps, and the boxes in wooden cases of 500, 1 000, 2 000, 3 000, or 5 000 caps. Electric caps and electric squibs are packed in cardboard boxes containing 25 or 50 each, and these are packed in wooden cases of from 250 to 500 caps or squibs. Safety fuse is in coils of two 50-ft lengths; shipped in wooden boxes containing from 1 000 to 6 000 ft.

6. STORAGE OF EXPLOSIVES AND BLASTING SUPPLIES

Explosives should be stored in well-ventilated buildings, erected for the purpose. Buildings for storage of black powder or blasting supplies should be fireproof; those for dynamite, both bullet-proof and fireproof.

Location of magazine. In selecting a magazine site the local topography should be considered, and advantage taken of such natural protection as is afforded by hills and areas of timber. The magazine should be far enough from adjacent buildings to minimize danger to life or property through an accidental explosion.

Table 6 gives distances depending upon quantity of explosives required, 1919, to be maintained between magazines and inhabited buildings, public railways, and public highways.

It is the result of an investigation of a committee appointed by the explosives manufacturers of the U S, and represents conclusions reached after prolonged study of available data. The Bureau of Explosives of American Railway Association has approved and applies the distances specified to be maintained between magazines and public railways. When there are specific state laws and local regulations, they must be complied with, but if there be none, the table of distances gives the accepted practice. Where explosives are distributed among several magazines the distances between magazines should comply with the following formula (distances given are for magazines fully protected from each other by natural or artificial barriers; lacking such protection, distance should be doubled). For magazines containing 25 000 lb or under, not less than 100 ft; for magazines containing over 25 000 lb, add 1 1/3 ft for each 1 000 lb of explosives added. When applying Table 6 for location, if *magazines are nearer* than the above distances, they should be *classed as one magazine* containing total quantity of explosives stored in all. Magazines containing blasting caps should never be nearer than 50 ft to any other magazine, and if quantity is over 20 000 caps, distance should be at least 100 ft.

Construction of magazines. Dimensions of magazine without aisles:

Capacity	Dimensions	Capacity	Dimensions
5 000 lb	8 ft × 8 ft	25 000 lb	12 ft × 12 ft
10 000	8 × 10	30 000	12 × 14
15 000	8 × 12	40 000	14 × 16
20 000	10 × 12	50 000	14 × 18

These capacities are based on sizes of dynamite cases (Art 5). If permissibles or the more bulky powders are stored, capacities will be somewhat reduced.

Magazines of these sizes are for temporary use, and should therefore be as small as possible for quantity of explosives stored. They are for consumers using explosives in 2 or 3 sizes or grades; dimensions are therefore minimum for given quantities, leaving floor space sufficient only for a man to enter magazine when filled to capacity.

Dimensions of magazine with aisle from front to back and cross aisle through center:

Capacity	Dimensions	Capacity	Dimensions
5 000 lb	8 ft × 9 ft	25 000 lb	12 ft × 18 ft
10 000	10 × 12	30 000	12 × 20
15 000	12 × 12	40 000	14 × 22
20 000	12 × 16	50 000	14 × 24

In constructing a magazine consideration should be given to permanency of storage, variety of explosives, quantities in which shipments to magazine will be made, and ease of replenishing stock from distributing magazines.

Construction specifications. Stone and concrete magazines are undesirable, because of danger from missiles in case of accident. Brick or sand-filled magazines may be used for dynamite, black powder, or blasting caps. Wood and iron magazines without sand filling are suitable for black powder; other types may be used, but this is the most inexpensive construction; it is not recommended for dynamite, because it is not bullet-proof. The nature and thickness of walls varies with the kind of small arms in general use in region where magazine is situated. Tests show that it requires 10 in of sand, between walls of 1-in boards, to stop the bullet from a U S Govt Springfield rifle. Where ordinary sporting rifles, such as 30-30 Winchester, are used, 8 in of sand is sufficient. A 9-in brick wall is bullet-proof against the strongest small arms in use in U S. In the case of doors it is found that $^3/_8$-in boilerplate, backed with 8 thickness of $^7/_8$-in hardwood, will stop the bullet from a U S Springfield rifle. This combination of iron and wood seems to be the most practicable, as any increase in thickness of either the wood or iron, with corresponding reduction of the other, adds materially to weight of the door.

Fig 3. Brick Dynamite Magazine

Magazines of various widths may be designed along lines indicated below, size and spacing of material being revised accordingly.

(a) Dynamite magazine of brick. Fig 3 shows a brick dynamite magazine 12 ft wide and of any desired length consistent with this width.

Foundations may be of brick, stone, or concrete. They should reach below frost line, or to a good bearing material.

Walls are 9 in thick, laid in cement mortar. Use as soft a brick as possible, consistent with good quality and durability.

Bullet-proof roof consists of ceiling-joists, floored as shown. A box is formed above this flooring by a 6-in strip around walls, the box being filled with 4 to 6 in of sand. Bullet-proof roof construction also helps to maintain a uniform temperature.

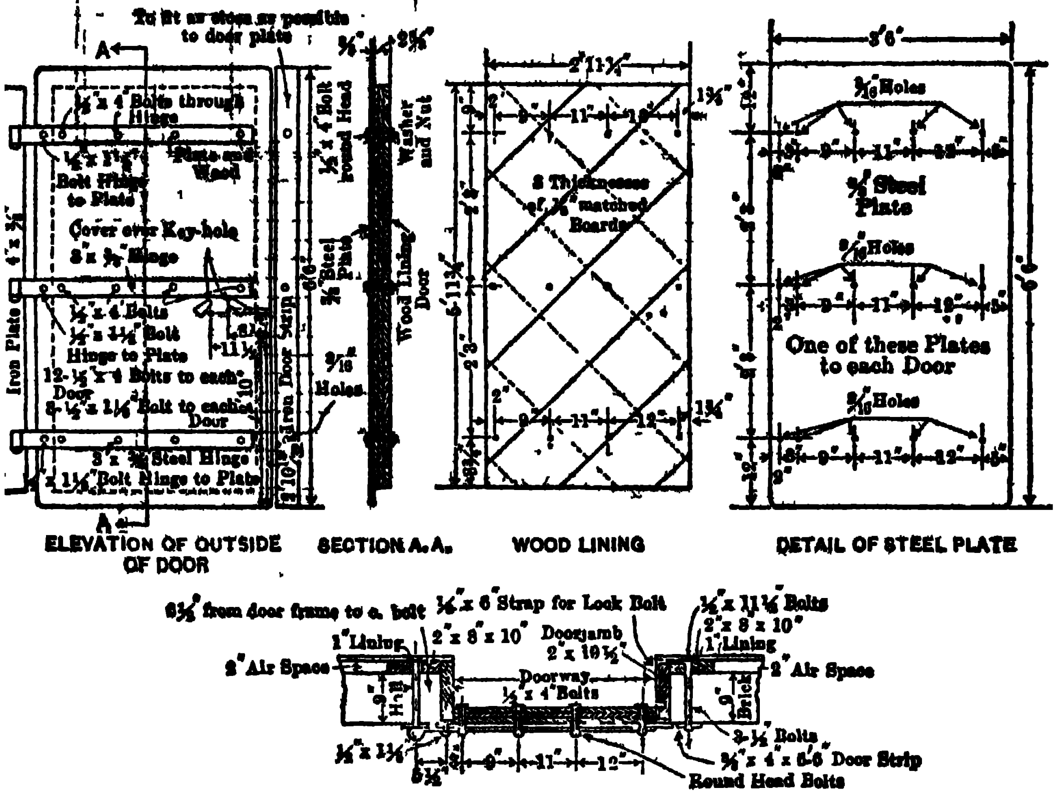

Fig 4 Bullet-proof Door for Magazine shown in Fig 3

Roof Rafters covered with rough boards or ship-lap, and then with No 24 corrugated galvanised iron The iron should have side lap of not less than two corrugations, and end lap of not less than 6 in Tin roof may be used, but is more expensive

Lining Brick walls are lined with 2 by 2-in nailing strips, covered with 1 by 6-in boards, forming a lattice work. Nails should be countersunk. The purpose of lining is to keep stock away from walls and assist ventilation.

Cornice Merely a strip of No 24 flat galvanised iron, bent and fastened over ends of rafters. All iron should be put on with galvanised nails and lead washers

Floors 1 3/8-in matched flooring, or a sub-floor of 7/8 in, covered with 7/8-in matched flooring. Note that floor stops 2 in from brick wall, to provide ventilation from under floor.

Ventilation. Foundation is ventilated as shown in Fig 3. Roof vents should be Star or Globe ventilators, or equivalent, size and number depending on climate, and size of building.

Doors. Fig 4 shows details of door for magazine shown in Fig 3

(b) Wooden dynamite magazine, covered with iron and sand-filled (Fig 5).

Foundation may be of posts, brick, stone, or concrete, as best suited to local conditions.

Walls are of two rows of 2 by 4-in studs, spaced as shown, desired quantity of sand determining spacing of studs across wall. Studs are held parallel by nailers at top, bottom, and intermediate, in number sufficient to prevent spreading under weight of sand. Studs are covered outside and inside by 7/8-in matched boards, to prevent sand from leaking away Space between is filled with coarse sand (never use coarse gravel or broken stone because of possibility of their becoming missiles). Lower foot of filling to consist of a weak mixture of sand and cement, to prevent remainder of sand from leaking away. Outer sheathing is covered with No 24 flat galvanised iron For other details, the specifications for brick magazine apply. When post foundations are used the board apron should be ventilated by holes, 8 by 4 in, covered with punched sheet steel.

(c) Black blasting powder magazine. Fig 6 shows a wood and iron magazine for black powder or blasting supplies.

Walls. Of 2 by 4-in or 2 by 6-in studding, covered on outside with 7/8-in boards and No 24 flat galvanised iron; on inside, by 1 by 6-in lattice work.

Roof, cornice and floors (see specifications for brick magazine).

Foundation and ventilation (see specifications for sand-filled magazine).

Door. Standard door for this type magazine consists of two thicknesses of 7/8-in boards, covered with iron of any desired weight, No 22 being considered the lightest for security. Either a mortise lock or padlock may be used.

(d) **Iron storage magazine.** A "knock-down" iron magazine is manufactured, which is satisfactory for northern or temperate climates. Obtainable in sizes from 6 by 8 ft to 15 by 30 ft.

Fig 5. Wooden Dynamite Magazine

When used for dynamite storage, it should be made bullet-proof by lining with 3 or 4 in of hard wood, or with studs and sheathing, sand-filled, or with brick.

(e) **Small portable magazine,** for storage of small quantities of explosives within mine or quarry, or at stores, or within city limits. A box may be made of 2-in oak, or other hard wood and covered with sheet iron. For dynamite, iron should be at least 1/16 in thick. Top of box, of like material, should be on hinges. Inside metal should be countersunk. Box should be kept locked and marked to indicate contents.

Care of stock in magazines. Magazines should be so constructed and located that they will not be brought to high temperatures by rays of sun. N G becomes less viscous at high temperatures, which may cause the dynamite to leak. In hot climates metal magazines should be protected by double roof and sides, with good ventilation between,

Fig 6. Black Powder Magazine

so that temperature in magazine will not rise above outside temperature. Dynamites containing large proportions of nitrate of ammonia, such as the ammonia permissibles, are liable to become set, so that, when subjected to high temp, they are difficult or impossible to prime. Painting roofs and sides of iron magazines with aluminum paint reduces the temp when magazine is exposed to sun's rays. Take care to keep dynamite dry, especially the ammonia dynamites, as they contain hygroscopic salts, and in humid climates may eventually attract enough moisture to impair their sensitiveness and strength. When dynamite is shipped in winter at very low temperatures, it should not be sent down immediately into the mine, as cold dynamite may condense enough moisture in the warm humid mine to impair its efficiency. Magazines should always be in charge of one person, responsible for condition of magazine and stocks, and their proper and safe handling.

Rules for dynamite and powder magazines.

Explosives must be handled carefully.

Do not throw down boxes of explosives violently, nor drag them along the floor.

Do not open boxes of dynamite or powder kegs in or near magazine.

Do not have in or about the magazine loose cartridges, open boxes of dynamite, or loose powder.

Do not make up primers in the magazine.

Do not smoke, have matches, oil-burning lamps or lanterns, fire-arms or cartridges in, or near, magazine. If artificial light be needed, use electric flashlight or electric lantern.

Do not store blasting caps nor electric blasting caps in this magazine.

Store dynamite and black powder separately. Store dynamite boxes flat, top side up, grades and brands showing; store powder kegs on sides with seams down, or on ends, bungs down.

Powder kegs should be rolled over and contents shaken every 2 or 3 months.

Always use old stocks first.

Keep magazine floor clean.

Keep the ground immediately around magazine clear of leaves, grass, trees, stumps, and débris, to prevent fire from reaching it.

Do not allow any shooting in neighborhood of magazine.

Keep the door locked. No unauthorized person should be admitted to magazine.

Do not keep any steel, or metallic tools or other implements, in the magazine.

See that good ventilation is maintained during all seasons of year.

When repairs have to be made to interior of magazine, all stocks of explosives should be removed to safe distance and carefully protected from weather during progress of repairs. Before starting repairs in a black-powder magazine scrub floor with water. If dynamite has been stored in a magazine, any stains on floor should be carefully scrubbed with solution consisting of: $1/2$ gal water, 1 gal denatured alcohol, $1/4$ gal acetone, 1 lb sodium sulphide (fused) or potassium sulphide.

Rules for blasting-supply magazines.

Store blasting supplies only in this magazine, i e, blasting caps, electric blasting caps, and fuse.

Do not store powder or dynamite in this magazine.

Do not have loose blasting caps, electric blasting caps, nor coils of fuse lying around magazine, nor take them out of original packages until required for use. Keep packages closed.

Open boxes with a wooden mallet, except when lids are screwed on; then use a screw driver. Do not keep any other metallic tools in magazine.

7. HANDLING OF EXPLOSIVES AND BLASTING SUPPLIES

The Interstate Commerce Commission in matters of transportation, and the majority of states in framing their laws, recognize that explosives are a commercial necessity, and furthermore that they can be handled with reasonable safety. Nevertheless, one must always recognize their nature; their function is to explode. All owners of explosives should require employes to observe rigidly the rules and regulations which experience has shown will best conserve safety of the men themselves, as well as of the public.

From cars or boats to magazine. Use only wooden or non-sparking metal tools in breaking the bracing in cars. Wooden wedges and mallets answer all practical purposes. Damaged or broken cases or kegs found in shipment should be set aside, and not taken to magazine with undamaged stock. If damage is slight, the cases or kegs should be taken to a safe distance from magazine, or from car, and repaired. If damage is too great for repair, take explosives to point of consumption and use immediately. If broken cartridges or loose grains of powder are scattered in the car, they should be carefully swept up and removed before proceeding with unloading, and afterwards destroyed. If there is a railroad siding to magazine, and runways and trucks are used, there should be no exposed metal on runways, and trucks should be rubber-tired. If an inclined chute is used, make of 1-in planed boards, with 4-in side guards throughout its length, fastened with brass screws. D-shaped strips or runners, not more than 6 in apart and running lengthwise of chute, should be fastened by wooden pegs to upper surface of bottom board. When dynamite packages are being handled, wipe down chutes with waste moistened with machine oil. A mattress, 4 by 6 ft, and not less than 4 in thick, or a heavy jute or hemp mat of like dimensions, should be placed under discharge end of chute. Chute must not be so steep that packages slide too rapidly. With a long chute, station men at frequent intervals along it, to check speed of packages and prevent bumping

together. Do not rehandle or switch the car to other points after the bracing has been removed; in case part of shipment is to go to another point, the part remaining in car should be rebraced (according to Interstate Commerce Commission regulations) before car is offered for shipment. The load on any vehicle should be braced. Always protect explosives from weather.

Within mine or quarry. Same rules and regulations should be adopted as apply around magazines and elsewhere above ground. Never bring exposed lights close to explosives. Only the smallest possible quantity for economic handling or operation should be taken underground at one time. In transporting into the mine by cage or tram-car, only the man in charge should be permitted to ride in same cage or car with explosives. Primers should be made up at a point entirely separated from regular stock of dynamite. If made up above ground, they should be taken into mine at a separate time and in separate car from other explosives. In opening dynamite cases, use no metal tools other than those made of non-sparking materials; wooden wedges and mallets are best. Blasting-powder kegs should be opened by turning back the four clips at the bung and lifting the cap and paper washer with the fingers. Never drive a hole in a powder keg even with a wooden pin. The rather common practice of driving a pick or other tool through the keg is dangerous. If possible, avoid leaving dynamite or powder in mine over night. If this can not be avoided, the explosive should be left in a place set aside for that purpose, protected from dampness, and posted so that all persons will know nature of material stored.

Thawing frozen dynamite. Practically all high explosives now made in the U S are formulated on the low-freezing or non-freezing basis, so that thawing dynamite, with its attendant hazards and expense, has ceased to be a factor.

Disposition of damaged explosives. Dynamite to be destroyed should be removed from magazine in quantities not exceeding 100 lb, to a safe place 400 to 500 ft distant from any magazine, and 1 000 ft or more from any dwelling, building, public road, or railroad; where, in event of its exploding while burning, no damage will be done. Lids of boxes should be carefully removed with wooden wedge and mallet, each cartridge slit, and the opened cartridges spread upon the ground over as large a space as practicable. To insure proper burning of the dynamite, spread a quantity of straw, paper shavings, or excelsior on ground first, on which dynamite is placed. A chain of straw paper, or other material, is then led away from the dynamite to such a distance that it may be lighted without danger of flame reaching the dynamite before operator reaches a position of safety, which should be 400 or 500 ft distant. Explosions sometimes occur, even with care, and operator should never remain near the burning explosive. Black powder may be destroyed by pouring it into a stream or large body of water; the greater part quickly dissolves and remainder becomes harmless. Cases which have contained dynamite are dangerous; they should not be used again for any purpose, but should be burned, using same precautions as described above for destroying damaged dynamite.

To destroy damaged blasting caps, place them, not more than 100 at a time, in a paper bag containing a small dynamite cartridge, with a good electric blasting cap in the middle, or in contact with the damaged caps; put the bag in a hole in the ground, cover it with sand, and fire with a blasting machine from a distance not less than 200 ft. Fuse and cap can be used with care when the bag and damaged caps are completely covered. If it is impossible to dig a hole, the caps may be drowned in deep water, but not in rivers, ponds or creeks. Before being destroyed, electric blasting caps should have their wires cut off an inch or two from capsule, as the wires are liable to cushion the shock and prevent complete explosion of all the caps. Observe utmost caution in handling blasting caps, as they are extremely sensitive to shock, friction, heat, and sparks.

Precautionary Rules:

Don't forget the nature of explosives; but remember that with proper care they can be handled with comparative safety.

Don't smoke while handling explosives, and don't handle them near an open flame.

Don't leave explosives in a field where cattle can get at them. Cattle like taste of soda and saltpeter in explosives, but the other ingredients may make them sick or kill them.

Don't carry loose caps in the clothing. Keep them in their boxes.

Don't tap or attempt to open a blasting cap or electric blasting cap.

Don't try to withdraw wires from an electric blasting cap.

Don't attempt to take caps from the box by inserting a wire, nail, or other sharp metallic instrument.

Don't store or transport blasting caps or electric blasting caps with high explosives.

Don't store fuse in a hot place, as this may dry it out so that uncoiling will break it.

Don't allow priming (the placing of the detonator in dynamite) to be done in thawing-house or magazine.

Don't leave explosives, caps, or blasting machines in a wet or damp place. Keep in a suitable, dry place, under lock and key, and where children or irresponsible persons can not get at them.

Don't use frozen or chilled explosives; it is dangerous and wasteful.

Don't thaw dynamite on heated stoves, rocks, sand, bricks, or metal, nor in an oven; don't thaw dynamite in front of, near, or over, a steam boiler, forge, or fire of any kind.

Don't heat thawing-house with pipes containing steam under pressure; high temperature is dangerous and escaping steam may spoil the explosive.

Don't place a hot-water thawer over a fire; never put dynamite into hot water, nor allow it to come in contact with steam.

8. CHARGING AND FIRING EXPLOSIVES (See also Sec 5, 6)

Priming is the placing of a detonator, electric blasting cap or blasting cap attached to fuse, in a dynamite cartridge, or placing an electric squib in a cartridge of blasting powder or pellet powder. For high explosives, place detonator so that its closed end points toward bulk of the explosive. For rotation shots it is advisable to put primer at or near bottom of hole, with the detonator pointing toward the collar, to prevent the primer from being thrown out in case the collar of the hole is cut off by a previously fired shot. If primer is inserted last, place the detonator so that its closed end points toward bottom of hole.

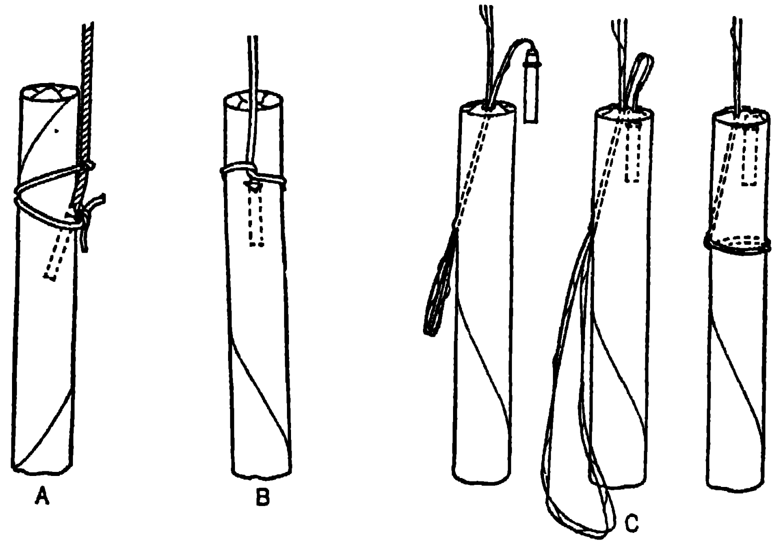

Fig 7. Methods for Priming Dynamite. A and C are recommended; B, often used

Fig 7 shows methods for priming dynamite, (A) with cap and fuse, (B) with electric blasting cap, in cartridges of 1 $^1/_8$ in diam or less, (C) with electric cap, in cartridges of 1 $^1/_4$ in diam or more.

The detonator should be so secured that it will not change its position, nor jam against sides of hole, nor come in contact with tamping stick. In priming dynamite with cap and fuse, the fuse should never be " laced " or run through the cartridge, because " side-spit " of fuse will often ignite dynamite, a part of which will burn, decreasing efficiency of charge and producing noxious fumes. Top of cap should be imbedded $^1/_2$ in deep in the dynamite, to cushion it from tamping stick. This small length of fuse will not side-spit before cap explodes.

Charging. Eliminate all air spaces by slitting cartridges lengthwise with a sharp knife and pressing them firmly home, so that they expand and entirely fill the hole. Exceptions to this are: (*a*) Blasting gelatin should not be slit, as it is so elastic that it can not be rammed solidly like other dynamites; (*b*) in certain veins of coal an air space is purposely left to cushion action of explosive and so prevent undue shattering.

There are 4 methods of "cushion" blasting (Fig 8): (*a*) leaving an air space of 4 to 6 in or more at bottom of hole; (*b*) using cartridges of much smaller diam than the hole and not expanding them; (*c*) leaving a spacer at the end of the cartridge and tamping up solid to the spacer; (*d*) putting in the first and second dummy of tamping very lightly, or using rock dust for the first dummy.

Tamping is required in practically all work except springing a hole (see below). The word "tamping" is now used to designate the act of compacting the explosive or the stemming in the drill holes, while "stemming" designates the material used for confining the explosive. Stemming is necessary for all explosives to develop their full power, to minimize amount of poisonous gases evolved, and to do the work at least cost. The only possible excuse for not using stemming is if misfires are expected, and these can generally be avoided by careful priming. It is easy to insert another primer and explode the missed charge if no stemming is used. Clay, sand, and loam make best stemming. Broken rock, screenings, and ore dust serve fairly well, but are liable to break or cut the fuse or wires.

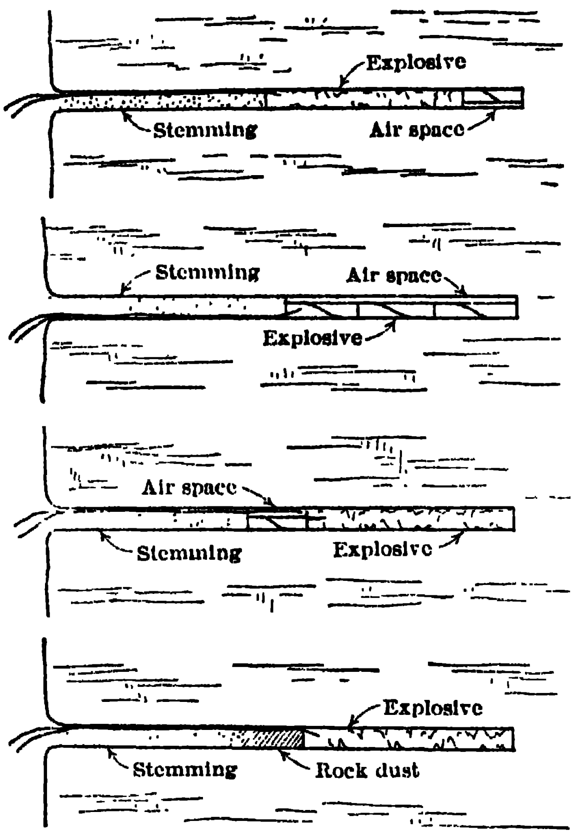

Fig 8. Modes of Charging for "Cushion" Blasting

Tamping is sometimes slighted in charging high explosives. But it should not be neglected, it produces better confinement of the charge, and the stronger the confinement, the completer the reaction, the more effective the explosion, and the more nearly do the gases approach the chemist's ideal of consisting only. of CO_2, N and steam. Whenever bad fumes appear, look to the tamping and make sure that it is adequate.

Sprung holes. A drill-hole may be "straight" or "sprung." A straight hole is one which is loaded and fired without enlarging. A sprung hole is enlarged at the bottom by exploding in it one, two, or more, successive charges. These charges are usually not tamped (stemmed). The first charge usually consists of 1 or 2 cartridges, increased in subsequent charges until the chamber is large enough to hold the required quantity of explosive. This operation is known as "springing," "chambering," or "squibbing."

Springing is done to concentrate a large amount of explosive in the bottom of the hole, thereby saving cost of drilling a number of holes. Sufficient time should elapse between successive springings to allow hole to cool completely; there is great danger in charging a freshly sprung hole. Except in soft rocks, quick-acting dynamites are better for springing than the slow-acting, as more of the rock is thrown out of the hole and there is less liability to cave and choke up. If sides of hole are very rough, final charge may be loaded through a tube of brass, tin, or galvanized iron, about 2 ft longer than the hole and as large as will fit into it. This prevents cartridges from being caught on or smeared along sides of hole. Where a loading tube is not available, the cartridges are usually attached to a sharpened stick, lowered to bottom of hole and shaken off. *Never spring* a hole adjacent to a loaded one.

Wiring for electric blasting. There are three general methods: series, parallel, and parallel series connection.

In series connection (Fig 9) one of the wires from first drill-hole is connected to the leading or firing line. The other wire is then connected to one of the wires from second hole and the other wire of that to one of the wires of third hole, and so on to the last hole; the remaining free wire from that is connected to the leading or firing line. Series connection is necessary when firing with ordinary blasting machine. The current required for series connection is at least 1.5 amperes, and the voltage sufficient to overcome resistance of electric caps. Resistance varies with length of wires. About one volt is required for each cap connected in series, although an excess, up to about 440 volts, is not harmful. Too high voltage may cause misfires from short circuits across the cap wires, especially when more than one cap is used in a hole. Direct current is generally used but alternating current is equally efficient when of a frequency of 60 cycles or more, and can be used down to 25 cycles. Alternating currents of lower frequency may cause trouble from misfires of the less sensitive caps in the circuit.

In parallel wiring (Fig 10) one wire from each cap is connected to one leading line, and the second cap wire to the other leading line. This method can be used only where a power or lighting current is available, having 1.5 amperes for each cap so connected. Thus, with 20 caps, firing circuit must have at least 30 amperes. The voltage required is very low. The greater the number of caps in circuit, the lower the resistance. Assuming resistance of leading wire at 3 ohms and resistance of each cap at 1 ohm, the resistance of 20 caps in parallel is (1 ÷ 20) + 3 ohms or 3.05 ohms. Parallel connections of ordinary electric caps are not often used on account of large volume of current required.

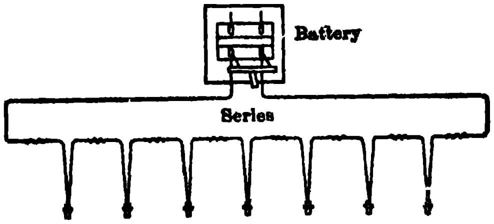

Fig 9. Series Wiring

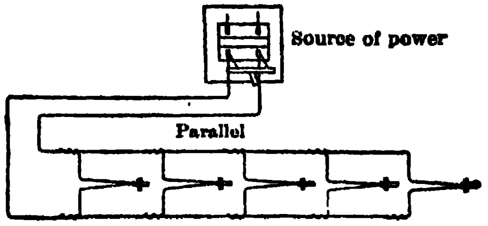

Fig 10. Parallel Wiring

In parallel-series wiring (Fig 11) the caps are first connected in series of say from 4 to 10, and each series thus connected is in turn attached at its two free ends to the leading wires. The current required is found by multiplying the number of series by 1.5, which gives the current in amperes. To determine required voltage, multiply resistance of each cap by number of caps in each series, and divide that by total number of series. This system is used frequently for firing a large number of charges, where power or lighting current is available.

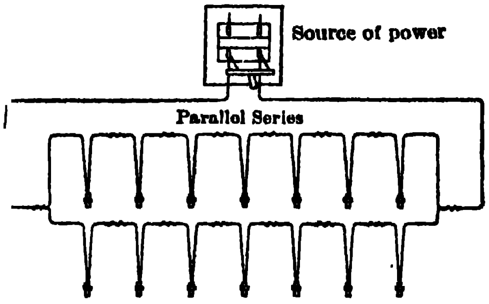

Fig 11. Parallel-series Wiring

Electric firing may be done with a blasting machine, or a power or lighting circuit. It is generally best and simplest to use a blasting machine, with the caps connected in series; but with modern, shunt-wound machines, having a capacity of 50 caps, parallel series connections have been used successfully, provided not more than four series, with 50 caps in each are connected to the machine. Ends of wires should be scraped bright and clean and twisted tightly together, and, if much water be present, covered with insulating tape. The two remaining free wires from the two caps at ends of series are then connected to the leading wires, which should be bent or hooked at end, to prevent the smaller wire from slipping if leading wires are subjected to strain. Test circuit with a blasting galvanometer at ends of leading wires which are to be attached to battery (Fig. 12). This is to be sure there are no broken connections or short circuits. Poor contacts and connections give abnormally *high resistance* readings. Looped connections of wires may show *no circuit* one moment and *normal resistance* the next. When spliced wires touch each other and make a short circuit, *no resistance* is shown (Fig. 13). The ends of leading wires are inserted into the binding posts of blasting machine and firmly secured by

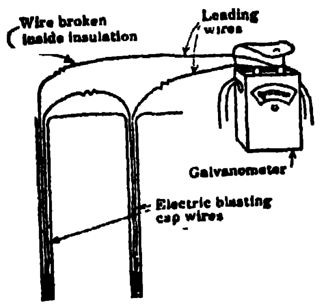

Fig 12. Testing Circuit with Galvanometer

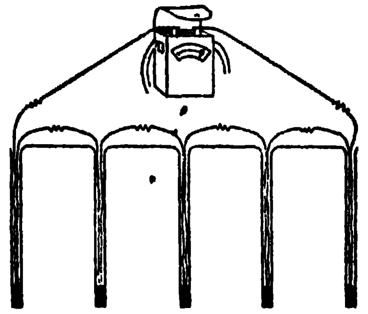

Fig 13. Detecting Poor Contacts in Electric Circuit

thumb nuts. Place blasting machine on a level spot (a dry board or plank is best), to prevent its tipping over, and operate handle with both hands and full force.

If firing is by means of a power or lighting circuit, use a special switch of such design as to show at a glance whether circuit is open or closed. Avoid complicated switches, especially those having springs. The switch should be so constructed that it can be locked in the open position. The cut-out on switches should be of ample capacity and, when delay electric caps are used, the switch should be closed and opened again as quickly as possible to prevent the wires in the holes from becoming heated, sometimes sufficiently to ignite the dynamite.

Mode of lighting for cap and fuse firing. Often done by taking an extra piece of fuse 2 or 3 ft long, and cutting notches in it with a knife at intervals of about 2 in. The end of this fuse is then lighted, and, when powder train burns up to a notched place, the flame spits out vigorously. By directing each of these flames against end of the fuse to be lighted a round of shots may be lighted with certainty, in a few seconds. This method may inflict disagreeable burns on blaster's hands unless care is taken. Lighting fuse with hot lamp or candle is unsafe, as the spit of the ignited fuse may extinguish flame and leave blaster in the dark. One of the surest and safest methods is to slit the fuse at the end to expose powder train, and light it by means of a LEAD SPITTER, which consists of a piece of lead tube $^1/_8$ in diam, filled with meal powder (Fig 14). It burns at about same speed as fuse, but emits a strong shower of sparks, even in wet dripping mines and tunnels.

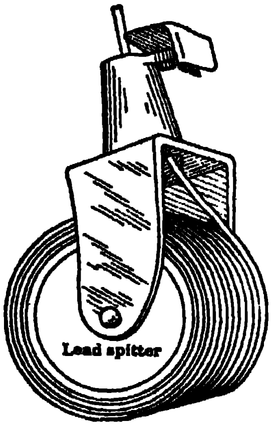

Fig 14. Lead Spitter

Fig 15. Hot-wire Fuse Lighter

The Hot-wire fuse lighter (Fig 15), which consists of an iron wire covered with a powder composition, is even more convenient than the lead spitter. They are in lengths from 7 to 12 in, and quite uniform in burning speed, so that they serve as a safety signal, showing the blaster when it is time to retire.

Precautions in Charging and Firing

Don't tamp with iron or steel bars. Use a wooden tamping stick, with no metal parts.

Don't force a primed cartridge into a drill-hole. Drill hole of ample size for cartridge.

Don't prime dynamite cartridges, nor charge nor connect drill-holes for electric firing during immediate approach or progress of a thunderstorm.

Don't fasten cap to fuse with the teeth, nor by flattening it with a knife; use a crimper.

Don't attempt to use electric blasting caps with ordinary insulation in very wet work. For this purpose secure waterproof caps.

Don't handle fuse carelessly in cold weather; when cold it is stiff and cracks easily.

Don't " lace " fuse through dynamite cartridges. This practice is frequently responsible for burning the charge.

Don't cut fuse short to save blasting time. It is dangerous economy.

Don't use fuse that has been injured by falling rock or in other manner.

Don't explode a charge before every one is well beyond danger zone and protected from flying débris. Protect supply of explosives also from this source of danger.

Don't explode a charge to chamber a drill-hole and then immediately reload it, as the hole will be hot and second charge may explode prematurely.

Don't use a " permissible " powder in same drill-hole with another explosive.

Don't hurry in seeking explanation for a misfire.

Don't drill, bore, nor pick out a charge which has failed to explode. Where safe, drill and charge another hole at least 2 ft from the missed one.

Don't expect high explosives to do good work if you try to explode them with a detonator weaker than No 6.

9. SPECIAL USES FOR EXPLOSIVES

High explosives in coal mining. Use of the " permissible explosives," as defined by testing station of the Bureau of Mines (21), is increasing in both anthracite and bituminous fields. They were used at first in gaseous and dusty mines solely as a safety precaution, because of their comparative freedom from liability to ignite gas and dust mixtures. It is now recognized that, by intelligent use of these explosives, the softest coal is shattered as slightly as with slowest grades of black powder (30). Permissible explosives are used for rock work in hard-coal mines, and in bituminous mines, where gas pockets may be encountered. Different kinds of permissible explosives should never be used in same hole.

Ore mining. The best type of explosive for a given case can be determined only by experience. It depends not only on character of ore, but on ventilation and class of labor. It is often feasible to substitute with satisfactory results a less expensive explosive for a more costly one, in mines where the miners may be made to adopt methods of drilling, charging, and firing other than those to which they are accustomed. Thus, in soft hematite, a slow-acting ammonia powder properly primed, loaded, and confined, will often break more ore per pound than a more expensive dynamite handled unintelligently. The use of short fuse, lacing fuse through cartridge, and insufficient tamping are dangerous and extravagant practices, often difficult to eradicate (24, 28).

Drifting or tunneling. It is desirable to " pull the cut " at the first shot; hence, it often pays to use a stronger explosive for firing the cut than is required for the relief, rib, and lifter holes. The effectiveness of a charge in the cut-holes can not be increased by increasing amount of explosive beyond a certain point, because a definite depth of tamping is required to prevent charge from blowing out.

Generally, cut-holes require an explosive having strength and density of 60% gelatin. Blasting gelatin is sometimes the most economical for this purpose, in spite of its relatively high cost. In refractory rock, or one with unfavorable stratification, cut-holes are often blasted more satisfactorily by electricity than with cap and fuse. Delay electric caps (Art 10) are advantageous where cut-holes bottom up well; but they should not be used in same circuit with cut-hole shots, if latter require to be loaded and fired a second time (6, 20, 25).

Stoping. Every mine is an individual problem. The principal point regarding the explosive is the size to which it is desired to break the material. For soft ore, ammonia dynamite breaks fine enough for easy handling without undue pulverizing. Where ventilation is poor, gelatin, semi-gelatin or ammonia dynamites are necessary, regardless of their other properties, and with much water, gelatin is best. Gelatin dynamite has added advantage that it will " stick " in " uppers." If necessary to blast out dry timbers in old stopes, to allow the top to cave and fill worked-out spaces, a permissible explosive should be used, to avoid possibility of fire.

When firing with cap and fuse, the LEAD (difference in length of fuse in holes designed to fire in succession) should never be less than 10%. For instance, if the first of such a round of holes has a 5-ft fuse, the hole to be fired next should have a fuse at least 6 in longer. With less " lead " than this, variation in burning speed of even the best fuse may cause holes to fire out of order, generally spoiling the shot. When fuses are not lighted in their proper order, the necessity for increased " lead " is apparent. When firing holes in rotation the priming cartridge is sometimes placed at or near bottom of hole, so as to have all fuses burning at a safe distance inside the holes, when first shot explodes; then, if the collar of a hole is shot off, its fuse will not be cut, causing misfire. This practice is good with ammonia dynamite or gelatin dynamite, but never with straight dynamites, which are readily ignited by the least side-spit from a fuse and are therefore liable to burn in the hole. EFFICIENT TAMPING SHOULD BE INSISTED UPON; it produces greater effect, and the more complete the detonation, the less noxious will be the fumes. Ready-made paper tamping bags are a convenience and their use leads miners to exercise more care in tamping.

Tunnel driving. The most satisfactory explosives are the gelatins, which have maximum density and water resistance, and produce minimum of fumes. In firing the heading, the charges must be concentrated in the bottom of the holes, to leave room for sufficient tamping to insure a clean break. The holes are usually wet, especially in the bench, and in dry holes or uppers, gelatin is desirable because it can be relied upon to " stick." Ventilation in tunnels is generally poor and the fumes from gelatins are the least noxious of all high explosives. For heading cut-holes, 60 or 75% gelatin is generally used; for relief, rib roof, floor, and bench shots, 40% gelatin is usually strong enough (48).

Shaft sinking. Gelatin dynamite is usually best for shaft sinking, due to its water resistance, plasticity, and freedom from noxious gases. Strength depends on hardness and toughness of the rock. This must be determined in each case. and sometimes a change in rock as shaft deepens necessitates a change in strength of explosive. Strong caps are essential, to insure max velocity and strength from the explosive, minimum of fumes, and to offset possible lack of sensitiveness in the explosive due to low temperature. When the shaft is not wet enough to require use of gelatin dynamite, considerable economy can be had by using semi-gelatins, which are also suitable in the same conditions where rock is comparatively soft. These explosives give off a minimum of obnoxious fumes.

Quarrying dimension stone; also stone for fills, rip-rapping, and cribbing, as well as for building. Use slow-acting explosives; the more powerful, quick-acting explosives shatter the stone. Granular, and other slow-acting powders, such as the low-freezing ammonia grades, may be used in holes where an air space is left for starting a line of fracture. For subsequent blasting, black powder is best, fired by electric squib or ordinary fuse. For large charges, blasting powder is fired with advantage by a dynamite primer.

Quarrying small stone (for crushers, cement works, kilns, etc) (29, 32). High explosive may be used, the one best adapted to be determined by experience. Quick-acting explosives are best for rock which readily transmits shock of explosion to a considerable distance. Hard limestone, trap, granite, etc, usually require dynamites of 50% strength and upwards. In very wet holes, where explosive is immersed several hours, gelatin dynamites must be used. In dry work, and in rock which absorbs much of shock of explosion, slow-acting explosives, like granular powder and low-freezing ammonia powders, are usually best. Quick-acting explosives should not be used in rocks like sandstone and marl, nor slow-acting explosives in flint, granite, or the like. Low-freezing explosives of all grades, especially low-freezing gelatins, are preferable in cold weather, because they do not suffer loss in efficiency as noted with the straight grades.

Straight nitroglycerin dynamites are not recommended for quarrying, as the gelatins have every advantage possessed by the straight powders and are much safer to handle. The only exception to this is that, for mudcapping, straight powders are much more effective than gelatins. In well drill holes good results are obtained by using 50% or 60% gelatin in the bottom and 50% or 40% ammonia dynamite as a top charge, and firing with Primacord. A special gelatin has been recently developed, known as Quarry Gelatin, made on an unbalanced formula and suitable for open work only. It gives excellent results in hard rock quarries. It must never be used underground.

Stripping. The slowest-acting high explosives are best; granulated dynamites and low grades of low-freezing ammonia dynamites (20 to 30%) being generally used. In heavy stripping, holes should be sprung and fired with slowest-acting explosive. For dry work, free-running dynamite or a mixed granulation of blasting powder is most economical. For moist ground use granular dynamite; if very wet, a low-grade straight dynamite. High-grade dynamite, such as 40% straight, is good for springing charges, but not for final charge except when holes are full of water.

Well sinking; quickest method. Small V-cut, of 4 or 6 holes, drilled by hand and loaded with 60% gelatin dynamite; subsequently trimmed up with vertical holes of same depth and blasted with well-tamped charges of same explosive. Even if holes are under water, always tamp with sand to secure best results.

Scrapping old machinery. When work warrants the expense, best explosive for breaking iron is blasting gelatin. It can be molded into shape as required, strung out to produce a break at point desired, and will " stick " where no other explosive will do so. If blasting gelatin is not obtainable, or is too expensive, use high-grade straight dynamite (50% or 60%). Charges should be well covered with wet mud, or wet clay free from particles of stone or rock; with clean, fine mud, shots are made with slight danger to surrounding objects. Scrapping old machinery in buildings may frequently be done without breaking any glass, if windows are open at top and bottom when shot is fired. High explosive may be used for driving out keys from shafting, driving a wheel from an axle, or loosening spindle from a crushing roll, by using plenty of mud with small charges, placed where blow is to be struck.

Road building. Explosives are used in road building principally for rock excavation, or loosening sand, loam, or clay. In dry work, 40% ammonia dynamite, and in wet work, 40% gelatin are best for hard rock, and 40% low-freezing ammonia for soft rock. For loosening soil, the weakest and slowest explosives are best, since their effect extends farther than that of quicker-acting explosives. Low-freezing 20% ammonia dynamite, granular dynamite, and railroad black blasting powder are economical for this work. In loosening earth, make holes not deeper than 30 in, and 4 to 6 ft center to center, loading each with not more than two cartridges of 1 1/4 by 8-in dynamite. This charge will not make deep pot holes and material can be handled with horse scraper without miring the animals. For blasting boulders, block-holing is most economical, and 40% low-freezing dynamite is suitable. If time is more important than economy of explosive, boulders can be broken quicker by mud-capping or " adobe shots," with 40 to 60% straight dynamite. Free-running high explosives have been developed to a point recently where they are used extensively in road building, and in general blasting where holes are sprung, or where it is undesirable to use blasting powder on account of the proximity of steam shovels and dinkeys, as they are not so inflammable as black powder. They are made in 4 or 5 strengths, are usually packed in bags, and can be poured into the holes, making for rapidity of the loading operation.

Submarine blasting. Though gelatin dynamites withstand action of water better than other high explosives (blasting gelatin stands water almost indefinitely), straight N G dynamites are usually preferred for submarine excavation because of their greater sensitiveness. The temperature of the water is usually so low that gelatins, less sensitive than straight dynamite under the best conditions, are very difficult to explode completely. Hence, holes are spoiled, rock is not broken, and unexploded gelatin is found by the dredges. Straight 60% dynamite is sufficiently sensitive to explode by concussion from an adjacent hole, if holes are not more than 4 or 5 ft apart. Consequently, in case of failure of one of the electric caps or connections, all the holes will be exploded by concussion. In submarine work, holes are generally untamped, except by water, and the quicker-acting straight dynamite therefore does better work. The cartridges should just fit the holes; especially necessary for shallow holes. Where range firing is not practiced and gelatin is used (usually 90%), a 2 by 8-in cartridge of 60% straight dynamite is often used as a booster for the electric cap.

Quite recently a high-velocity gelatin has been developed which is well suited to submarine blasting. It picks up its full velocity at once, thus differing from other gelatins which take from 4 to 8 inches to reach full velocity. High-velocity gelatin also detonates with full strength and velocity under water pressure where any other high explosive would fail. It is much less likely to propagate from hole to hole than the straight nitroglycerin dynamites.

Miscellaneous uses: clearing land of stumps and boulders; ditching and draining swamps; breaking log and ice jams; destroying wrecks; cutting off pilings; breaking soil for tree planting; hardpan and subsoil blasting; digging holes for posts and poles; excavating for foundations and cellars; trenching for tiling and pipe lines; breaking frozen ore and other materials; loosening frozen material in railroad cars; tearing down old buildings; splitting logs for railroad ties, fence rails, etc; cutting off large fires; starting snow slides; breaking old building foundations; blasting old mine timbers; controlling forest fires.

Black blasting powder in coal mining has so long been used that, as regards execution only, it is considered best for this work. Most coal miners are so familiar with its use, and good miners can judge it so accurately, that excellent results are usually obtained with it (10). The slow heaving action of black powder produces a large percentage of lump coal. Because of its bulk, it can be charged advantageously and estimated so closely that it can generally be used more economically than other powders. But, as black powder is loose, care and judgment are required to get best results.

Black powder is made up by the miner in paper cartridges or shells, observing following points: Make cartridge of proper diam to slip into the hole without too much waste space, and of proper length to hold just the quantity of powder necessary. Shake the powder down into the shell, to compact it, to minimize air-space and get the full force. After cartridge is placed in hole it must be well pushed back, unless an air-space is desired to cushion force of explosion (Fig 19).

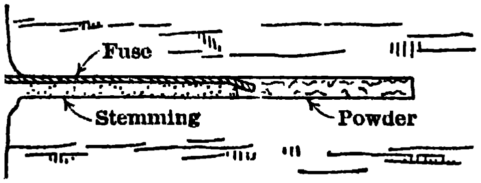

Fig 16. Blasting in Coal with Black Powder and Fuse

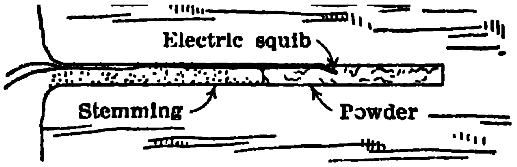

Fig 17. Blasting in Coal with Black Powder; Middle Cartridge Primed with Electric Squib

Fuse or electric squib (Fig 16 and 17) is fastened in cartridge to ignite powder, or a "needle" (Fig 18) or a "blasting barrel" (if hole is wet) is inserted into the powder, and the stemming compacted firmly around it. The more securely charge is confined, the greater the force developed. When unconfined it will simply burn (23, 39).

If a miner's squib (Art 10) is used, pull out needle and insert squib, large end first, into hole made by needle, or in the blasting barrel, and ignite small end of squib. The squib burns for a few seconds, and then shoots back into the powder, igniting it. Use right kind of stemming, so that needle-hole will be smooth, or, if barrel is used (1/4-in iron pipe), see that the hole in it is clear and clean.

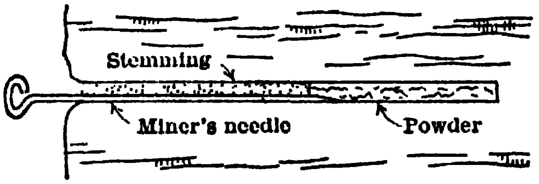

Fig 18. Miner's Needle, for Squib

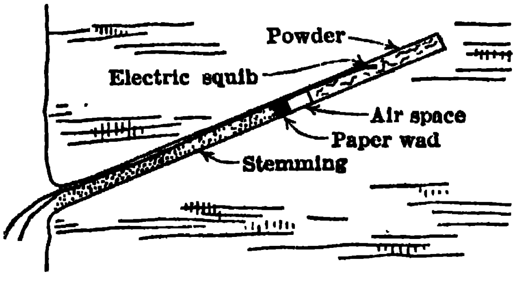

Fig 19. Blasting in Coal. Air Space between Charge and Stemming

When black powder is ignited with squib or fuse, the force seems to spread through seams of the coal, displacing it forcibly. It does not exert a sharp shock and therefore does not produce much fines, if proper granulation of powder and correct quantity be used. When very slow action is desired an air-space is left, either between powder and stemming or around cartridge (Fig 19). The proper granulation of black powder is determined only by knowledge of the powder and the coal, and by trial. A test is necessary to determine conclusively which size of grain is best for any particular coal.

Earth-work and soft-ore mining. In blasting soft iron ore in open-pit work, holes are drilled by a well drill, operated by steam, electricity or gasolene, or by piston or hammer drills. Where there is unusual danger in using black powder, due to sparks from steam shovels and locomotives, special high explosives may be employed. These are somewhat similar to permissibles, and are difficult or impossible to ignite by a spark. But they are not, as a rule, so economical as black powder.

Railroad work. In cutting through fairly solid rock, the holes are usually 18 or 20 ft deep, spaced 8 ft apart; they are sprung with 50% straight dynamite until each hole will hold sufficient explosive to break material small enough to be handled by steam shovel. Roughly, from 25 to 75 lb explosive per hole is used in rock of average hardness.

As it is economical to fire simultaneously as many holes as possible, a large-size blasting machine, or a power or lighting circuit, should be used for firing. For soft rock, shale, clay, loam, or sand, it is economical to use a power churn drill. This makes a 4 to 6-in hole, of any required depth, usually 40 to 100 ft; holes usually spaced 15 or 20 ft apart. The holes are often sprung with dynamite, and after thorough cooling, usually overnight, are charged with black powder, sometimes several tons in a blast. Black powder or granulated dynamites can be used only when holes are dry, and with great care when working near steam shovels, locomotives, etc, as many accidents have occurred from sparks dropping into black powder. If work is wet and sparks can not be avoided, use a fairly low-grade low-freezing ammonia dynamite. In firing simultaneously a large number of holes (50 to 100), use waterproof electric caps, to prevent leakage of current through rock, with attendant chance of misfires.

10. BLASTING SUPPLIES

Blasting caps. A cap is a copper cylinder, closed at one end, containing a pressed charge of detonating composition, and is fired by a fuse. Caps are graded according to quantity of detonating composition contained (Table 7).

Table 7. Fulminate of Mercury Blasting Caps.

	Grade	No 6	No 8
For Fuse Firing	Length of shell, in	1.375	1.875
	Calibre of shell "	0.234	0.234
	Weight of charge, grains	15.430	30.860
	" " " grams	1.000	2.000

	Grade	No 6	No 8
For Electric Firing	Length of shell, in	1.562	2.000
	Calibre of shell "	0.273	0.273
	Weight of charge, grains	15.430	30.860
	" " " grams	1.000	2.000

Note. The table refers only to caps charged with fulminate of mercury composition (consisting usually of 80% fulminate of mercury and 20% chlorate of potash), which is the standard against which other detonating compounds are graded.

Caps are often tested by placing them upright on a square lead plate, and noting size and character of the hole made in the plate by exploding the cap. This is only applicable for comparison of same type of caps, and then only to determine if caps have deteriorated. No 8 caps usually make no better lead-plate test than No 6, because only a small part of charge in contact with the plate produces effect on the plate itself. Many other materials have been tried, some of them much superior to fulminate of mercury.

For high explosives, the stronger the cap the better the execution, as a rule. No 6 detonators should be used for tunneling, shaft-sinking and similar work; large charges sometimes require No 8. Caps should never be crimped on fuse except with special crimpers made for purpose; biting them, or nicking them with a knife, is neither efficient nor safe. They should be stored in a dry place, as moisture weakens their force. Do NOT ATTEMPT TO EXTRACT COMPOSITION FROM CAP SHELLS; it is exceedingly sensitive and is often detonated if scratched or picked out with a pin or similar instrument. Miners should not wear oil or paraffine hat-lamps when handling caps; many accidents have occurred from sparks falling into a box of caps.

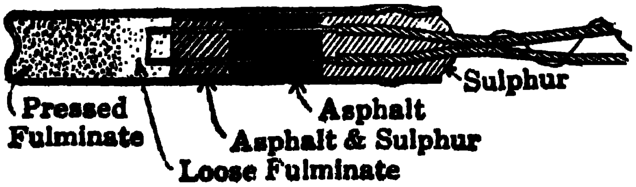

Fig 20. Electric Blasting Cap

Electric blasting caps (fuzes) (Fig 20). An electric cap consists of a copper shell $1\,^9/_{16}$ to 2 in long by 0.273 in diameter, closed at one end. It contains a charge of detonating composition, in which is embedded a fine platinum wire, connecting the two copper

wires. These copper wires are held in place and insulated from each other by three plugs: of mixed asphalt and sulphur, asphalt alone, and sulphur alone, the latter being retained by corrugations in the shell. Electric caps are used for safety in gaseous and dusty collieries, and for firing charges simultaneously, thus economizing explosive. ONLY ONE KIND OR BRAND OF ELECTRIC CAPS SHOULD BE CONNECTED IN ONE SERIES. Different brands vary in sensitiveness, and if the caps in a series are not uniform, the least sensitive will probably misfire.

Delay electric blasting caps are for firing blasts in 2 or more volleys with one application of electric current. They are used in series with ordinary electric caps. When current is transmitted, about one second elapses before first-delay caps detonate, and same period between these and second-delay. These detonators are useful in tunnel driving and are especially recommended for shaft-sinking, often enabling blaster to fire entire round without returning to the face. Fig 21 shows the recently introduced "Ventless Delay Electric Cap."

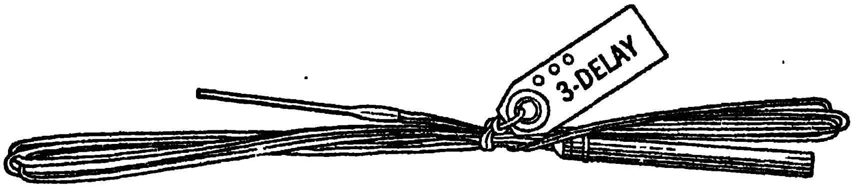

Fig 21. Ventless Delay Electric Cap. (Aluminum foil shunt)

This new development, has a uniform diam shell, in which the delay element gives off no gas in burning. This permits making various periods of delay, regardless of the pressure under which the cap is placed. Being completely sealed and waterproof, delay is uniform, regardless of the confinement or amount of press developed in water strata from firing previous adjacent holes.

The holes of a round are best connected in parallel and fired with power current, if available. The best way to make a parallel connection is to drive stakes into two end holes at each end of shaft section, stretch number 16 bare copper wire tight across the face between each pair of stakes, and connect one wire from each cap to each of these buss wires. Then, if one leading wire is connected to one end of a buss wire, the other leading wire to the other end of the other buss wire, a balanced parallel connection results, which will minimize trouble. The number of connections on each buss wire should equal the total number of holes.

Special electric blasting caps. For very wet work, and where sludge and water possess high conductivity, special insulation of cap wires is necessary to prevent current leaking from wires at one end of series to wires at other end, thus forming a shunt around wires at middle of circuit. This condition can be detected by making resistance readings of firing circuit on a direct-reading ohmmeter. If reading is the same, there is no leakage; if there is a drop in resistance, after loading in wet holes, there is liability of electric leakage, indicating necessity for special waterproof cap wires. For firing charges in deep water, a special, highly waterproof electric cap is made. There are other modifications for various purposes, such as having wires of larger gage than ordinary to decrease resistance in deep-hole blasting. Electric caps are also made with iron wires; used where only 2 or 3 shots are fired simultaneously. These have much higher electrical resistance than caps with copper wires, and are not recommended for lengths over 8 ft. Electric caps with tin-coated copper wires are used in certain mines where it is objectionable to have particles of bare copper in material mined, and where number of charges fired simultaneously makes use of iron wires impracticable

Electric squibs are somewhat similar to electric caps, except that the shell is aluminum instead of copper, and cap filling is fine-grained black powder instead of a detonating compound. They are for black powder only; can not be used for high explosives. They possess advantage of simultaneously firing several charges, and permit more perfect confinement of charge than with miner's squibs; also, the charge can be ignited in middle, giving a little quicker and stronger action and insuring explosion of entire charge before any portion can be cut off by fall of surrounding material. Fig. 22 shows an electric squib with twisted shunt.

Electric squibs are safer than fuse or ordinary squibs, because shots are not fired until every one, including blaster, is at a safe distance, and hang-fires are entirely prevented. They are made with iron or copper wires; iron wire is cheaper but requires stronger current (see above).

Delay electric squibs for rotation firing with pellet or black blasting powder are similar in construction to delay electric blasting caps, but can not be used to detonate high explosives as they merely shoot out a small, hot flame.

Miner's squibs are for firing black powder only. The squib consists of a core of powder composition tightly rolled in paper; one end terminates in a slow match, made by dipping twisted end of paper in melted sulphur or other combustible. In using, the squib is laid in mouth of hole formed by withdrawal of needle, or in the blasting barrel (Art 9). The other end of hole so formed terminates in the charge. Outer end of squib is lighted, and burns several seconds until its powder core is ignited, whereupon it shoots down into the charge and ignites that. Time between lighting of fuse and firing of charge can be varied to a certain extent by position of tail of squib: when turned up it burns more slowly; when turned down, much faster. The squib is very cheap, but not so safe as ordinary fuse. Since it requires an opening through which to travel, the charge is not confined so effectually as with fuse or electric squib.

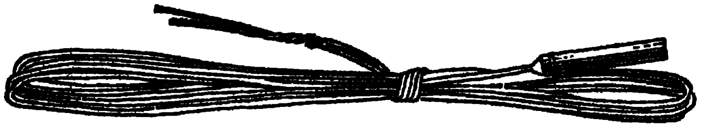

Fig 22. Electric Squib, Closed Shell. Twisted Shunt

Safety fuse consists of a train or core of a special kind of powder, tightly wrapped in successive turns of hemp, jute, or cotton yarn, and tape, made more or less waterproof by addition of asphalt or other varnish, or gutta-percha. When tightly tamped, so that gases from burning powder train can not escape, the pressure causes fuse to burn slightly faster.

The manufacturers make no warrant or representations as to the burning speed of their product, owing to the variety of conditions to which fuse is subjected after leaving the factory, including differences in altitude, weather conditions, character of tamping, and mishandling, all of which may affect the burning speed. The makers state, however, that they use every care and precaution in the manufacture, to bring their standard products to a standard burning speed of 90 sec per yard, with an allowable variation of 10% either way when burned in the open at sea level; except Clover, Sequoia, Aztec and Charter Oak brands, where the makers endeavor to approach a standard of 120 sec per yard, with an allowable variation of 10% either way when burned in the open at sea-level. Length of fuse must always be sufficient for the blaster to reach a place of safety.

For dry work, hemp fuse is good for black powder, but is too small in diameter properly to fit standard caps. The cheaper grades are usually the least waterproof; the more expensive, the better they resist water. For very wet work, or under water, gutta-percha fuse will usually serve. When extra precautions are necessary, the end of fuse and the blasting cap may be dipped into asphalt paint and dried, or joint between cap and fuse covered with tallow or soft soap. Do not use oil or grease, which is liable to affect powder train by dissolving the asphalt paint. As the powder in core of fuse absorbs moisture always cut off an inch or two from end, before inserting in cap. Cut off end square across, push into cap without twisting until it just touches the cap charge. If fuse is cut at an angle, pointed end may bend over, and by covering end of powder train, cause misfire. Nearly every kind of fuse spits out of sides more or less in burning, and therefore should not be buried in the dynamite. When necessary to have priming cartridge at bottom of hole, a fuse should be selected that will spit from the sides as little as possible, and cartridge shells must not be slit; fuse is less likely to ignite dynamite through the paper wrapper.

Detonating fuses. Primacord comprises a high explosive core of penta-erythrite-tetranitrate (PETN), contained in a waterproof sheath overlaid by reinforcing coverings, and detonates at very high velocity, about 20 300 ft per sec. It is very light and flexible, hence easy to handle and connect; has good tensile strength and is quite water resistant. It is used chiefly in multiple shooting in deep-well drill holes and similar large blasts. The violence with which it explodes is sufficient to detonate high explosives lying beside it in a bore hole, and a column of dynamite alongside in a deep hole detonates almost instantaneously throughout its entire length. In spite of high velocity and violence of detonation, Primacord is very insensitive, and can not be exploded by fire, friction or ordinary shock, or even by a 30-cal bullet fired through a spool of it; however, since it contains high explosive, its handling and storage as an explosive is recommended. Proper method of initiating is to detonate it by blasting cap or electric blasting cap butted against its end. Fig 23 and 24 show the proper method of connecting branch lines to trunk line, and the proper knot for splicing trunk line.

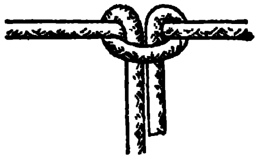

Fig 23. Primacord; Connecting Branch Line

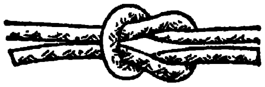

Fig 24. Primacord; Splicing Trunk Line

Cap crimpers are of 3 types (Fig. 25): (1) sleeve-type (*a*) leaves a vent between the fuse and copper shell, and in wet work must be dipped in some cap sealing compound to exclude water; (2) sleeve-type crimper (*b*) has an efficient fuse-cutter which cuts the fuse square across, but while this is desirable, it does not make a water-tight crimp; (3) type *c* makes an air-tight crimp on smooth-surface fuse and will resist water well enough in ordinary wet holes. If there is much water, any kind of crimp should be further protected by sealing the joint between fuse and cap.

Blasting machines. The usual form is a small dynamo, the armature of which is rotated by a downward thrust of the rack-bar transmitted by a pinion. There are two types; one (Fig. 26), which is series-wound, uses the entire current generated during descent of the rack-bar, to excite the field magnets. At end of stroke, this current is transmitted to the binding posts and firing circuit. In shunt-wound type, the dynamo is fully enclosed and part of the current is shunted through the field magnets until the end of stroke, when a contact is made, sending the entire current out on the line. Shunt type is easier to operate than the other, and having a greater volume of current, is better adapted to firing more than one series of holes at a time. Place machine in a firm, level position, and operate with both hands and full force; an attempt to operate it with one hand, or in a half-hearted way, will often result in misfires from insufficient current. Keep blasting machines in dry, cool place. The commutator, brushes, and circuit-breaking contact points should be kept clean, bright, and free from oil. Oil bearings and gears occasionally.

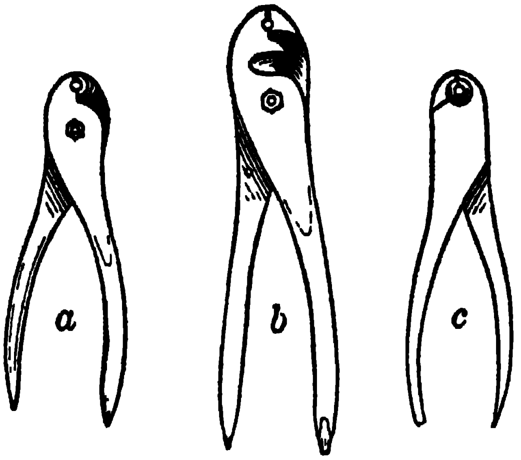

Fig 25. Cap Crimpers

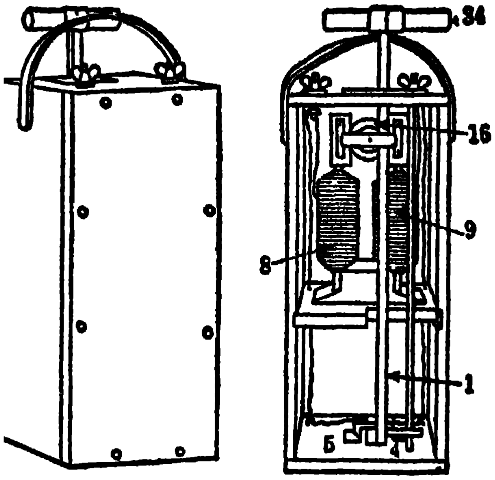

Fig 26. Blasting Machine

Single-shot blasting machines (also called pocket, or permissible machines) are employed, usually in coal mines, where it is necessary or desirable to fire one shot at a time (Fig. 27). They are capable of firing up to 3 shots simultaneously. Constructed on the magneto principle, they are operated by a quick twist of the handle, which is removable and acts as a lock to prevent premature or accidental operation. Dry cells also are sometimes used for single-shot firing, usually consisting of 3 carbon-zinc elements, connected in series; but, as the contact points are always alive, they are not as safe as the magneto machines, the binding posts of which are dead except at end of stroke.

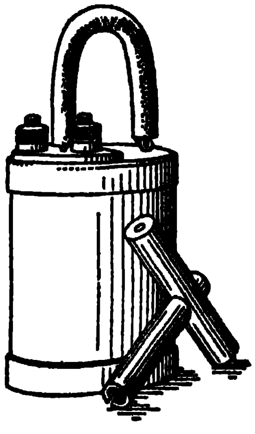

Fig. 27. Single-shot (Pocket) Blasting Machine

Blasting galvanometers are of two general types: one merely indicates whether circuit is open or closed; the other is essentially a small direct-reading ohmmeter, indicating by movement of a needle across graduated scale the approximate resistance of blasting circuit in ohms. With the latter, it may be determined whether a given blasting circuit is complete, or broken, or short-circuited. By a table, given below, showing resistance of electric caps with different lengths and sizes of connecting and leading wire, the exact condition of blasting circuit at moment of firing may be determined fairly accurately. The blasting galvanometer is a valuable adjunct, and, where a considerable amount of electric blasting is done, should form part of blaster's equipment. In addition to breaks and short circuits, it also detects leakage of current through ground, rails, air pipes, steam pipes, and imperfect connections. The instrument is furnished with a silver chloride cell, which is constant in its current output. The current thereby generated is less than one-tenth of that required to explode an electric blasting cap. The ordinary type of direct-reading ohmmeter and battery tester, containing regular or flash-light dry-cell batteries, will readily send sufficient current through a blasting circuit to explode an electric cap, and should never under any circumstances be used for testing any sort of blasting circuit or electric blasting cap.

Blasting machine testers (rheostats). These are for determining inexpensively the capacity and condition of a blasting machine. There are several types. One provides a means of sending a current through different resistances and a small lamp, so that, when connected to the poles corresponding to type of blasting machine tested, a bright flash shows that the machine is up to standard. Another tester has 6 posts, with different resistances so arranged that 20 combinations of varying resistance may be obtained in connection with use of an electric blasting cap in series, acting as an indicator. It is thus possible to determine whether blasting machine is up to strength, and if not, just how many caps in circuit it is capable of firing. By its use overloading a given blasting machine is avoided, with consequent danger of insufficient current and misfires.

Connecting and leading wire. Connecting wire is used for connecting the electric cap wires of one hole to wires of cap in an adjacent hole. As sold by dealers in blasting supplies, it is usually No 20 or No 21 B & S gage, wound on 1 and 2-lb spools. The use of the larger gage wire is advisable, as it adds less to the resistance of firing circuit

Table 8. Resistance in Ohms of Electrical Firing Devices *

Length of wires, ft	Regular and waterproof electric caps with plain or enameled copper wire (includes duplex wrap)	Seismograph electric caps	Delay electric caps, delay electric igniters and electric squibs with plain or enameled copper wires	Electric caps with iron wire	Delay electric caps, delay electric igniters and electric squibs with iron wire
4	1.25	0.99	1.03	1.99	1.73
5	1.29	1.01	1.07	2.19	1.93

40	2.48	1.75	2.26	....	....
50	2.83	1.96	2.61	....	....
60	3.17	2.18	2.95	...	....

* These figures, from E. I. duPont de Nemours Powder Co, apply to products made by that concern. They are approx correct for most other makes of caps.

This wire should not be used for connecting a line of holes to blasting machine; for that purpose LEADING WIRE should be used, of No 14 gage or larger. No 14 B & S gage wire, in coils of 500 ft, is satisfactory for all kinds of dry work. For wire gages, see Sec 42, Art 3.

Resistance tables. The resistance of copper wire, B & S gage, per 1 000 ft, of sizes usually employed in electric blasting, is:

Gage No	Ohms	
8	0 6271	Power and lighting circuit
10	0 9972	
12	1.586	
14	2 521	Leading wire
16	4 009	Sometimes used for leading wire, but not recommended for firing large circuits
18	6 374	
20	10.14	Connecting wire
21	12 78	
22	16.12	Size attached to electric caps

Wires of electric caps have a resistance of 0.032 ohm per ft (doubled). The resistance of the bridge wire in the cap varies from 0.859 to 1.1 ohm, depending on the manufacture; it does not necessarily indicate the sensitiveness of the cap.

Resistance of electrical firing devices. These include electric blasting caps, electric squibs, delay electric blasting caps and delay electric igniters, with both copper and iron wires. Enameled copper wires have same resistance as plain wires, but much better resistance to electrical leakage.

ROCK EXCAVATION

This section contains data on blasting in general, and surface excavation of rock, as in open-cut mining, quarrying, railroad and highway through-cuts and side-hill cuts, and trenching. Related subjects are: Explosives (Sec 4), Tunneling (Sec 6), Shaft Sinking (Sec 7) and Machine Drills and Compressors (Sec 15).

In this revision, much material of the first edition has been retained, including many cost figures when accompanied by sufficient information for converting them to present-day values.

1. FACTORS AFFECTING METHODS AND COSTS

Open-cut methods depend upon size, location and purpose of the work. Costs vary greatly with the method adopted, together with the character of rock.

Character and formation of rock affect drilling speed, amount of explosive, size into which the rock breaks, mode of breaking, and tonnage handled. DRILLING SPEED. In hard, tough rocks this is generally much lower than in soft, though, in some shales and other friable rocks, accumulation of sludge in the hole prevents the drill from striking an effective blow and retards drilling. This is especially true with solid steel, and may be remedied by using a water jet, Art 4. In soft rocks a heavy blow may seat the bit so that it sticks. Seamy, blocky rock also causes sticking or FITCHERING; overcome by withdrawing the bit and dropping into the hole a handful of quartz or C-I fragments. Hard, friable minerals may make easy-drilling rock, as some pyrites and sandstone. Grains of soft sandstone easily break loose and are blown from the hole, whereas sandstone cemented with SiO_2 may drill as hard as solid quartz. AMOUNT AND KIND OF EXPLOSIVE (Sec 4) is determined only by test or experience (Table 1). SIZE OF PIECES INTO WHICH ROCK BREAKS depends somewhat on toughness, but more on presence or absence of joint planes. Pieces too large to load require blockholing, which is costly and delays loading (Art 7; also see Sec 10). MANNER OF BREAKING is affected by position of joint planes and the dip of strata. As rock can not be excavated to neat lines by blasting, more must be removed than required; this excess is called OVERBREAKAGE. Unit of measurement of open-cut excavation is the cu yd. Table 2 gives weights of rocks.

Table 1. Relative Toughness of Rocks, Tested with Drop Hammer (23)

Kind of rock	Toughness. Limestone = 1	Ft lb per sq ft of fracture	Kind of rock	Toughness. Limestone = 1	Ft lb per sq ft of fracture

Overbreakage for 8 months during 1909 in open-cut work on the Livingstone improvement of the Detroit River was 14.7%; 273 750 cu yd of limestone excavation was paid for, and 314 000 cu yd loosened (12). Overbreakage in open cuts (mostly in granite), on Grand Trunk Pacific R R, was 10 to 40% (20) Overbreakage in the approaches to a tunnel near Peekskill was 10%, the strata dipping at a high angle (20).

Voids in hard rock, when broken by a crusher, amount to about 35% if all sizes are mixed and the stone slightly shaken, but, if screened, each size has 45 to 48% voids. Soft, friable rocks, as shales, break into widely varying sizes and therefore have a lower percentage of voids Hard rock blasted in large pieces and thrown into cars has about 40 to 45% voids, 1 cu yd of solid rock making 1.67 to 1.82 cu yd broken.

Voids...........................	30%	35%	40%	45%	50%	55%
No of cu yd, loose measure, from 1 cu yd of solid rock...........	1.43	1.54	1.60	1.90	2.00	2.22

* Refers to possible wt of ores; pure minerals usually weigh more.

Swelling in fill. On excavating a mixture of solid and loose rock and earth, 1 cu yd in place makes about 1.4 cu yd in fill. If rock be first stripped of earth, and then blasted and dumped by itself, the percentage of voids is larger. At Boulder, Colo, 3 600 cu yd of solid rock made a 5 340 cu yd embankment; a ratio of 1 : 1.51. In Virginia, 50 000 cu yd of limestone and mica schist, broken and put in embankment, made 90 000 cu yd, an increase of 80%. In subaqueous excavation, Ashtabula Harbor, O, 62 869 cu yd (place measure) gave 103 537 cu yd measured in scows, an increase of 65%.

2. DRILL STEEL AND BITS

Shape and temper of bits greatly influence efficiency of drilling. While quality of drill steel has in late years approached standardization, its proper heat treatment for given working conditions is still debatable, notwithstanding much research and experimentation (2, 4).

Types of bit in common use (Fig 1). For machine drills in general, usual shapes of cutting edge are: right-angle cross, X and Z, and modifications, like the Carr bit and others. For HAMMER DRILLS, the 6-point bit is common, but its advantages are not apparent, except for the smaller machines, like sinkers. There is little difference between cross and 6-point bits in respect of ease of sharpening. Z bit is less readily made, and difficult to temper for standing up under high air press, due to weakness of tips of cutting edges. Carr bit is easiest of all to make and readily takes a hard temper.

Bit wings should be thick enough (usually 0.5–0.75 in) to stand up well, but as thin as consistent with strength, to leave space for free ejection of cuttings; the bit then "muds" well and cuts faster. Gage and shape of bit must permit of free rotation in the hole. Cutting edge must be symmetrical, to equalize wear and prevent RIFLING, with consequent FITCHERING of the bit; which causes abnormal strains, with danger of breaking bit or machine.

Angle of cutting edge (angle between its sides) averages about 90°; if much greater, the bit crushes rather than fractures the rock; if less, it cuts faster, but also dulls faster and is more liable to break. In soft rock, a slender cutting edge tends to penetrate past the point of fracture, thus wasting energy in crushing and wedging out the rock. Outside taper of the wings of a cross bit is measured by their angle with the axis. This angle, in a bit good for rapid cutting, long wear and ease of resharpening, begins at about 14° and, near cutting edge, ends at 5°. Diam of bit's outer guiding surfaces then nearly equals that of the cutting edge, which is thus well supported, increasing life of the gage, and minimising tendency to rifle.

Comparative tests of hammer-drill bits, by Forbes and Barton (4), in drilling very hard granite, led to the following conclusions: (*a*) in down holes, cutting speed varies inversely as diam², at least for small gages; (*b*) drilling speed increases almost uniformly with increase of air press. About 85 lb seems best adapted to all bits for drilling in the granite used for tests; (*c*) speed of drilling appears proportional to coarseness of cuttings, as shown by screen analysis and study of bottoms of drill holes; (*d*) considering its cutting qualities, small loss in gage, and ease of making and tempering, the Carr bit is excellent for rock of aver hardness; (*e*) at low air press and in soft rock, Z bit may surpass the Carr bit in cutting speed; but, due to difficulty of forging and tempering, it is less desirable; (*f*) 6-point bit is apparently inferior for ordinary work, but may be useful for starting holes and shallow drilling; (*g*) for high air press and very hard rock, the cross bit, with a 5° outer taper on the wings, seems superior to all others.

While tests in other rocks might show different results, the relative cutting quality of different bits would probably be the same in all rocks. Other characteristics, as mudding freely and freedom from fitchering, may make one bit better than another for soft rocks.

To find length of bar required for any length of steel, add to the length given in table for shank and bit, the "drilling length" (depth of hole).

Hints on drill steel (Sullivan Mach'y Co), that may well be posted in blacksmith shop:

Don't use poor or dull drill steel, nor steel with a soft striking or shank end; don't use steels if shank end is not properly squared, or if shank is not of correct length; don't attempt to use a steel the shank of which will not enter the chuck bushing freely; don't overheat the steel; don't forge a bit and use only the regular dolly, as it will result in a very short upset, which does not give cutting edges any support while drilling, resulting in broken wings; don't leave round corners after sharpening. Make them square; resulting in faster drilling speed, and prolonging life of bit; don't forget that the bit tips are hotter than the center when heated hurriedly, and that they cool quicker; don't hammer cold steel; it is hard work, and injures the steel.

Be sure that: drill steel is straight and bit and shank are formed in alinement with the steel body; shank is of proper length and shape; lugs or collar at base of shank are of proper diam and length; hole throughout the steel is of proper size and free from obstruction; striking end of shank is flat and square, with inner and outer edges slightly rounded; bit is of proper shape, with cutting and reaming edges formed full and to required size; gage of bit is of correct size for the length of steel; reaming edges are concentric with axis of steel; angle of reaming side corresponds to the standard established for existing conditions; there are no sharp corners at shoulder, where bit blends into the steel body; drill steel is free from cracks and other imperfections that might result in breakage; steels are of proper length to correspond with the established length of steel change; hole in hollow steel used with air-tube and water-tube drills is punched out at shank end, to a diam of 3/8 in, for at least 3 in.

Hand sharpening. Bits should be constantly turned in the fire, removed when cherry red and dressed. The edge of a badly-worn chisel bit is first upset to give it proper width. The bit is then held on the anvil at a slope of about 1 rise to 2 horiz, with its edge even with edge of the anvil. While hammering it is turned after each half-dozen blows. A file may be used on the hot bit for final dressing. Blows should be light and glancing, to draw the fibers of the steel towards the edge, thus toughening the metal. There are 2 methods of sharpening machine-drill bits: SET-HAMMER and FULLER-AND-DOLLY. In the first, a set-hammer is placed on the bevels for driving the steel back. After being sharpened a few times a drill bit must be reformed. In the second method the steel is first drawn sharp at the corners with a fuller and then set back in the center with a dolly.

Machine sharpeners (Sec 15) should be used except for small work, where cost of a machine would be prohibitive. Large saving results from proper heat treatment, starting with the initial forging heat. Unless this is correct, later heat treatment is useless.

Physical properties of the bit depend upon the temperature of the steel preceding both forging and quenching, and the care exercised in forging. The finest grain exists as the steel passes through the critical range on the rising heat. Further heating coarsens the grain, which effect remains in the steel if allowed to cool undisturbed. Hammering produces a finer grain if continued until the critical temp is reached if it be stopped while the steel is above the critical temp, coarse crystallisation again sets in, if continued below that temp, distortions and internal strains are caused, resulting in brittleness and breakage Steel should not be allowed to soak ' in the furnace, as it increases coarseness of structure

Critical temperature can be practically understood by watching the slow heating of a piece of steel. It brightens in color with rising heat, until a point is reached where it apparently becomes a trifle darker than the furnace The darkening is due to absorption of heat, and the temp at which this absorption takes place is the DECALESCENT or CRITICAL POINT If heating continues the steel again assumes the same brilliance as the furnace If the furnace is now allowed to cool slowly, a point is reached where the steel remains visibly brighter than the furnace, but in a few seconds it assumes color of the furnace and darkens with it The brightening, due to throwing off heat, occurs at the RECALESCENT POINT

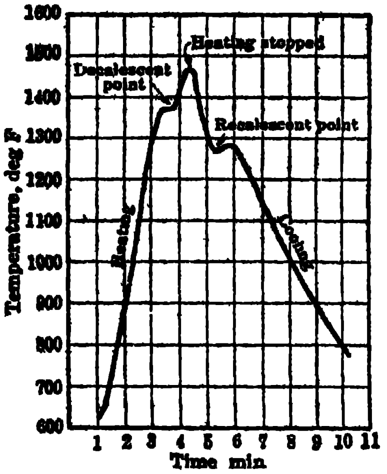

Fig 2 Critical Temperatures for High-carbon Steel (Steel and its Treatment, E F Houghton & Co)

Fig 2 shows the critical temp for high-carbon steel, heated slowly to about 1 500° F and then allowed to cool slowly The critical point varies according to the carbon contents for steel containing 0 6–0 9% carbon the range is 1 420°–1 350° F As steel becomes non-magnetic at about the critical temp that point can be determined for a given steel by bringing the heated bit close to an ordinary magnet if the magnet is attracted the temp is below the critical point Magnetic indicators for blacksmiths' use display a lighted lamp to show that the steel is still magnetic and requires further heating

Cooling bath for quenching heated steel may be of water brine rape-seed oil, tallow, or coal tar Brine is the fastest quenching medium but is difficult to keep at constant temp tar is slowest Oil is used when a high degree of hardness is not necessary Circulating cold water is best, for uniform results its temp must be fairly constant When the steel reaches proper temp quenching should be rapid its object being to retain the characteristics of the metal as produced by proper heating

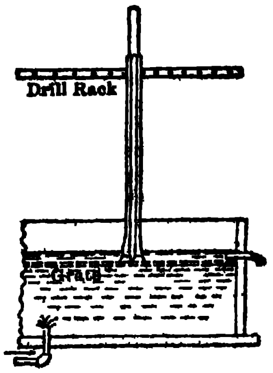

Fig 3 Drill tempering Tank

Important points for heat treatment of drill steel (2) (*a*) Use only best grade of steel (*b*) Use oil gas or elec furnace which permit close regulation of temp impossible with coal or coke (*c*) For both forging and tempering heat in a non-oxidizing furnace atmosphere Oxidizing action causes scaling and decarbonization Indirect (reflected) heat is desirable (*d*) Forge bits at a temp above the critical point but never above 1 600° F Never forge bit or shank when steel is too cold, forging should stop at or just above the critical point if necessary, reheat Forge by rapid hammering not by squeezing or bulldozing, (*e*) For tempering heat to 1 450–1 500°, quenching on a rising heat, never after temp has fallen below 1 375° The lower the temp while still above the critical range the greater the density hardness and toughness of steel (*f*) Always quench the steel by holding it vertically (*g*) Temper bits only as far back from cutting edge as will give desired results (*h*) After forging anneal by heating to 1 550° covering with powdered lime if possible better tempering is thus obtained (*i*) Never forge and temper on same heat (*j*) Keep quenching bath cool; if necessary agitate the bath to prevent its heating too rapidly (*k*) Heat-treat cutting end of bit to insure a core of max density and hardness and that all surfaces subject to wear are supported by a toughened core (*l*) Chemical composition of drill steel should be within following limits, C 0 85–0 90%, Mn, 0 30–0 40% Si, 0 10–0 20%, P not over 0 03%, S, not over 0 03%

Reclaiming short lengths of steel by welding (6) For 1¼ in hollow steel time required is grinding ends square and removing scale 2 min countersinking 1 min welding by elec butt method, 0 25–0 35 min total, 3 3 min Power consumption about 0 25 kw hr per weld of open circuit, voltage about 4 volts to insure ease in flashing One man can prepare and weld 2 pieces of steel of aver size in about 5 min Subsequent heat treating may be done in the welder, by increasing the opening between dies to 3 or 4 in again clamping the welded steel in the dies, heating to proper temp and slowly cooling in lime Tests by Sullivan Mach'y Co on steels thus welded gave satisfactory results, as compared to those of original steels

Sectional drill rods (Fig 4) have been used for holes to 270 ft depth, with hammer drills like Waugh Models 31 and 34, of Denver Rock Drill Mfg Co, which makes and heat-

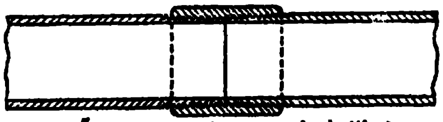
treats the special steel sleeves for joining the sections. The heavy duty thrown on the drill's rotating mechanism in deep holes requires use of the independent rotation type (7, 8). Deep holes can thus be drilled at any reasonable angle, for exploring and sampling orebodies (42).

Table 5. Cost of Deep-hole Hammer Drilling (8)

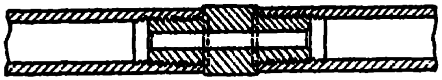
	Per ft
Labor	$0.44
Misc labor and supplies	0.13
Air charge, bit sharpening, and making up new steel	0.11
Deprec of equipment	0.17
Supervision	0.07
Blasting out for set-up room	0.05
Total	$0.97

Table 5 gives cost of such work by Chief Consol Mining Co, Utah, in 1924. The figures include charging off deprec of equipment in 2 years; sleeves and steel were taken at 10¢ per ft drilled, other charges being direct distributed. Wages: driller, $5.25, helper, $4.75. Monthly costs, 28–90¢ per ft of hole; monthly aver drilled per shift, 12.2–34 ft; deepest hole, 272 ft. About $1 per ft covered all costs of actual drilling. During 8 months' use of diamond drills for same work, cost averaged $4.94 per ft. It was considered that, to depth of 250 ft, hammer drills had a 5 to 1 advantage over diamond drills.

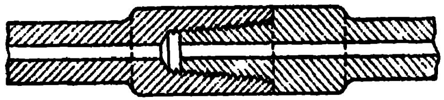
Detachable rock-drill bits. Use of detachable bits has greatly increased in recent years. Many regular steel and drill manufacturers supply them in various bit gages from $1^{1}/_{4}$ to 4 in. Chief types are the 4-point cross bit, 6-point or rose bit and Carr bit with either side or center hole; the commonest is the 4-point cross bit. The bits are threaded to the drill shank, and are easily changed. They are especially advantageous for scattered or isolated work, such as rock excavation in road construction. A number of large metal mines have adopted them and reports indicate savings of 10% to 35% over the conventional type. In the U S Bureau of Mines Inform Circ 6911 the following advantages are listed: (1) saving in transport between shop and working face (nipping); (2) faster drilling; (3) reduction in loss of steel from all causes; (4) more inches drilled per bit; (5) less stock of steel required, hence less investment; (6) smaller gage loss per bit; (7) smaller gage changes, due to precision and uniformity of factory shaping; (8) lower total cost per ft of hole.



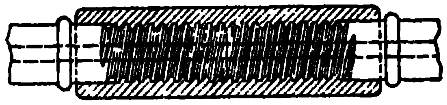
1¼″ Common wrought pipe (ends abutting)



Diamond drill "E"



Braly-North Butte Mining Co



Waugh-Denver Rock Drill Mfg Co

Fig 4. Evolution of Sectional Drill Rods (7)

Bits can be reground 3 times in most cases to next following gage; and then rehardened and reground 2 or 3 times more, making in all an aver use of 5 or 6 times per bit.

3. METHODS OF HAND DRILLING

Methods. SINGLE-HAND DRILLING is usually practicable in the softer rocks to depth of about 3 ft; wt of hammer, 3.5 to 4.5 lb. DOUBLE-HAND drilling is good for deep holes or very hard rock; 2 strikers may be employed; wt of hammer, 10 lb. For 6 to 8-ft holes, the starting bit is usually 1.25 to 1.5-in gage. CHURN DRILL, well handled, is effective for deep vertical holes. It is raised and dropped by one or more men. (See Sec 9.)

Effect of diam of hole on the speed of drilling has never been fully determined. In general, doubling the diam divides the speed by from 2 to 4.

Direction of hole. A horiz hole is drilled at about 0.5 the speed of a vertical down hole; in "uppers" the speed is materially less. Horiz and up holes are usually dry, and the cuttings prevent the bit from striking the rock effectively; water in down holes keeps the cuttings in suspension, permitting the bit to strike against a relatively clean face.

Hardness of rock as affecting speed of drilling. In vertical holes (1.5-in starting bit), 1 man holding and 2 men striking can in 10 hr drill 6-ft holes at following rates: granite, 7 ft; trap, 11 ft; limestone, 16 ft.

Hand churn drilling. 30-ft holes in blue sandstone, 2.75-in diam at start and 1.5-in at bottom, can be made in 10 hr; 3 men working on first 18 ft, 4 men on last 12 ft; brown sandstone is slightly harder to drill. On Mesabi Range, Minn, 4 men drill 40 ft of 1.5-in hole in stripping overburden and 96 ft in iron ore.

Hand-power auger drills are sometimes used for prospecting and boring blast holes in soft ground, as coal, slate, shale, salt, gypsum, and talc. They vary from simple hand augers to elaborate machines with tripod or post mountings. Mounted machines weigh 80 to 100 lb (Sec 9).

Table 6. Rate of Hand-hammer Drilling (Original)

Kind of work	Kind of rock	Men per drill	Hr per day	Diam of bit, in		Depth of hole, ft	Ft per hr

4. METHODS AND COST OF OPEN-CUT MACHINE DRILLING

Drill mountings (Sec 15) for open-cut work are the tripod, quarry-bar, gadder, special carriage for deep holes, and the derrick or wagon mounting, commonly called "wagon drill". QUARRY BAR is a horiz bar supported at each end by legs. It is 3 to 6 in diam, 8 to 12 ft long. These bars are primarily for drilling in quarries a number of rows of vertical holes close together, but may be used for similar work in trenches, etc. GADDER is a quarry device for drilling a number of parallel holes in a plane at any angle, from horiz to vertical, as the undercutting holes in a bench partly freed by channeling. A heavy carriage, running on a track, has hinged to it a standard, adjustable at different angles, on which slides a saddle carrying the drill. **Wagon mounting** is a steel frame and derrick, on 3 or 4 wheels either all steel or with pneumatic tires; or on steel skids. Various type drills can be used. The whole mounting is easily moved by hand. In some types the derrick can be canted, for drilling at angles other than vertical. Holes to 40 ft deep can be drilled with steel changes of 6 to 10 ft. Some drills are equipped with air motors and automatic feed. In larger types for down holes, say to 40 ft, the drill is fed by its own weight, plus a slab-back with adjustable weights. Drill is raised by hand or air hoist. Speeds of 25 to 70 ft per hour are possible, depending on hardness of rock, depth and diam of hole and air press. For cost of mountings, see Sec 15.

Drill trucks are used to some extent for deep-hole drilling, and for trench work. They are operated from a central compressed-air or steam plant, or may carry their own boiler. The drill may be stationary, or mounted on a turn-table. The cuttings are removed from the hole by a water jet or by special steels. There are other devices for mounting one or more ordinary machine drills on a bar. A special device for sewer work is described in Art 10. Respecting drill carriages, see also Sec 6, 15 (11, 20).

Cost of machine drilling comprises: (*a*) wages of drill crew; (*b*) proportion of wages of power-plant crew; (*c*) fuel; (*d*) drill sharpening; (*e*) repairs and renewals; (*f*) oil and water; (*g*) interest on plant; (*h*) depreciation of plant; (*i*) proportion of general expense including taxes; (*j*) erecting, dismantling, and moving plant.

Factors affecting speed of drilling: (*a*) character of rock, as hardness, stickiness, seams, sludge, and dust-forming qualities; (*b*) time for changing bits; (*c*) time for taking down, moving, and setting up machine; (*d*) depth of hole; (*e*) direction of hole; (*f*) diam of hole; (*g*) use of air or water, or both, in the hole; (*h*) shape of bit; (*i*) quality of blacksmithing; (*j*) percentage of time lost by blasting, breakdowns, delays; (*k*) size, weight, and type of drill and mounting; (*l*) air or steam press at the drill; (*m*) skill of crew.

Time occupied by the different operations in drilling may be classed under CUTTING TIME and DELAYS, the sum of which gives total CYCLE TIME for drilling one hole. Delays comprise time to (*a*) raise drill, (*b*) loosen bit, (*c*) remove it, (*d*) get bailer and bail, (*e*) get bit, (*f*) insert bit in chuck, (*g*) tighten chuck, and (*h*) get started. Besides the cycle time, there is the time required to move the drill to other holes, set it up, start it, and miscellaneous delays. For time studies of work with piston drills see (12), where drills were mounted on tripods for holes 7 to 24 ft deep and 2.5 to 5.5 in diam at start, in granite, limestone, and slate. From these records, cutting time averages 58.2% of cycle time; cycle time, 74.7% of total time; time for moving and starting a drill, 12.5% of total time: time lost in delays, 12.8% of total time. Cutting speed: in granite, 0.18 ft per min; limestone, 0.13 ft per min; slate, 0.17 ft per min.

Table 7. Average Time Drilling Vertical Holes (Tripod-mounted Drill)

Kind of rock	Lm	S	Sd	Gr	Tr
Length of shift, hr	10	10	10	10	10
Air pressure, lb per sq in	70	70	70	80	70
Diam drill cylinder, in	3.25	3.25	3.25	3.25	3.25
Diam starting bit, in	2.5	2.5	2	3.5	2.5
Diam finishing bit, in	1.75	1.5	1.25	1.25	2
Depth of hole, ft	12	6	12	20	6
Drilling first 2 ft, min	9	10.5	8	12	14
Cranking out, removing bit, min	1	3.5	1.25	1	1.5
Cleaning out hole, min	1	3	1.25	1	1.5
Putting in new bit, cranking, min	1	2.5	1	1.5	1.5
Drilling second 2 ft, min	13	10.5	1	1.5	14
Drilling last 2 ft, min	12	10.5	6	11	14
Moving machine, setting up, min	15	35	12	11	36
Ft drilled per shift			96	48	36

Note.—Lm = limestone; S = sandstone (hard); Sd = sandstone (soft); Gr = granite; Tr = trap (diabase).

Rate of drilling. Formula for estimating number of ft drilled per shift (20): $N = S \div \left(r + \frac{m}{f} + \frac{s}{D}\right)$; where, N = ft drilled per shift; S = working time per shift, min = 600 per 10-hr shift, if no time is lost by blasts, breakdowns, etc; r = actual time to drill 1 ft, min; m = time to crank up, change drills, clean out hole, and crank down = 3 to 4 min ordinarily; f = length of feed = 2 ft in ordinary percussion drills; s = time to shift machine and set it up = 5 to 60 min, usually 12 to 20 min; D = depth of hole, ft.

Records of work with 3 1/8-in piston drills, at 70 lb air or steam press, starting bit about 2.75 in, finishing bit 1.5 in, gave following speeds for 1 ft of hole (20): soft sandstone and limestone, 3 min; medium sandstone and limestone, 4 min; hard granite and sandstone, 5 min; very hard trap and granite, 6–8 min; soft rocks that sludge rapidly, 8–10 min. (For other drilling records, see Sec 15; also "Compressed Air Plant," Peele, 5th Ed, Chap 20.)

Drilling rate is not significant without specification of diam and direction of hole, air press, type of machine, method of removing cuttings, and nature of the rock. Hard, tough rocks have been drilled at 12 in per min; softer rocks faster, especially in down holes. As long as a bit retains its cutting edge it will maintain its initial drilling rate. As depth of hole increases, the drilling rate of hammer drills decreases less than that of piston drills. Theoretically, as follower bits are of smaller gage, drilling rate should increase in inverse proportion to square of diam of hole, but the tightness and sludge in small diam holes keep the rate approx constant (1).

Hammer drills. Speed of cutting. A Sullivan, Class D-19 drill, 1.25-in cylinder, hollow steel, and air at 100 lb, drilled in granite 1.25-in holes, 1 ft deep, in an aver of 1.75 min, using 25 cu ft free air per min. A Class D-15 drill, in same granite, drilled 5/8-in holes at rate of 1 4 5/8-in hole in 10 sec, and a 5.25-in hole in 15 sec. In trench work in oölitic limestone, 12 DB-15 drills averaged 40 1.5-ft holes per drill per 10-hr shift for 12 mo work. Best record was 100 1.5-ft holes in 10 hr and 36 3.5-ft holes in 7 hr. In dark green granite, a DB-15 drill in 16 hr made 47 ft in 25 holes, from 19 to 36 in deep; a DB-19 drill made 19 ft in 5 holes, from 32 to 60 in deep. A DC-19 drill in soft sandstone, made 20 holes 18 in deep, at rate of 25 sec per hole.

Sets of drill steel, comprising a starter and 1 or more follower bits, generally have length increments of 1 to 2 ft. For hard, tough rock the increment is usually 1 ft; for softer rocks, 2 ft. Tests should be made to determine max and aver distances drilled per bit in the different rocks encountered. The fewer the changes, the shorter the drilling time for a given depth of hole.

Starting diam of hole depends upon its depth, reduction in gage of follower bits, depth drilled per bit, and diam of cartridges.

Commonest sizes of cartridge are 1 1/8 and 1 1/4 in, more rarely 1 in; the size being generally constant in any one mine. Bottom diam of hole is thus 1 1/8 – 1 3/8 in. Gage of bits composing a set varies by 1/8 or 1/16 in; for hammer drills, 1/16 in is satisfactory. With 12 steels, a 12-ft hole

requires a starting diam of 2 in for $^1/_{16}$-in change in gage. The smaller the starting diam, the higher the aver drilling rate. Depth of hole is determined by blasting conditions.

Fitchering or sticking of the bit is caused by: poor alinement of steel in the hole, bent steel, improper type or poorly sharpened bit, too much or too little feed water, worn or broken shanks, seamy rock, pebbles or spalls falling alongside of bit and jamming, mud collar behind the bit, hard nodules in the rock causing poor alinement of hole and bending of drill shank.

In soft rock a bull bit may penetrate so far that the drill's lifting force on up stroke is insufficient to withdraw it. Remedy is to use a cross or X bit, which is less likely to jam. Sludge is washed out of the hole by the rising stream of water, or blown out by the air or water jet, the larger cuttings falling back and jamming when the drill shank is too small relatively to diam of hole. If hollow steel is not used, a good jet can be made by a 0.5-in pipe, connected to a hose through which water is pumped. Where water is not available in quantity, a fair substitute is a narrow barrel-hoop shoved down the hole; in rotating slowly around the bit, it stirs up the sludge.

Cable, well, or churn drills (Sec 9) are extensively used for deep holes for blasting in quarries and open-cut excavation. Advantages, as compared with machine drills: any depth can be drilled, to the possible limit of blasting; no stripping of the overlying earth is necessary; holes in high faces are drilled to full depth, instead of working in benches; the large-diam holes hold larger charges, hence wider spacing of fewer holes, and saving of time; smaller consumption of fuel for power.

Size of churn-drill holes. Bits are 4 to 9 or 10 in diam, the smaller sizes best for low faces and soft material (but where bank is low, machine drills on wagon mounting are more economical). Common sizes are 5 $^5/_8$ and 6 in; best adapted to limestone formations where drilling cost per ft is not high and relatively closer spacing permits better distribution of explosive. However, use of 8- and 9-in holes has much increased, especially in deep faces and hard rock, where cost per ft is always high. The larger bits permit wider spacing of holes, and greater weight of tools prevents excessive drifting and seems to compensate for greater area of rock cut, so that the cost per ft is no more (often less) than for 6-in bits, while drilling cost per ton or yd is less, with little difference in cost of explosive.

Following are comparative costs of 6- and 9-in drills at Tilden Pit, Cleveland Cliffs Iron Co, using Bucyrus–Armstrong 29 T, 9-in bit (*E & M Jour*, Nov, 1937):

	6-in bit	9-in bit		6-in bit	9-in bit
No of holes	14	14	Total explosive, lb	9 300	20 040
Total footage drilled	1 416	1 377	Tons per lb explosive	3.8	3.04
Aver depth of hole	105	100	Drilling cost per ton	$0.074	$0.0334
Spacing of holes	15×22	20×30	Operating cost per ft	$1.95	$1.69
Burden per ft of hole, cu yd	12.2	22.2	Drilling rate, ft in 8 hr	13.7	15.6
Total tons blasted	35 400	62 000			

N Y Trap Rock Corp, on Hudson River, aver of 4 years' operation in 4 quarries, based on 5 000–35 000 ft drilled per yr:

Kind of rock	Aver depth of hole, ft	Diam of hole, in	Spacing, ft	Ft per hr elapsed time	Cost per ft
Dolomite, hard	70	8	17 × 24	2.03	$1.13
Limestone, soft	35	6	14 × 18	2.75	0.64
Limestone, medium	110	10	15 × 27	3.11	1.06
Basalt, hard	120	8	22 × 30	1.4	2.12

Cost of operating churn drills (see Sec 9 for tabulated data). For steam power about 10 or 12 bbl of water and 500 to 650 lb of coal per day are required; for gasolene power (gasolene @ 12¢ per gal), cost is from 70¢ to $1.20 per day; with electric power at 2¢ per kw-hr, cost is about $1.25 per day. A compressed-air operated churn drill uses about as much air as a 3.25-in piston drill. About 2 gal wash water are required per ft of hole. If necessary, it can be collected and used repeatedly. SHARPENING BITS costs much less than for machine drilling; one bit, drilling 10 to 50 ft of hole, requires 1 hr to dress.

Comparative cost of churn and machine drilling. A Cyclone drill, making 3-in holes, 24 ft deep, in solid brown sandstone in Ohio, put down 602 ft in 14 days of 10 hr, or 50 ft per day (20). A 3.25-in machine drill, making 1.75-in holes, 20 ft deep, put down 28 holes in 8 days, or 70 ft per day.

Table 8. Speed of Blast-hole Drilling with Churn or Cable Drills (Original)

Kind of material	Ft per hr	Diam hole, in	Depth, ft	Machine	Remarks
Clay, soapstone	10	5 5/8	18	....	Railroad work
Limestone	9	5 1/2	30	Cyclone	Cement quarry
Limestone	8	5	34	Cyclone	Lime, crushed-rock quarry
Shale	6	5 5/8	20	Cable drill	....
Overburden, porphyry ore	5.7	....	55	Keystone	Open-cut mining
Limestone	5.5	5 5/8	....	Keystone	Crushed stone
Hard basalt	1.6	8	120	Cyclone	Crushed stone
Soil, gravel	5.2	2 1/2	23	Cyclone	....

Shale	2–8	4 1/2–6	20–80	Star	....
Limestone	3.2	10	110	Armstrong	Crushed stone
Copper ore	1.5–2.5	6	30–35	Star	Mining
Limestone	3.0	6	200	Loomis	Cement quarry
Limestone, sandstone	1.0	5 5/8	20	Cable drill	....
Hard limestone	2.1	8	70	Armstrong	Crushed stone

Daily field costs (exclusive of sharpening) of the above work were: Churn drill. Runner, $3; helper (and fireman), $2; water, 60¢; coal @ 10¢ per bushel, 60¢; total, $6.20; cost per ft, $12.54. Machine drill. Runner, $3; helper, $1.50; fireman, $2; water, 75¢; coal, $1; total, $8.25; cost per ft, 11.8¢. The larger diam of the churn-drill holes saved dynamite, as each hole was sprung but 3 times, whereas the machine-drill holes had to be sprung 4 or 5 times. See also Sec 9.

5. THEORY AND PRACTICE OF BLASTING

Conditions influencing results of blasting: size and number of free faces; cohesive strength of the rock; structure of rock (massive, jointed, laminated, stratified, or fissured); strength and nature of the explosive; character of fuse and stemming; whether the shot acts alone or simultaneously with others; whether the broken rock falls or must be lifted by the blast; form and size of chamber containing the explosive; proportion of length of line of least resistance to length of the hole, and to height of free face (3, 11, 20). See also Sec 4.

Rules for blasting. Many have been formulated, but all neglect some of the conditions stated above. Also, most published rules are applicable to black powder only and are valueless for high explosives; and practically all ignore the use to which the blasted rock is to be put. Hence, experience and judgment are more useful in determining proper methods than the theories and rules summarized below. Theory of blasting is discussed in detail in (5). According to the CRATER THEORY, a charge in a mass of earth or rock with horiz surface will blow out a funnel-shaped crater, the sides of which have a slope of 1 to 1 to the FREE FACE (Fig 5). Distance *DB* (more exactly, *DF*) is the LINE OF LEAST RESISTANCE $= l$; hence, volume of crater is $V = 0.33\ l \times \pi l^2 = l^3$ (nearly). Hence, general formula for volume of rock loosened is $V = ml^3$. According to Schoen (5), $m = 0.4$ for tough, soft rock, and 0.9 for hard, brittle rock.

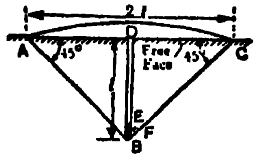

Fig 5. Theoretical Crater, Normal Hole

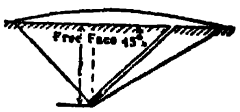

Fig 6. Theoretical Crater, Oblique Hole

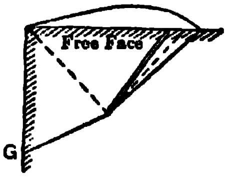

Fig 7. Hole with Two Free Faces

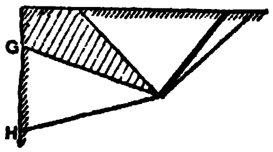

Fig 8. Hole with Two Free Faces

Direction of hole. If vertical (normal, as in Fig 5), the charge may blow out stemming and fail to break; hence, hole should be inclined (Fig 6), to reduce chances of a blow-out, as well as to increase area of free face and volume of rock broken. Limiting inclination of drill hole is 45°.

Effect of free faces. The greater the area of free face, the easier can rock be blasted. Fig 7 shows area of volume broken when there are 2 free faces (point *G* being uncertain). Fig 8 shows area when charge is at unequal distances from the 2 faces; shaded area will probably not be removed by the direct force of the blast, but may be broken indirectly. When 2 or more free faces are exposed, the longest line of resistance should not exceed 1.5 *l*. To obtain the aid of gravity, *l* should be horiz, and the longest line of resistance vertical.

Relation of factors. Length l should be proportioned to size and diam of the hole. In general, in open-cut work the depth of holes should approximate 1.5 l.

Table 9. Relations of Diam and Depth of Hole, and Line of Least Resistance

Diam of hole, in	Depth of hole, ft	l, ft	Diam of hole, in	Depth of hole, ft	l, ft
1.25	3.50	3.50	1.5	12.00	6.00
1.25	5.75	3.75	1.75	5.00	5.00
1.25	10.00	5.00	1.75	9.00	6.00
1.5	4.00	4.00	1.75	14.00	7.00
1.5	7.50	5.00			

Holes blasted simultaneously. Fig 9 shows the effect. If a and b are blasted separately, c would not break out; when blasted together c is broken, if x is not too great. In aver hard rock $x = 1.5\,l$ to $2\,l$; in weak rock, x should be about equal to l.

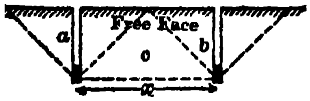

Fig 9. Effect of Holes Fired Simultaneously

Rock coefficient. To obtain it, select a homogeneous bench 2 ft wide by 3 ft high. In this drill several vertical holes, so spaced that the blasting of one will not crack nor start the rock around another. Charge each with different weighed amounts of the explosive to be used, beginning with a small quantity. Fire the holes separately. If C = rock coeff, P = wt of powder, lb, l = line of least resistance, ft; then $C = P \div l^3$, and $P = Cl^3$. For 3 free faces, use 0.66 P; for 4 faces, 0.5 P; for 5, 0.4 P; for 6, 0.25 P.

Size of drill hole for charge. If P = wt of explosive, lb; g = sp gr of explosive, and d = diam of hole, ft; then, $P = 0.34\,gd^3$.

Spacing holes in open-cut work. Much depends on depth of cut, character of rock and diam of hole. In aver size machine-drilled holes for shallow cuts, 6 ft and less, vert holes in most rocks should be set back from face a distance equal to depth, and spaced apart a distance 0.85 of depth. With holes to 12 ft deep, spacing and burden should be about 0.65 of depth; to 20 or 25 ft, spacing and burden should not exceed 0.5 depth (usually less in hard rock) unless holes are sprung, in which case spacings may be wider.

Deep holes for quarry blasting (22). In homogeneous rock having a vert face, 3 resistances tend to counteract the explosive force (Fig 10): (A) resistance distributed along the hole, caused by the rock's tensile strength. This may be resolved into a single force acting midway between top and bottom of face, and of a magnitude equal to total distributed resistance; (B) shearing resistance across the horiz line between the hole and bottom of face, represented by the rock's shearing strength; (C) frictional resistance to sliding at the bottom.

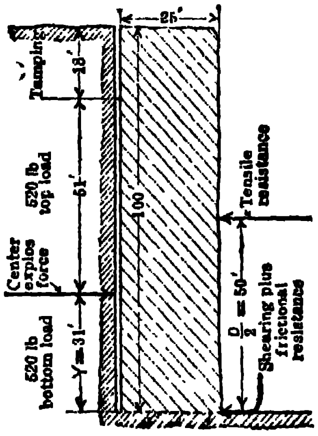

Fig 10. Forces to be Overcome in Deep-hole Blasting (22)

Computations. Limestone of 165 lb per cu ft has tensile strength of 82 000 lb and shearing strength of 184 000 lb per sq ft; granite of 168 lb per cu ft has tensile strength of 101 500 lb and shearing strength of 287 000 lb per sq ft. If d is depth of hole and b its distance back from face, then in limestone for each ft of width of spacing between holes: 82 200 d = tensile resistance, considered as concentrated at midpoint of depth; 187 000 b = shearing resistance concentrated at bottom; and 165 × b × d = wt of the block. Assuming coeff of fric = 0.65, 107 bd = fric resistance to sliding at bottom. For granite, the computations are similar. Values of shearing resistance apply to homogeneous rock; not where there is a parting line at the quarry floor.

Ideal method would be to concentrate enough explosive in bottom of hole to overcome shearing and frictional resistances, and distribute enough explosive throughout the hole to overcome tensile resistance. In practice this is rarely feasible; if the charge be distributed throughout the hole, its total force may be considered as concentrated at a given point, half above and half below. For max effect, this point should be so located as to balance opposing resistances. In Fig 10 it is at a distance Y above the bottom, proportional to the rock resistances. That is,

$$Y = \frac{d}{2} \times \frac{\text{Tensile resistance}}{\text{Tensile resistance} + (\text{shearing resistance} + \text{frictional resistance})}.$$

For limestone (see above) $Y = \dfrac{d}{2} \times \dfrac{82\,200\,d}{82\,200\,d + 187\,000\,b + 107\,bd}$.

Similarly for granite. Thus, for practical purposes, Y is the dividing point of the charge, half the total being below this point and half above.

To find the wt of explosive required, the depth of hole, its distance from the face, and the spacing between holes, must be known. From these factors the BURDEN in cu ft and tons on each hole is computed. Location of holes to give best fragmentation at low cost must be determined for each case by trial. If there is no parting at the quarry floor, the holes must go below floor line to insure breaking to bottom (Table 10).

Table 10. Aver Spacing of Deep Holes in Quarry with Vert Face (22)

Depth of hole, ft	Height of face, ft	Distance back, ft	Spacing, ft	Height of bottom charge, ft	Diam hole at bottom, in	Depth of top tamping, ft
20	18	13	10.5	3.5	4	9
30	28	14.5	12	6.5	4.25	10
40	37	16	13	10	4 5	12
50	47	17.5	14	13	4.75	13
60	56	19	15.5	16	5	14
70	66	20.5	16.5	20	5.25	15
80	75	22	18	23	5.5	16
90	85.	23.5	19	27	5.75	17
100	94	25	20	30	6	18
160	152	35	20	52	8	25

Height of bottom charge given in Table 10 is an aver between limestone and granite. Assuming aver duty of explosive to be 4 ton of rock broken per lb of explosive, and spacing as shown, a 100-ft hole in limestone would have a burden of $\frac{100 \times 25 \times 20 \text{ ft}}{12 \text{ cu ft per ton}} = 4\,166$ ton, requiring a charge of 1 040 lb. Applying previous formula,

$$y = \frac{82\,200 \times 100}{(82\,200 \times 100) + (187\,000 \times 25) + (107 \times 25 \times 100)} \times (100 \div 2) = 31.4 \text{ ft.}$$

Thus, half the charge (520 lb) should be in the lower 31 ft of hole. Wt of explosive contained in a given depth of hole depends on diam of hole and density of explosive. In Table 11, cartridges are assumed to be slit and well tamped to fill the hole completely, with no air spaces.

Table 11. Approx Weight (Lb) of Explosive Contained in 1 Ft of Hole

Diam of hole, in	Straight N G	Gelex type	Red Cross Extra	Quarry Gelatin	B Blasting Powder	Du Pont Extra D
4	6.60	6.1	6.33	7.35	5.28	5.46
$4\,^1/_2$	8.40	7.7	8.06	9.35	6.72	6.95
5	10.50	9.7	10.08	11.69	8.40	8.71
$5\,^1/_2$	12.6	11.3	12.1	14.0	10.1	9.80
6	15.0	13.8	14.4	16.7	12.0	12.55
7	20.4	19.0	19.6	22.7	16.3	17.09
8	26.7	24.5	25.6	29.7	21.4	21.85
9	33.7	31.2	32.4	37.6	27 0	27.68

Depth of lift. In deep open cuts or pits, rock is usually excavated in 2 or more benches or lifts. Depth for economical drilling, size into which the rock breaks on blasting, and presence or absence of seams or of horiz drill holes (called toe holes) which might assist breaking, all determine economic height of lift. $3\,^1/_8$ and $3\,^1/_2$-in machine drills are good to depths of 16 to 24 ft. Churn drills are efficient for almost any depth, and where they are used lifts of 100 ft are common. Max depth for hand drilling is usually about 8 ft with hand hammer, and for machine drills, 18 ft. As a rule, the higher the bench, the farther back from the face may the holes be located; but, the farther back the holes, the coarser will the rock break. In deep holes, the explosive should be separated into several charges with stemming between; for, if the entire charge is at the bottom of the hole, the bottom of the bench may be blown out and the top left overhanging. If 2 rows of horiz holes are drilled in the face, besides the vert holes, height of bench may be increased.

Examples of open-cut blasting indicating that 4–6 ton of rock can be broken per lb explosive (25). Limestone quarry in Tenn, stone used for R R ballast, etc. Blast was of 16 $5\,^5/_8$-in holes; aver depth, 75 ft; spaced 18 ft apart; aver face burden, 22 ft. Charge of 3 750 lb 60% and 3 700 lb 40% low-freezing dynamite broke 5.7 ton per lb.

Blast in cement rock, in Penn, of 14 $5\,^5/_8$-in holes; aver depth, 86 ft, spaced 18 ft; face burden, 30 ft. Charge of 4 850 lb 60% and 3 250 lb 40% dynamite broke 55 000 ton, or 6.8 ton per lb.

Kentucky limestone quarry, for R R ballast; 9 holes, aver depth, 50 ft, spaced 18 ft apart and 25 ft back; 3 250 lb 40% dynamite broke 16 200 ton, or 5 ton per lb.

Table 12. Spacing of Holes, Charges, and Results of Machine-drill Blasts (Original)

A. Dynamite. *B*. Black powder. (*a*) 35 holes. (*b*) Holes sprung with 2 lb dynamite. (*c*) Holes sprung. (*d*) 45 holes. (*e*) 60 holes; top holes, vertical, 26 ft deep. (*f*) 75 holes; 2 toe holes, one at 15° and one at 60° with vertical, 10 to 14 ft deep, the former being 6 ft away from & 2.5 ft in front of latter. (*g*) Sprung 3 times. (*h*) 1st row 6 to 15 ft, from face; 2nd row, 7 to 10 ft from first row· about 2.5 lb of 75% dynamite & 6.25 lb of 60% per hole. (*i*) Holes staggered. (*j*) 30 holes; holes at angle of 15° with vertical. Sprung with 3 lb of dynamite.

Oklahoma quarry, for R R ballast; 8 holes, 95 ft deep, spaced 28 ft; aver face burden, 33 ft. Charge of 2 200 lb gelatin, 3 350 lb 60% and 1 250 lb 40% dynamite broke 62 000 ton, or 9 ton per lb. Blast badly balanced, requiring very strong explosive at bottom. Cost per ton was as high or higher than a well-balanced blast.

Blast in iron ore of 26 5 $^5/_8$-in holes; aver depth, 84 ft; spaced 15 by 15 ft; triple loaded; 8 500 lb 40% dynamite broke 50 000 ton, or 5 ton per lb.

Blast in cement rock, in N J, of 11 holes; aver depth, 102 ft; spaced 20 by 22 ft; 2 040 lb 60% and 4 475 lb 40% gelatin broke 40 000 ton, or 6 ton per lb.

A 75 000-ton blast, West Va, cost 3.3¢ per ton (1915). Of 15 6-in holes, 13 were 125 ft deep, drilled about 5 ft below quarry floor; 2 holes were 72 and 85 ft. Aver spacing, 15 ft; top burden of 8–12 ft; bottom burden 25–35 ft. Charge per hole, 400–500 lb 60% gelatin, on top of which were 150–600 lb du Pont quarry powder. Cordeau fuse was held taut while cartridges were dropped down the holes. In 10 holes, charges were split near middle by 10–20 ft clay tamping; 5 holes were loaded solid, with 30 ft tamping. On each line of Cordeau was 1 No 6 du Pont electric cap. Caps were connected in series and tested. About 50% of the stone was broken to 1-man size; none thrown over 100 yd from face. Aver burden per hole, 2 000 cu yd; aver charge, 900 lb. Total rock broken, 60 500 loose yd (75 000 ton), or 5.5 ton per lb. Cost per ton: explosives, fuse and caps, 2.2¢; drilling and charging, 1.1¢.

6. CHARGING AND FIRING

For facts respecting ordinary methods of charging black powder and dynamite, including data on fuse, detonators, squibs, tamping, and electric firing, see Sec 4, 6 (14, 20). *Note.*—Stemming is the tamping material; tamping, the act of inserting stemming.

A. Dynamite. *B*. Gelatin. *C*. Nitramon. *D*. Black blasting powder. *E*. Limestone. *F*. Sandstone. *G*. Porphyry. *H*. Basalt. *I*. Copper porphyry. *J*. Tough carbonate. *K*. Gravel. *L*. Ore and capping. (*b*) Per hole. (*e*) Sprung with 150 lb of 40% dynamite. (*f*) Holes in 5 parallel lines: 1 center line, 2 lines 10 ft away; 2 lines 24 ft from center line. Holes staggered, 14 ft apart, and chambered with 60% dynamite. Loading required 8 days. (*g*) Per hole. (*h*) Holes on center line, the first being 18 ft from face. Holes sprung with 15 sticks 60% dynamite, then 55 sticks, then 275 sticks. Tamping, after springing, cost $12 to drill out. (*i*) Per hole; cost of blasting about 5¢ per cu yd.

Deep-hole blasting. For this it is often advisable to place the dynamite in several distinct charges separated by stemming, each charge having its own primer, or all connected by a line of Cordeau fuse or Primacord. If the rock consists of hard and soft layers, charges should be placed in the hard layers. Contractor's powder and free-running high explosive grades are charged like black powder, but are exploded by a dynamite primer. Other grades and all dynamites are exploded with detonators. If black powder and dynamite are charged in the same hole, the dynamite should contain the primer.

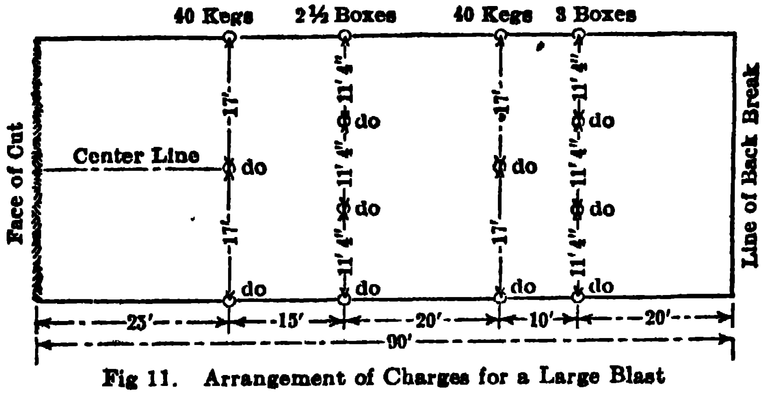

Fig 11. Arrangement of Charges for a Large Blast

Dynamite and black powder in one blast. In blue sandstone large charges of black powder and dynamite in alternate rows of holes were found effective (20). In Fig 11, the 24-ft holes were made with churn drill, with 3-in bit. Holes marked "kegs" were loaded with 25-lb kegs of black powder; and those marked "boxes" were loaded to within 4 ft of the top with 40% dynamite, as shown. Before loading holes with black powder, each one was sprung (see below); first with 15 sticks of 1.25 by 8-in size dynamite, second with 40 sticks, third with 80 sticks, and a final charge of 130 sticks of 40% dynamite per hole. The dynamite and powder were fired together, on the theory that the powder would lift the rock and the dynamite would shatter it. About 2 700 cu yd of rock were broken in one blast, with 800 lb of dynamite for springing and 6 000 lb of black powder and 1 100 lb of dynamite for the final charges.

Springing deep holes (26) (Sec 4, Art 8, 9). By starting with a small charge, followed by gradually increased charges, the chamber at bottom of hole can be made nearly spherical, giving best concentration of explosive. First springing charge should not occupy more than 0.05 of total depth of hole.

Gelatin dynamite is best for springing; it is safe, its plasticity and density eliminate air spaces, and, though slow in action when shot in the open, it has max quickness when confined, except in hardpan, clay and similar material; in these soft materials, ammonia dynamite is preferable. Charge should be packed solidly, to exclude air; stemming free from broken rock and small in amount, so the springing charge will drive it out of the hole. Water stemming has advantages due to ease of application; it reduces amount of rock blown out and keeps the hole cool, which is necessary before making the main charge. Springing shots should be fired electrically. After study of bore-hole temperatures, the du Pont Co recommends that no explosive be placed in a sprung hole if a tamping stick left in the hole about 5 min feels warm to the hand. When holes are left to cool naturally, it is well to regulate the intervals between charges as follows: after first spring, 1 hr; second, 2 hr; third, 3 hr; fourth, 4 hr; fifth, 5 hr. After last springing, wait until next day before charging. Heavy springirg is not advisable in soft shales, as it may fill the chamber with debris. In highly inclined strata, the shock of springing may cause a slip and close the hole.

Charging deep holes. If the rock is seamed and cracked, the charge should not extend to upper part of hole; there must be ample space for stemming.

Referring to Table 10, for 6-in holes of depth and spacing as in Fig 12, 18 ft of stemming is recommended; leaving 51 ft between bottom charge and stemming for second half of charge. 520 lb of Red Cross Extra would fill 36 ft of the hole, leaving 15 ft for stemming. For max effect, it would be best to divide the charge into 4 sections, with 5 ft of stemming between them. For electric blasting, it is unwise to split the charge into so many sections, due to difficulty of wiring. Where there are both hard and soft strata above bottom charge, the explosive is placed in the hard strata and stemming in the weaker. In uniform rock, broken charges are placed in adjoining holes so that explosive and stemming alternate along the line of holes.

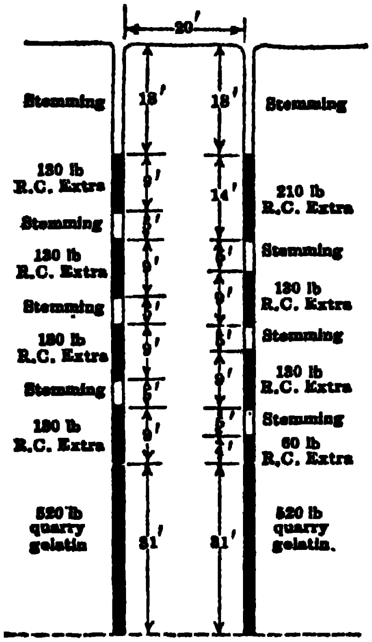

Fig 12. Alternate Methods of Charging a 6-in Hole

Length of bottom charge is worked out as above for the different depths and spacings of holes in Table 13. When the face slopes, causing heavy toe resistance, explosive can be concentrated at the bottom by drilling larger diam holes, or decreasing the spacing; a row of staggered holes at the toe assists in such cases. With a well-defined parting line at the quarry floor, it is rarely necessary to drill below grade; and, as the shearing resistance is then reduced, less explosive is required near the floor.

Separate calculations for each hole (38) give best results and at lower cost. Fig 13 shows a blast that might have done serious damage had its charge not been carefully computed. The bank was irregular; parts having considerable overhang, and some holes an unusually heavy toe. If charges in holes 2, 7, and 8 had not been broken

near the bottom, where the bank sloped inward, fragments of rock might have damaged buildings and plant, which were within 300 ft of the face. By care in computing each charge, no rock was thrown more than 150 ft.

Force of explosives (23). Total energy of an explosive (Table 14) is the sum of its shattering (percussive) and propellent forces; for practical results, the relative shattering and propellent values must be known (Table 15).

If for a given case an explosive is not sufficiently shattering, use one of equal total energy but greater percussive value. For throwing broken rock farther, use an explosive of greater propellent force; or, if in this case, the rock was breaking to desired size, use explosive of greater total energy.

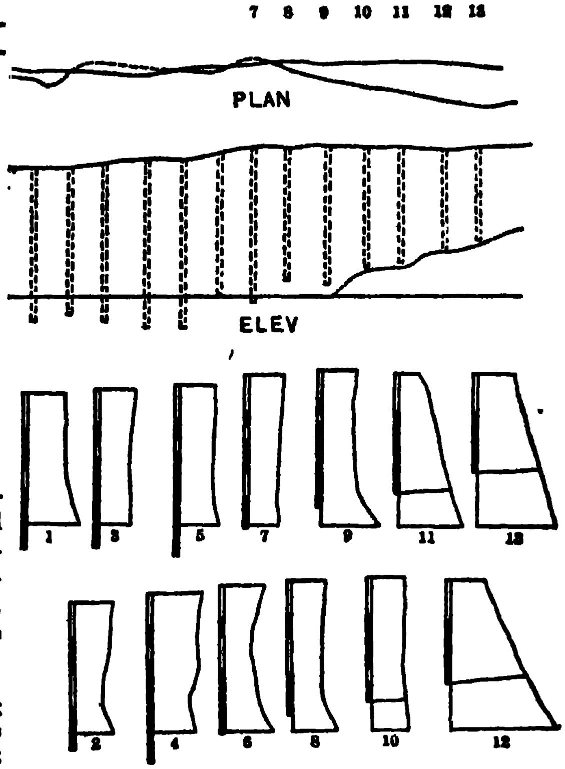

Fig 13. Different Loadings for Varying Conditions of Quarry Face

Blasting formulas are inaccurate, because of difficulty in measuring the actual force developed, uncertainty as to the BURDEN on the charge, and varying rock characteristics. Tests are always necessary, but empirical formulas and all available data are useful as guides.

General remarks on explosives: shattering effect increases with speed of explosion; effic varies with degree of confinement of charge; excessive noise means wasted energy. Useful effect depends upon suitability of an explosive for its work, as well as upon its strength, i e, upon the force it develops. Straight dynamites are rated on percentage by weight of nitroglycerin (NG) contained; a 40% straight dynamite contains 40% NG, and any other kind (regardless of content) which develops the same force, weight for weight, is rated as 40%, the rating of straight dynamites serving as a reference. A dynamite of 40% *bulk strength* develops the same force *volume for volume*, as a 40% straight dynamite. Some high explosives, as the permissibles, the du Pont "Extras" and certain others for special work, are not rated by percentage, but marked by numbers or letters designating strength. Force developed is not in direct ratio to percentage rating; a 40% dynamite does not develop twice the force of a 20%, because ingredients other than NG and ammonium nitrate have some explosive effect of their own, altering the ratio. True ratios are shown in Table 16; 1 cartridge of 40% is equal in force to 0.87 cartridge of 60% or 1.31 cartridges of 20%, except that in soft material the ratios may be lowered by greater spreading and heaving effect of the lower grades of explosive.

Table 16. Equivalents of Dynamite of Different Strengths

One cartridge % N G	60%	50%	45%	40%	35%	30%	25%	20%	15%

Chamber blasting is done by driving a small tunnel or sinking a shaft, at the end of which chambers are excavated for the main charges of explosive. For black powder the chamber may be below the floor of the drifts, for convenience in pouring loose powder into large wooden boxes, built in the chambers. The tramping of the men packs it tightly and the solid sides of the excavation offer greater resistance to the explosion. **COYOTE HOLES** are one-man tunnels or drifts (Fig 15).

Chamber blast, St. Helena, Ore (Fig 14). The rock was basaltic, weighing 175 lb per cu ft. Explosive was No 2, MV Trojan powder; charge, 3 500 lb. The tunnels were tamped to the portal with muck. The rock was sufficiently broken to be handled by steam shovel, little bulldosing (sledging) being necessary. Vol broken, 14 280 cu yd.

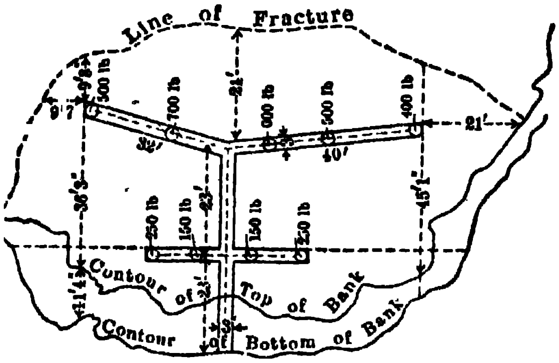

Fig 14. Chamber Blast at St Helena, Ore

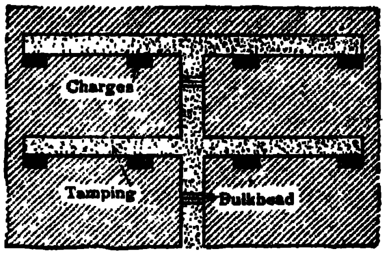

Fig 15. Tunnel, Crosscuts and Powder Pockets for Coyote Blasting (27)

Coyote-hole blasting (27). A tunnel about 2.5 by 3.5 ft section is driven into the face, length being equal to $^2/_3$ height of face above tunnel. At end of tunnel and forming a T is a crosscut, approx equal in length to main tunnel. At each end of crosscut is sunk a powder pocket, large enough to contain the charge; their depth = 1 ft for each 10 ft of toe in front of pocket; vertical banks required less depth (Fig 15).

An offset to hold the charge may be driven from the crosscut, or the charge is simply placed on floor of crosscut, but a sunken pocket confines the charge better. When length of tunnel is greater than height of quarry face, 2 or more crosscuts are driven to distribute the charges properly; this may also be necessary when rock is blocky. If rock is hard and high fragmentation desired, 2 or more powder pockets, 15–25 ft apart, are made in each crosscut.

Charges. Coarse-grain black powder, primed with 5–10% of its wt of 40 or 60% straight dynamite, gives best results. To find required charge, first compute the cu yd of material above the tunnel ("yardage in the square of the shot") = (length of tunnel × length crosscut × aver height of face, ft) ÷ 27. A well-designed blast often breaks twice the yardage in square of shot, but the above is conservative. For road-surfacing rock, the charge is 0.3–1.5 lb per cu yd in square of shot. To throw rock clear of right of way, as in sidehill road making, the charge may be 1.75–3.5 lb per cu yd; for this purpose, better err on side of over-charging; a good blast will throw 60–80% clear of right of way.

Charging (27). One 50-lb case 40% straight dynamite is placed in bottom of each powder pocket, 3 cartridges being primed with electric caps. Electric blasting cap wires are connected in series, if a blasting machine is used, or in parallel if fired by a power current (Fig 16). Free ends of wires are connected to No 14 gage duplex leading wire, running out to the face. All joints well taped and leading wire wrapped in roofing paper or gunny sacking to protect from injury.

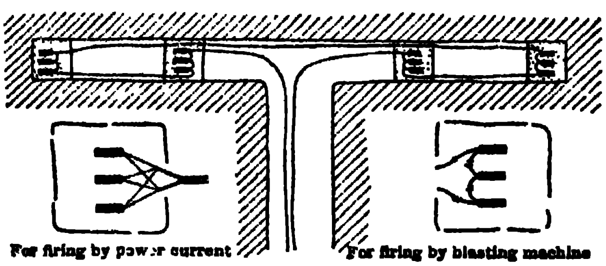

Fig 16. Modes of Wiring for Coyote-hole Blasting (27)

Computed charge is placed in the pockets on top of primer. Loading explosive in original packages saves time, and is safer; but, in charging blasting powder in sidehill work, for wasting the rock, it is best to pour it into the pockets. The charge is covered with dry earth or rock screenings. One wire from right-hand pocket is connected with a wire from left-hand pocket, and the 2 free wires are connected through the leading wires to the blasting machine. For max detonating effect, run a line of countered Cordeau fuse from unit to unit, with a coil on bottom of each pocket. When any one charge explodes, the Cordeau detonates the others.

Crosscuts and tunnel are finally tamped with broken stone. Logs are often used to aid in confining filling; a row being laid crosswise on floor at end of tunnel, their ends projecting into the crosscuts. Spaces between the logs are filled with clay. Other layers of logs follow, to the roof of tunnel. Main tunnel is then tamped, and blast is ready for firing.

Best theoretical length of tunnel (27) is equal to about $^2/_3$ the height of face; but, with only 1 crosscut, a tunnel more than 60 ft long is impracticable. A shorter tunnel and 1 crosscut generally give best results at least cost; for high banks and large charges several crosscuts may be driven.

(a) Champion powder, 7 and 9% Ngl. (b) Trojan powder.

Notes on Table 17 (20). I. West Beaver Creek dam, Col. Tunnel 75 ft below apex of rock, 135 ft long, with several bends. Cross drifts, 35 ft long, each way from end of tunnel. Charges at ends of cross drifts, with 3 000 lb of powder along outer wall of remainder of cross drift. Stemming: rock, earth, timber. II. Otay, Cal. Tunnel, 4 by 5.5 ft, 50 ft long. 18-ft Y-branches at end for chambers. Charges: 4 000 lb Judson powder and 50 lb dynamite in one chamber; 8 000 lb powder and 50 lb dynamite in other. Cost: drifting, $645; powder, $960; charging, $75; total, 3.6¢ per cu yd. Further breaking by powder in seams made total cost 5¢ per cu yd. III. San Diego, Cal. Morena dam. Open cut perpendicular to face, with 4 by 5-ft drift, 115 ft long, parallel to and 100 ft from cut. Chambers sunk beneath floor at end and 70 ft from face. Face chamber contained 500 lb 7% Champion powder and 1 500 lb 40% dynamite; end chamber, 28 550 lb 7 and 9% powder, 1 900 lb 40%, and 2 000 lb 60% dynamite. Stemming: earth, timber. Cost: open-cut, $3 500; drifting and charging, $2 478; explosives, $3 116; total, 5.05¢ per ton. IV. Northampton, Pa. Quarry. Face, 135 ft high. Drift, 3 ft wide and 238 ft long, along a fault 50 to 100 ft from face. 4 chambers below tunnel, 45 ft apart, and 3 crosscuts each way, 25 to 56 ft long. Total cost, $3 825. V. Ferrino, Wash. Quarry. 65-ft face. Two 3.5 by 4-ft drifts, 200 ft apart; one 150 ft long, with 3 crosscuts 50 ft apart, each 80 to 100 ft long; the other 180 ft long, with 4 crosscuts, each 70 to 100 ft long. 60% dynamite. Stemming: muck, timber, and cement bulkheads. VI. Piedra, Cal. Quarry. Aver height of face, 91 ft; aver overburden, 68 ft. 6 drifts, each 80 ft long, with 2 crosscuts each side. Crosscuts 40 ft apart, 40 ft long. Pits at ends of cuts. 60% dynamite and Judson R R P. Cost of explosives, 2.6¢ per cu yd. VII. St Helena, Ore. Quarry. Drift, 3 ft wide by 46 ft long, with crosscuts at end, one 32 ft, the other 40 ft long. Halfway from face, a crosscut in each side, 32 ft long. No 2 Trojan powder in 4 charges of 150 to 250 lb in short cut and 5 charges of 400 to 700 lb in long cut. Cost: explosives, $359; loading, $58. VIII. Corona, Cal. Quarry. Overburden, 80 ft. Drift, 110 ft long, with side drift 60 ft from face, 15 ft long to left and 40 ft to right; diagonal drift 80 ft from face, 40 ft to left, and at the end a diagonal drift 50 ft to left and a straight drift 50 ft long to right. End of drifts charged with Judson R R P and 60% dynamite. IX. U P R R. 18-ft cut. 2 pits charged with 26 lb dynamite and 2 775 lb of powder. Cost, about $1.10 per cu yd. X. Long Cove, Me. Shaft, 4 by 4 ft, 64 ft deep, with 2 drifts at bottom, each 27 ft long. Crosscuts from ends of drifts, 26 ft long. Explosives in crosscuts. Estimate of 1 000 000 tons broken seems too high. XI. Paragon hydraulic mine. Face, 150 ft high. Drift, 110 ft long. Crosscut at right, 70 ft long, with drift at end, parallel to main drift, 55 ft long. Crosscut at left, 60 ft long, with drift at end, 30 ft long. Much space left untamped for expansion of gases. Cost: drifting, $300; explosives, $2 700. XII. Blue Point hydraulic mine. Drift, 3 by 4 ft, 275 ft long. 6 crosscuts, each 120 ft long on left; 6 on right, each 80 ft long. First drift on right, 75 ft from portal, and at end a 15-ft drift, parallel to main drift. XIII. Dardanelles mine. Face, 175 ft high, 1 200 ft long. 5 parallel drifts, across each of which were 2 or more crosscuts. Total length of drifts, 1 200 ft. XIV. Hydraulic mine. Giant powder No. 2. XV. Colorado. Dam. Coyote or one-man tunnel, 40 ft long. 2 crosscuts from end,

each 12 ft long, with pits at end. Explosive, FFB powder and 40% dynamite, charged in pits. Stemming: earth. Cost: labor, $384; dynamite, $155; powder, $1 140; caps and fuse, $11. Total, 16.9¢ per cu yd. XVI. Oregon. R R. Coyote hole, 2.5 by 3 ft in hillside, 50 ft deep. Crosscuts at end, 75 and 45 ft. Charges in the 3 openings. XVII. Crooks Landing. R R. 4 or 5 coyote holes, 80 ft long, with Ts 40 to 60 ft long at ends. XVIII. Oregon. R R. 165 ft breast. XIX and XX. Oregon. R R. XXI. Snake River, Wash. R R. 75 coyote holes, 2.5 by 3 ft, each averaging 89 ft long, run into and then parallel to sidehill face. 3 500 ft of cliff mined by 6 177 ft of coyote holes. 20 000 lb of dynamite used in preparing for main blast of F to 5 F black powder. XXII. Oregon. Coyote holes. No 2 Trojan powder. XXIII. Smartsville, Cal. Hydraulic mine. Shaft, 74 ft deep, with main drift 185 ft long from bottom. 3 crosscuts, 70, 120, and 170 ft from shaft, 40 ft long on either side. 10 lifter drifts from crosscuts, each 15 ft long, parallel to main drift. Total drifts, 570 ft long by 2.5 ft wide by 3.5 ft high. Material moved, 270 by 180 by 100 ft. *Note.*—Above costs are pre-war.

Gophering is a mode of blasting used in breaking the overburden in the Mesabi, Minn, mining districts, and elsewhere, in sandy, loose ground, where vertical holes can not be kept open (20). (See *Eng & Min Jour*, Vol 88, p 696.) A hole is bored with a pointed bar, at a down angle of 15° to 20° in the side of the bank. Dynamite cartridges, placed end to end, are pushed into the hole and exploded. The muck is removed with a long-handle shovel, the hole deepened further, and the process repeated until a hole 10 or 12 in diam and deep enough is obtained. A chamber is made at the end by springing with 2 or 3 cartridges. A long-handle box filled with powder is pushed in and overturned.

Boulder blasting is done by: mudcapping or bulldozing; blockholing; and undermining or snakeholing. Other cheaper methods are: by sledging; by drop-hammer or drop weights; by heating with fire and then cracking by applying cold water; by a combination of 2 or more of these methods. Heating can not be used with boulders larger than 0.5 to 0.75 cu yd. Mudcapping consists in exploding a charge of dynamite on the surface of a rock, after covering it with earth (Fig 17); it is most effective when a depression is selected for the explosive, if the cap is laid on the dynamite and not shoved into it, and if wet clay is used as a covering. Snakeholing consists in boring a hole beneath a boulder and firing a charge in it (Fig 18). It is more efficient, but not so rapid as mudcapping. Blockholing consists in drilling a shallow hole in the boulder for small charge of dynamite.

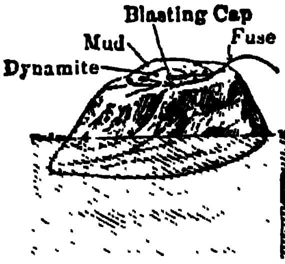

Fig 17. Mudcapping

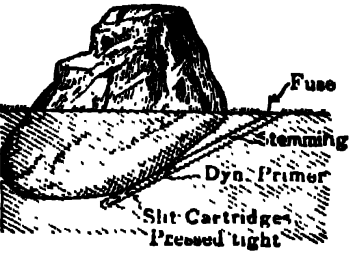

Fig 18. Snakeholing

Relative costs per cu yd of breaking boulders, from a number of pre-war records (20) was: sledging, 4.3¢; drop-hammer, 6.5¢; heating, 14.9¢; blockholing, 16.8¢; undermining, 17.5¢; mudcapping, 31¢; mudcapping and sledging, 32.1¢.

Table 18. Charges for Boulder Blasting (du Pont Co)

Weight of boulder, lb	Approx No of 1.25 by 8-in cartridges (40–60% dynamite)			Weight of boulder, lb	Approx No of 1.25 by 8-in cartridges (40–60% dynamite)		
	Mud-capping	Snake-holing	Block-holing		Mud-capping	Snake-holing	Block-holing
500	1.5	1	0.25	4 000	4	3.5	1.25
1 000	2	1.5	0.5	5 000	4.5	4	1.75
2 000	3	2.5	0.67	7 500	6	5	2.5
3 000	3.5	3	1	10 000	8	6	3.5

Details of charging, tamping and firing (see Sec 4, Art 8–10). In general, a charge should not occupy more than 0.5–0.6 the depth of hole (24). The wasteful practice of nearly filling the hole with explosive should be prohibited. In close-spaced holes, the primer is sometimes placed at bottom, as the fuses are then less liable to be cut off by adjacent shots; but this position of primer may cause side-spitting of fuses; primer is best inserted last. Complete detonation being essential for max force, use only strong caps in good condition.

Burning speed of fuse is affected by differences in atmos press. A fuse burning at 30 sec per ft at sea level burns at 40 sec per ft at 5 000 ft, and 50 sec at 10 000 ft. Fuse in a hole full of water burns faster than in a dry hole. For firing holes in sequence, at least 2-in difference in length of fuses is essential; thus, in a 6-hole round, shortest fuse is 12 in shorter than longest.

For electric firing, delay electric blasting caps, electric igniters, wiring of holes, and circuit testers, see Sec 4, Art 10. Switches for taking current from power lines should be enclosed in a box that can not be closed or locked unless switch is open.

Results of tamping experiments by U S Bur of Mines, Traual lead-block method (28): (*a*) for black powder, the best tamping is requisite for max effect; (*b*) for 40% dynamite, even small amounts of good stemming show, by lead-block tests, at least 50% increase in effic (other tests, in actual rock, 20–25%), rate of effic decreasing with more tamping; (*c*) good tamping diminishes danger of ignition of coal gas or dust from blow-out shots; (*d*) considering effic only, the length of stemming should be at least 3 times that of explosive (but in actual practice is usually 0.5–1.0 times). In gaseous or dusty mines, holes should be completely filled with best stemming; (*e*) more stemming is necessary for old or frozen dynamite; (*f*) the larger the diam of hole, the greater the length of stemming required; (*g*) well-stemmed holes produce most perfect detonation, with smallest evolution of poisonous gases; (*h*) moist fine clay or other plastic material makes best stemming for all explosives; dry powdery material is least effic. Wooden tamping bars should always be used.

Table 19. Characteristics of Modes of Firing Dynamite

	Cap and fuse	Electric cap	Delay elec cap	Delay elec igniter and cap
Full energy from explosive	1st	1st	1st	1st
Freedom from misfire	3d	1st	1st	2d
Relative safety to blaster	3d	1st	1st	2d
First cost	1st	2d	4th	3d

Summary: electric firing is best, for both black powder and dynamite, in everything but first cost, which may be greatly increased by misfires or a single major accident.

Use of paper tamping bags (30), containing specially mixed stemming, increases blasting effic; breakage is improved, with possibility of using lower-grade explosive or smaller charges. Cartridge-shaped bags of different sizes, obtainable from makers of explosives, are now widely used.

Anaconda Copper Mining Co has developed a machine for filling tamping bags. At a Virginia coal mine the filling apparatus consists of an inclined receiving table for the screened clay, set on a pitch of 35°, with a horiz shelf at its base. In the shelf is a row of holes 4 in apart, each with a brass tube 1.25 in diam by 10 in long, extending below the shelf. A hinged drop table underneath the shelf supports a series of 1.5-in tamping bags, which are slipped over the tubes and filled. With this device, 1 man fills 4 000 bags in 8 hr.

Avoiding waste of explosives (31). Blasters should be taught to think in terms of cost of explosive, and to figure tonnage of rock broken per ft of hole in number of shots, hole spacing, etc; all of which leads to economy.

Prevention of misfires (33). Use good explosive materials. Keep explosives in dry storage (Sec 4, Art 6). Carefully prepare cap and fuse; cut off 0.25 in of all fuse exposed to air for any length of time; cut fuse squarely across, and push it without twisting motion into the cap (Sec 4, Art 8).

Note.—Table 4 of Sec 4 contains data for making preliminary determinations of the character, grade and strength of explosive for different kinds of rock and of excavation. It is advisable, however, for large-scale operations, and particularly for underground coal and metal mining, to supplement the recommendations given in the table by actual blasting tests and data of work in similar ore or rock (see Art 4, 5; also Sec 6, 7 and, in Sec 10, the data on drifting, crosscutting, stoping, etc).

7. HAND AND MECHANICAL LOADING AND HAULING

Hand work. One man can load 2 to 20 cu yd of rock (place measure) in 10 hr, depending mainly on size of pieces and height to be lifted.

On Chicago Drainage Canal the aver per man in 10 hr was about 7 cu yd loaded into dump cars. Sledging took about 14% of the time. Aver per man loading into low cableway skips, 10 cu yd; LARGE STONES were rolled into the skips, very little sledging being required. In loading wagons with high sides, 1 man will average 10 cu yd solid measure (17 cu yd loose) of easily-lifted stones per 10 hr. Stones handled singly can be thrown off a wagon twice as fast. Stones can be loaded on wagons having stone racks at rate of about 13 cu yd per 10 hr, and rolled off at 50 cu yd per hr (20). CRUSHED STONE can be shoveled from smooth boards or steel sheets at the rate of 13 cu yd solid measure (22 cu yd loose) in 10 hr; in shoveling from the ground or hopper-bottom cars, 1 man will handle only 7 to 8 cu yd solid measure (12 to 14 cu yd loose).

Steam shovel work. Cost of rock excavation varies greatly. In the soft iron ore of Mesabi range, under fair conditions, a steam shovel easily loads 250 cu yd per hr; but, in poorly drilled and blasted rock, broken in large pieces, it may do as little as 17 cu yd per hr.

Table 20. Output of Steam Shovels, Loading Blasted Rock. One 10-hr day's work (13)

Material.....	Iron ore				Limestone			Slate, lime-stone	Por-phyry, granite	Por-phyry	Sand-stone

In N Y mica schist, broken large, a 65-ton, 2.25-cu yd dipper shovel averaged for several weeks about 280 cu yd solid measure per day into cars; part loaded by the dipper, part lifted by a chain hooked over the dipper teeth (20). On Chicago Drainage Canal, 2 Bucyrus 55-ton shovels, with broad shallow 2.25 cu-yd dippers, loaded limestone on one section (Table 20). The rock was in large pieces, much of which had to be lifted with chains. Combined output of the 2 shovels was 118 650 cu yd (solid measure) during 406 10-hr shifts, or an aver of 296 cu yd per shovel per shift (20).

Steam shovels for rock excavation are now largely of the revolving type, with 0.75–4 cu yd dippers and caterpillar treads. They have greater mobility than R R type on car trucks and can always be kept within the most effective range of work. Bucyrus 120B revolving shovel for rock work is in 3 sizes: STANDARD, 4-cu yd dipper, 29.5-ft boom, 20-ft dipper handle; HIGH-LIFT, 3.5-cu yd dipper, 32-ft boom, 22-ft dipper handle; EXTRA HIGH-LIFT, 3-cu yd dipper, 36-ft boom, 25-ft dipper handle. Makers report 260 cu yd blasted rock handled per hr; under favorable conditions, 300 cu yd possible (see Sec 3, Art 8 and Sec 27).

Loading with derricks, and bucket or skip. A horse-operated derrick, with a crew of 1 foreman, 1 hooker, 6 shovelers, 2 tagmen, and 1 dumpman, water boy and team and driver, unloaded 120 cu yd loose measure in 1 day. In using an engine-operated derrick, with a bullwheel for slewing, tagmen (for slewing the boom) and team are eliminated, and an engineman and coal are required. A crew of 1 engineer, 1 signal man, 1 dumpman, and 7 loaders, unloaded from a scow 21.3 cu yd of $^3/_8$-in crushed stone per hr. Clamshell buckets are good for unloading cars and scows.

Cableways (Sec 26) are frequently used in quarry work, canal and trench excavation, and in open-pit mining.

Table 21. Output of 4 Chicago Drainage Canal Cableways (1 month)

	1

Chicago Drainage Canal (20) employed 19 cableways with spans of 550 to 725 ft, traveling towers 73 to 93 ft high, and equipped with aerial dumps. Main cables, 2.25-in, hauling and hoisting cables, 0.75-in, button and dumping cables, 5/8-in. A 70-hp boiler and 10 by 12-in engine gave a hoisting speed of 250 ft, and a traveling speed of 1 000 ft per min. A complete outfit, with 2 by 7 by 7-ft skips, weighed 225 tons. Crew: engineman, fireman, signalman, rigger and laborers for loading. Capac of cableways, 300 to 450 cu yd solid measure per 10 hr.

Arrowrock Dam, Boise irrigation project, Idaho. Two Lidgerwood cableways handled 101 263 cu yd of blasted rock, boulders, gravel and sand. Span, 1 300 ft; aver traveling distance, 500 ft; aver hoisting distance, 300 ft. Hoisting load, 8 tons, at 300 ft per min; conveying speed, 1 200 ft per min. Skips, 8 by 8 by 2 ft. In July, 1912, 2-shift work; in Aug, Sept, and Oct, 3 shifts. Output for 4 mo, 40 624 loads, averaging 2.49 cu yd, practically all handled in 2 shifts. Cost of operation (not including loading), 37¢ per cu yd, as follows: labor, 11.1¢; power, 4¢; supplies, 1.5¢; repairs, 4.7¢; deprec, 6.4¢; preparatory expense, 9.2¢. Wages: laborers, $2.40 per 8 hr; cableway operators, $4 to $5; riggers, $3 to $4. Power cost, 1.5¢ per kw-hr. Deprec was figured on charging off 75% of first cost and all the installation cost (20).

Canal work. On St Mary's Channel Improvement, 4 cableways handled 1 700 000 cu yd of limestone in 2.5 yr. Rock was loaded into skips by 4 60-ton traction-mounted steam shovels. Skips held 6 cu yd each, but sometimes 8 cu yd (18 tons) were handled. 2 cableways had spans of 1 100 ft and 2 of 800 ft. Aver haul, 300 ft. Best month's record for all, 22 000 cu yd each; best month's record for one cableway, 30 000 cu yd (20).

Stone-boats are wooden or sheet-iron platforms, best mounted on runners, for hauling large stones short distances. If the runners are greased, 1 ton can be pulled by a team weighing 2 400 lb. A SKID ROAD is formed of partly imbedded round sticks of timber set like ties of a track 3 to 6 ft apart. A stone-boat holding 0.5 cu yd (solid measure) of rock can be drawn over such a road. A LIFTER or DEVIL is a wooden stretcher on which 2 men can carry as much as 0.5 cu yd. On the Grand Trunk Pac R R (20), rock was cheaply hauled by stone-boats on pole tracks in summer for hauls less than 600 ft, and in winter any distance. Track was of 2 lines of 20 to 30-ft poles, 4 to 8 in diam, 5.5 ft apart for 2-horse team and 3 ft apart for 3-horse team. Poles were joined by 2-in hardwood pins. Boats were of 10 or 12 logs, 7 in diam by 8 ft long, fastened together by 2 1.25-in rods. In winter the track was iced; in summer, greased (1 gal per 100 ft per day). In winter, a team could haul 3 yd rock; in summer, 1.5 yd; aver load, 7/8 cu yd. On a 500-ft haul a team and 6 men took 40 to 60 loads per 10 hr. Aver yardage per man loading, 7.3 cu yd; many rocks were large and had to be blockholed. The excavation comprised: 20% shovel dirt, 30% easily lifted stones, and 50% pieces 1 to 5 yd in volume. Cost of loading, 31¢ per cu yd; cost of transport, 17¢. Wages: muckers, $2.00 to $2.25; foremen, $3.75; maintenance of each horse, 75¢ per day.

Wheelbarrows hold about 0.04 cu yd solid rock; loaded by 1 man in 2 min, and wheeled at 180 to 250 ft per min, losing 0.75 min per round trip.

Carts and wagons. In aver rock, 1 cu yd solid equals 1.75 cu yd broken, and weighs about 2.2 tons. Over poor dirt roads, with occasional steep rises, 0.5 cu yd (1 ton) solid rock may be hauled by 2 horses; on hard, level road, 1.5 cu yd; aver load on good roads, 1 cu yd (2 ton). Aver speed of haul, 220 ft per min. A 1-horse cart, on short, downhill hauls, takes an aver load of 0.25 cu yd solid rock; under favorable conditions, 1/3 cu yd aver. For short hauls, 1 driver can run 2 carts. With wagons, 2 men and a driver can load 1 cu yd on a stone rack in 15 min and 1 man and driver can unload it in 7 min, or total lost time of 22 min. Aver of each loader, 7.5 cu yd in 10 hr (Sec 27).

Cars on track. For tractive power of horses and resistance of ordinary dump cars see Sec 3. On level track, a team will haul 2 cars, each of 3 cu yd solid rock; on slight down grade, 1 horse will haul 2 cars holding 1 to 1.5 cu yd. On good track, at slight down grade, 1 horse can haul 4 light rocker-dump cars holding 4 cu yd, if assisted by laborers in starting. If rock be broken into sizes that 1 or 2 men can lift, 6 to 7.5 cu yd can be loaded per man in 10 hr. About 4 min are lost in changing teams from empty to loaded cars, provided the track arrangement is good. Speed should be 200 ft per min.

Steam-shovel loading. In loading rock by steam shovel, the output of the attendant train and locomotive is limited chiefly by the shovel output, not by the speed at which a train may be handled. Following work was done in a quarry of hard crystalline limestone, by 2 Bucyrus 95-ton, 2.5-cu yd dipper, shovels (13). SHOVEL A. First day: Working time, 691.5 min; lost time, 59 min, of which 41 min were for blasting, clearing track, and tightening jacks, 13 min waiting for cars to be spotted, and 5 min idling. Second day: 138 min were lost waiting for cars, of which 87 min were spent in drilling, blasting, leveling, and preparing to move, and 55 min idling. On 2 days, 197 min, or 15.5% of the time, was lost waiting for cars, while cars lost on account of shovel, for no apparent reason, 7 min; moving forward, 107 min; drilling, 125 min; blasting, 67 min; clearing track, 9 min; total, 315 min, or 25%. SHOVEL B in 2 days worked 1 290 min. A total of 266 min or 20.6% was spent waiting for cars, of which 87 min was in idling. On same days, 327 min (25.4%) was lost to the trains by the shovel, as follows: oiling, 10 min; getting up steam, 42; repairs, 5; waiting for cars to be loaded, 52; blasting, 81; moving forward, 113; coaling and miscellaneous, 25 min. There were 5 35-ton dinkey locomotives, 4 working and 1 being overhauled. They hauled 10-car trains. Cars held 5 cu yd and weighed 4 tons. While moving, the engines averaged 527 ft per min; minimum speed, 156 ft; maximum, 1 000 ft per min (see also Sec 27).

8. QUARRYING (see also Open-cut Excavation, Art 9)

Kinds of stone. DIMENSION STONE is quarried and split to assigned dimensions ready for dressing. RUBBLE STONE is in rough slabs or blocks of irregular sizes. For dimension stone, there must be a good WORKING FACE and usually a CHANNEL at each end, to expose 3 faces. Then, by wedging or careful blasting, long blocks are secured, which are split into short blocks for handling by derricks. To get a cushioning effect in blasting dimension stone, several inches of hole above the charge may be filled with hay; called "expansion tamping." For rubble or backing stone, but little channeling is done; the rock is shaken up by light blasts and irregular slabs barred and wedged out.

Joints and cleavage planes must be carefully considered. All sedimentary rocks and some others, as granite, have 3 perpendicular cleavage planes called the GRAIN, RIFT, and HEAD. Trap rocks, diabase, diorite, porphyry, etc, often have no rift and are unfit for dimension stone. Cost of

quarrying depends partly on thickness of beds and their DIP (slope) to the horizontal. With steep dips, both thick and thin-bedded stone must usually be removed simultaneously; as the quarry deepens, the depth soon becomes too great for profitable work. If joints are irregular a quarry is a BOULDER QUARRY; if vertical and at right angles, BLOCK QUARRY; where there is practically no vertical joint, but a series of horiz joints, a SHEET QUARRY.

Plug and feathering consists of splitting rocks by shallow holes, in which 2 FEATHERS or shims (pieces of half-round iron, the sides of which are curved to fit the hole) are forced apart by hammering a wedge plug between them (Fig 19).

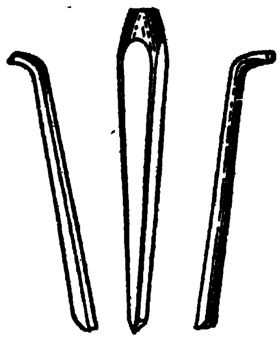

Fig 19. Plug and Feathers

Holes required. A granite block 6 ft thick may be split with a row of plug holes 5 in deep and 6 to 8 in apart; for a 3-ft block, holes are 2.5 to 3 in deep. Marbles and sandstones require deep holes. For sandstone, holes are 1.25 to 2 in diam, 4 to 16 in apart, depth being $^2/_3$ the thickness of the block.

Drilling methods. Plug holes are drilled by hand, pneumatic hammer drill, or reciprocating drill. For shallow holes, the hammer drill is cheapest; hand hammer next. For deep holes, a reciprocating drill on a quarry bar, or a hammer drill, is most economical. HAND PLUG-HOLE DRILLING. In granite, 1 man can drill in 8 hr 80 $^5/_8$-in holes, 2.5 in deep; total, 17 ft. With holes 24 to 30 in apart, and wages at 30¢ per hr, cost of splitting a block is 2.5 to 3¢ per sq ft. PNEUMATIC HAMMER DRILLS. In granite, 1 man can drill in 8 hr 250 $^5/_8$-in holes, 3 in deep, if the driller does not drive the plugs. In sand stone, 4-ft holes have been drilled in 18 min, and 20 holes, 18 in deep, were drilled at rate of 1 hole in 25 sec. BABY DRILL, on quarry bar, will drill a 3- or 4-in hole in 0.75 min, averaging about 100 holes per day.

Special quarry methods. BROACHING or broach channeling consists in drilling a row of holes very close together, and then, with a BROACH or chisel, cutting out the rock between them. One drill on a quarry bar (Sec 15) will broach per day: in granite, 10–20 sq ft; marble, 20–30; limestone, 15–35; sandstone, 20–40 sq ft. GADDER is for drilling rows of horiz holes near the quarry floor, or a vertical or inclined row in the face. One drill has made 350 ft of 2-ft holes in marble in 10 hr. TRACK CHANNELER is a self-propelling machine, traveling back and forth on a 10 to 30-ft section of track, and cutting a narrow groove with a single bit, or one or more GANGS of bits. See "Compressed Air Plant," Peele, 5th edn, Chap XXII.

Some channelers cut vertical grooves, others can be swung at varying angles, or are arranged for undercutting. Ingersoll "Broncho" channeler is mounted on 2 parallel bars, resembling a quarry bar. Channelers may carry a boiler, or be operated by steam or compressed air from an independent plant. Ingersoll-Rand Co builds an air-electric channeler, similar in operation to their air-elec drill. Channelers cost $2 500–$4 500 (pre-war). In dimension-stone quarries (other than granite) they are economic necessities, because fully 20% of the stone quarried without channeling is lost in subsequent cutting. In granite, broaching or wedging is usually cheaper. Cost of running a channeler is about the same as of a steam drill; 2 men and 0.5 ton coal per day are required. COST OF CHANNELING LIMESTONE, N Y State Barge Canal, for 16 consecutive months follows: Sullivan Y-8 channelers, costing $2 800 each, were used. Operating crew per channeler: 0.16 to 0.5 of the time of a foreman @ $4 per day, 1 runner @ $3.50, 1 fireman @ $2, 1 helper @ $1.75, 1 laborer @ $1.50. Cost per sq ft for 126 544 sq ft: labor, 22¢; coal, 2.3¢; water, 0.2¢; repairs, 0.1¢; int and deprec, 2.4¢; total, 27¢ (1908–9).

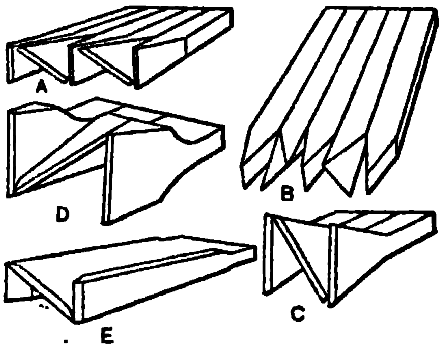

Fig 20. Channeler Bits

Standard or rigid-back channelers cut to depths of 10 to 16 ft; swing-back and bar channelers, 6 to 12 ft; undercutting channelers, 7 ft. Max inclinations of swing-back channeler having boiler or reheater, 24°; other types, 28°. The bits do not rotate. In Fig 20: *A* shows the gang used in marble or rocks which chip freely; *B*, that used for tough rocks which do not chip freely; *C*, for slate; *D* is used in both quarry and contract work for sharp, gritty stones; *E* is the solu Z-bit, common in contract work in rough broken stone.

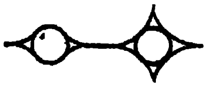

Fig 21. Knox System of Blasting

Knox system of blasting. A number of round holes are drilled, and then reamed by hand to the shape shown in Fig 21. In medium sandstone, holes should be 10 to 15 ft apart; in limestone, about 4 ft apart. Black powder or contractor's powder will split the rock in the direction of the angles (20).

Quarrying by compressed air is practiced at Mt Airy, N C, where the granite has few joints, and splits readily in almost any direction. A centrally located hole, 2 to 3 in diam and 6 to 8 ft deep, is sprung with dynamite. Then, repeated charges of

black powder, beginning with a handful and gradually increasing in size, start and extend horis cleavage cracks. When the cleavage reaches 75 or 100 ft in all directions, air at 70 lb press is admitted through a pipe cemented into the hole. In say 0.5 hr, the cleavage reaches the surface 250 ft ± from the drill hole, and the large flat slab is split into blocks by plugs and feathers.

Table 22. Rate of Cutting with Sullivan Channelers (from Sullivan bulletins)

For quarrying a granite dome at Lithonia, Ga (34), free from joints and sheeting planes, an artificial sheeting plane was necessary. For this, 2 3-in holes about 8 ft deep were drilled close together, each charged with a spoonful of black blasting powder, tamped with clay, and fired simultaneously. The "rift" being horis, the light blasts started a horis fracture from the bottom of the holes, which were cleaned out and refired repeatedly with gradually increasing charges, never large enough to disturb the stemming. Care was taken to avoid making vert cracks, through which the compressed air subsequently used would be dissipated. Solar heat is said to assist this process; during the hottest weather the fracture extended without explosives. The light blasting was continued until the boundary of the horis fracture roughly formed a circle with a radius of 160–180 ft. An iron pipe was then set in each hole with sand and melted sulphur, to make an air-tight joint. Air at 100 lb was forced through the pipes into the horis fracture, which widened with a rending noise until it reached the surface on the flank of the rock dome; the sheeting plane thus formed having an area of 1–2 acres.

Quarrying broken stone (36, 37). Size of crusher (which depends on character of rock) affects size of shovel dipper. If the rock can not be easily broken with sledges at the crusher, secondary blasting is necessary before loading on cars; use of a small shovel dipper prevents feeding excessively large pieces to crusher. Height of quarry face has some effect on size of shovel, but more on type of drilling equipment and mode of working. To prevent injury to shovel, combined working length of boom and dipper handle should equal the height of face, which should generally be less than 40 ft for any size of shovel. Though high faces are more cheaply drilled and blasted, the stone may break too large, with greater cost of secondary blasting.

Quarrying flux for blast furnaces in western Penn (36). The strata are horis, faces 7–22 ft high. Drilling is done on top and at such distance back from face that large shovels can clean up a blast on 1 passage. With higher faces, or smaller shovels, 2 or more passages are necessary. The face is developed with a gradual spiraling, causing highly effic operation.

R R shovels on track, with 2.5 to 4-yd dippers, deliver 1 200–1 500 ton a day; smaller sizes undesirable. Small shovels on traction wheels may serve for: (*a*) say, less than 800 ton per day; (*b*) splitting up total tonnage into several units; (*c*) where a light-weight track is used: (*d*) where quarry conditions prevent adoption of spiral faces.

Transport systems for quarries (36) depend upon relative size of shovel, car and crusher, and unit of train movement. For R R type shovels, the quarry track should be at least 42 in gage; standard gage (4 ft 8.5 in) is preferable, for cars to 15-ton capac.

High cars are cheaper to load than low, because, when the shovel completes its working stroke, the dipper is usually elevated, ready for dumping. Large cars save time in spotting the dipper; hence, faster dumping with less spill. Capacity of train unit on 1 movement should equal at least 20 min nominal shovel duty. A 1 200-ton R R shovel should load a 40-ton train in 10–15 min, 5–10 min being allowed for moving shovel, shifting trains, hard digging, etc; 300-ton traction shovel requires at least a 10-ton train.

In many quarries, especially where length of haul is moderate, motor trucks are used from shovel to crusher. Advantages over track and car are greater flexibility of operation, elimination of track and usually lower cost. Truck bodies vary from 5 to 10 cu yd capac, either side or end dump;

penumatic tires are common (Sec 27). Aver transport cost, on 36 trucks, based on 3-yr records in four different quarries in N Y, Conn, and No Carolina, is 2.5 to 5¢ per ton mile.

Quarry blasting problems (33). At a sandstone quarry, when the holes were in straight lines, the rock broke large, the explosive force being mainly expended in shearing from the face. This was largely overcome by staggering the holes (Fig 22). In another case, in very tough rock, holes rarely broke to the bottom. Drilling as in Fig 23 improved the work. In hard limestone, better results were obtained by drilling as in Fig 24. The rows farthest from face were made with well drills, and charges concentrated near bottom. Two rows in front of these were tripod-drilled and charged from a point halfway up to within 5 ft of surface; this greatly reduced secondary blasting. At a quarry in hard, stratified limestone, ordinary methods failed to break rock small enough for handling. Fig 25 shows the remedy. Holes in back row were 60 ft deep; in front, 35 ft. The deep holes were charged with 150 lb 40% straight dynamite and 40% gelatin, front holes, with 50 lb of 40% straight dynamite

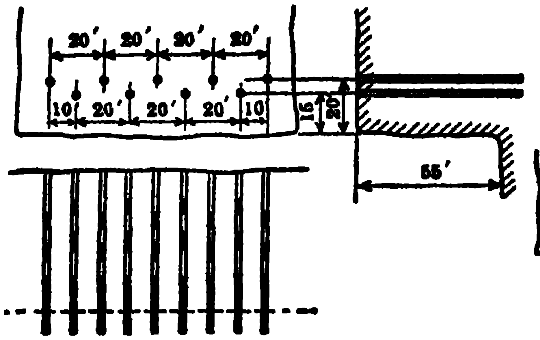

Fig 22. Staggered Holes to Increase Shattering Effect

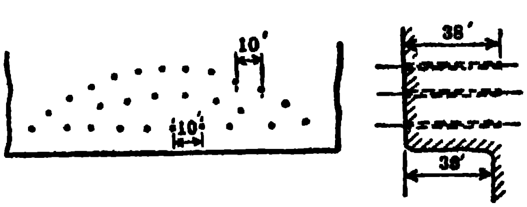

Fig 23 Arrangement of Holes for Breaking Hard Bottom

Secondary blasting (39), required when main blast breaks too large for shovel or crusher, is done by blockholing or mudcapping (Art 6), blockholing is usually the cheaper. Holes are 1 1/8 in, for 1-in cartridges; with small diam cartridges there is less waste in cutting them for small charges. Mudcapping requires only a few min to prepare, and saves shovel time in waiting for boulders to be drilled. Large boulders, which can not be handled by the shovel are rolled and nosed out of the way, to be broken later.

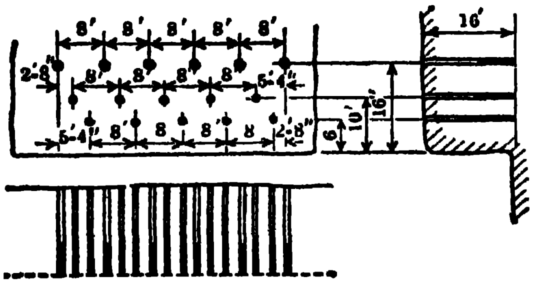

Fig 24. Arrangement of Holes to Reduce Secondary Blasting

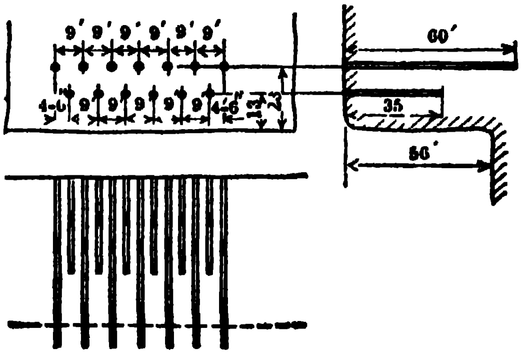

Fig 25 Arrangement of Holes on High Face to Reduce Secondary Blasting

Underground quarries (35) avoid cost of removing deep over-burden, and permit year-round operation. When topography is suitable, they are opened by tunnels.

The methods often resemble breast and bench stoping for mining flat deposits (see Sec 10, under details of Open Stopes, showing bottom headings, suitable for faces 16–24 ft high; also see bench work for 24-ft faces and over). Due to low value of the material, the quarry stratum should usually be at least 16 ft thick. Fig 26 shows saw-tooth method of slabbing off in horiz strata, leaving pillars to support roof, it resembles rill stoping, Sec 10. Sectional steel (Art 2) has been used in benches 12–24 ft high, so that entire bench can be shot at one time. An 8-ft heading is first cut, then, with sectional rods, holes can be drilled to bottom.

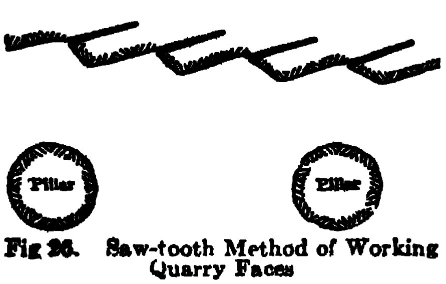

Fig 26. Saw-tooth Method of Working Quarry Faces

9. OPEN-CUT ROCK EXCAVATION

For this work are used many of the methods and machines considered in preceding Articles. It resembles some kinds of quarrying, and is similar in nearly all respects to stripping operations and open-cut mining, detailed in Sec 10. For machine drills, see Sec 15; churn drilling, for deep-hole blasting, Sec 9; for steam shovels, Sec 3 and Sec 5, Art 7.

Side-hill cuts, where rock is wasted directly in front of the excavation, are usually the least expensive type of open cut. Ratio of the propulsive effect of black powder to its shattering effect is about 8.6, while that of dynamite is about 1; hence, it is often desirable in side-hill work to use black powder, so that the rock may be thrown as far as possible from its bed.

Side-hill cuts (20) on Watauga and Yadkin Valley R R, N C, were made by blasting rock clear of right of way in one operation; about 0.5 cu yd being thrown out per lb of explosive. In a cut of 8 000 cu yd (95% hard mica schist), 23 holes were drilled in 2 rows; upper holes approx 20 ft deep, to 2 ft below grade; lower holes, 16 ft deep, to 6 ft below grade. They were sprung twice, first by 5–6 sticks of dynamite, then by 25–30 sticks. Experience showed that 1 springing, with 10–12 sticks, would have chambered the holes better. Main charge of 7 925 lb powder broke 7 000 cu yd.

A small side-hill cut in hard rock, made by hand-drilled holes, 7–11 ft deep, contained 1 300 cu yd. Cost, including $126 for removing loose rock after blasting and dressing the face, was (in 1913) 34.3¢ per cu yd. About 320 ft of holes were drilled at about 40¢ per ft; 0.24 ft of hole per cu yd blasted. Springing required 0.12 lb dynamite per cu yd; main blast, black powder, 2.3 lb per cu yd.

Through cuts occur oftenest in canal and R R work. Depth and width of cut, and mode of removal, determine the plan of attack. Excavation in through cuts generally costs more than in side-hill cuts.

Excavating rock in open cuts, Grand Trunk Pac R R (20). Cuts, 20 ft wide at bottom, sloped 3 in to 1 ft. Overbreakage, usually paid for, was 10 to 40%. Rock was granite, trap, and diabase. Steam drills used in large cuts, hand drills in small. HAND DRILLS (1-in steel, 1 $^{3}/_{8}$-in bit) made holes as deep as 30 ft. To depths of 6 ft, 2 men struck and 1 held the drill; below 6 ft, all used hammers, the drill rotating automatically on the rebound; wages, $2.25 per 10 hr (day's work), or 45¢ per ft, sharpening and nippering furnished. 3 men, drilling 10 to 14-ft holes, averaged in dark hornblende 29 ft per day, in red granite, 20 ft, and in trap and diabase 18.5 ft. In drilling block holes, 1 gang made 49 holes, averaging 15 in each, in 6 days. Drill sharpening for one month, for 5 gangs who drilled 2 142 ft, cost: blacksmith @ $3.50, $87.50; helper @ $2, $48, nipper @ $2, $48; coal, $12; total, $195.50, or 9¢ per ft. Average cost by 5 gangs, each drilling 18 ft per day: drilling, 37¢; sharpening, 9¢; total, 46¢ per ft.

Holes to 30 or 35 ft deep were made by 3.25 and 3.5-in steam drills; holes to 25 ft deep, by 3-in drills. Starting bits, 3.5 in; finishing bits, about 1.25 in. Cost of running 1 drill per 10-hr day: runner, $3.75; helper, $2.25; fireman, $2.50; 0.5 blacksmith, $1.87; 0.5 helper, $1.13; 1 cord wood, $2.25; coal, 30¢; repairs and oil, 38¢; total, $14.43. Aver, 30 ft drilled per day, costing 48¢ per ft. When 2 drills were run from 1 boiler, cost was about 38¢ per ft.

Cuts over 25 ft deep were made in 2 lifts. In bottom benches, 1 ft of hole and in top benches, 2 or 3 ft of hole, were chambered. A 26-ft hole, 14 ft from face, was sprung by: (*a*) 2 sticks 60% dynamite, water-tamped; (*b*) 5 sticks, water-tamped; (*c*) 12 sticks, water-tamped; (*d*) 30 sticks, sand-tamped; (*e*) 70 sticks, sand-tamped; total, 119 sticks. Another similar hole: (*a*) 2 sticks, water-tamped; (*b*) 5 sticks, water-tamped; (*c*) 12 sticks, water-tamped; (*d*) 35 sticks, sand-tamped; (*e*) 100 sticks, sand-tamped; total, 154 sticks. First hole was charged with 275 sticks of 40% dynamite; second, with 150 sticks of 60% and 175 sticks of 40% dynamite. (1 stick = 0.35 lb.) These holes broke 450 cu yd of rock. Cost: drilling, 4.8¢; springing, 6.3¢; blasting, 9.3¢; total, 20.4¢ per cu yd. Blaster, 37.5¢, and powder monkey, 22.5¢ per hr. Dynamite, 18¢ per lb for 40% 22¢ for 60%, about 0.4 lb of 40% being used per cu yd for the main blasts, and 0.38 lb of 60% for springing. About 75 lb black powder equaled 50 lb 40% dynamite. Cost of excavating 7 024 cu yd red granite from a tunnel approach on same R R was $1.019 per cu yd.

10. TRENCHING

Overbreakage. Specifications should name a minimum width of trench, beyond which NEAT LINES the rock removed shall not be paid for. Depth should also be named. Overbreakage in rock sometimes exceeds the specified cross-section by 25 or 30%.

Depth and spacing of holes. Holes in thin-bedded, horizontally stratified rocks are usually drilled 6 in below specified bottom of trench; in thick-bedded, tough limestones, about 12 in below; in tough granites and traps, 18 in below.

For hand drilling in granite, holes are often spaced about 1.5 ft apart. In trenches 2.5 to 3 ft wide, rows, 3 ft apart, of 2 holes each, are common. In a trench 6 ft wide in hard trap 3 holes per row were drilled, the rows being 3 ft apart. In an 8-ft trench in granite, there were 3 holes per row, rows 4 ft apart. In the 6-ft trench named above, about 4.5 ft of hole were drilled per cu yd, the holes going to 1.5 ft below grade. Steam drills made 35 ft of hole per day @ 30¢ per ft. Dynamite, 2 lb of 40% per hole, or 2.6 lb per cu yd of net excavation. Hence, drilling cost $1.35 and blasting 40¢; total, $2.15 per cu yd. The above 8-ft trench was 12 ft deep; holes drilled to 1 ft below grade, making 2.74 ft of hole per cu yd net. Drills averaged 45 ft in 10 hr; cost per ft, 23¢. Dynamite, about 4 lb of 40% per hole, or 1.1 lb per cu yd. Drilling cost 63¢ and blasting 17¢; total, 80¢ per cu yd (pre-war costs).

Cost of trenching in limestone, St Louis, Mo (20), about 1906. Rock was in horiz strata, the upper 4 or 5 ft being seamy and rotten, the rest hard and difficult to break. Rock was excavated 6 in below all pipes of 18-in diam or less, and 9 in below larger pipes. Excavation was paid for to widths 1 ft greater than diam of pipes of less than 18 in, and 15 in greater than the diam of larger pipes. Drill holes were 6 in from side of trench, and staggered 4 ft apart in top rock (Fig 27) and 2.5 ft apart in hard rock. Projections were sledged or shot off. Holes were drilled in 2 lifts, top holes going halfway through the ledge, bottom holes 0.66 to 0.75 the thickness of ledge. Drilling was single-hand, with 1.75-in bits, 10 ft being drilled in 8 hr. Dynamite, about 4 300 lb (2.25 lb per cu yd). Aver rock broken per 8-hr day per quarry man, 0.96 cu yd. Overbreakage, about 20%. Cost of earth excavation, 50¢ per cu yd. The cost of the rock work was as in Table 23.

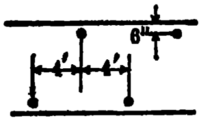

Fig 27. Arrangement of Trench Holes

Table 23. Cost of Trenching in Rock per Cu Yd. St. Louis, 1906

Size of pipe, in	Length of pipe, ft	Aver depth in solid rock, ft	Cu yd excavated	Foreman @ $5, ¢	Quarrymen @ $3	Laborers @ $2, ¢	Total direct labor	Blacksmith, ¢	Dynamite, ¢	Total cost, breaking rock	Cost of removal	Backfilling cost, ¢	Grand total
21	370	14	600	56	$3.50	24	$4.30	20	40	$4.90	$1.40	15	$6.45
18	287	12	317	85	3.24	34	4.43	20	40	5.03	1.40	15	6.58

Special carriages, for carrying a boiler, and a drill mounted on a bar, were used in sewers at Havana, Cuba. Wt per outfit, 5 000 lb; drills were Sullivan, 3.25-in. Rock varied from very soft to flint-like hardness. Time studies of 4 machines drilling 40 holes: total drilled, 366 ft; aver depth of hole, 9.15 ft; aver drilling time, 26.4 min per hole = 2.9 min per ft; changing steel, 1.4 min per ft; moving drill on bar, 0.6 min per ft; moving machine from hole to hole, 1.0 min per ft; total time, 2 231 min; average per ft, 6.1 min (20).

11. SUBAQUEOUS EXCAVATION

Methods employed are: exploding dynamite on the rock surface, unwatering the rock by cofferdams or caissons, and drilling from platforms or scows. This work is a branch of Civil Engineering, to books on which the reader is referred (12, 20).

TUNNELING

Introduction. The following discussion deals with tunnels or adits of small cross-section and larger tunnels in which the entire area is excavated in one operation, in contrast to the tunnels where an advance or pilot heading is driven first and enlarged later to full section. It includes, however, tunnels driven by the heading and bench method, wherein a top heading is carried only a round or two in advance of the bench. For methods of enlarging, timbering and lining railroad tunnels, see the works of Drinker, Prelini (27), Stauffer (28), Lauchli (29), publications of the mining and civil engineering societies and the technical press. "Rock Tunnel Methods" (30) contains summaries of data from "The Explosive Engineer" and illustrations of methods employed in R R tunnels, also data on mine and other tunnels of small cross-sec. Additional data on tunnels and drifts driven in immediate connection with mine development will be found in Sec 10, where full details of procedure and costs are given.

1. REPRESENTATIVE TUNNELS

Tables 1 to 3 contain data on 28 tunnels, from various sources as noted. Tables 1 to 7 present summaries of data on different phases of tunneling operations.

It may be remarked that many of the examples given are of tunnels for purposes other than mining. Within the past decade, comparatively few important mine tunnels have been driven.

2. ORGANIZATION OF WORK

Organization of work in tunnel driving depends chiefly on rate of advance required, size of cross-section, power and equipment available, and magnitude of project; in some cases, especially in the last few years, laws governing hours of work are a factor. For each tunnel job there is an approx rate of advance for max economy, depending on whether there are penalties for finishing after, and bonuses for finishing before, a given date; whether prompt completion will effect savings in total operating costs of the mine or other project to be served; overhead costs; and other similar considerations. Rapid advance requires a high degree of organization; precision in performing the several operations in the work cycle; equipment to provide adequate ventilation for continuous work at the face; and often other special equipment not essential in slower work. A break-down at any point in the work cycle is apt to disorganize the entire job and increase costs. Up to a certain rate, which varies with conditions, rapid driving obviously results in spreading supervision and fixed charges over a greater footage, thus reducing cost per ft; but constant pressure to attain max speed involves sacrifice of numerous small economies otherwise possible, and tends to increase the direct cost per ft.

One shift of drilling and blasting, with mucking and tramming on the opposite shift, constitutes the simplest organization. With the latest drilling equipment and enough machines at the face, almost any round can easily be completed in an 8-hr shift. In a tunnel of large section, a round of deep holes may break more muck than can be hand-shoveled in one shift, whereas modern power loaders will clean up as large a round as can be pulled. Thus the organization of the mucking shift will depend on whether loading is by hand or machine. If by hand, the mucking shift may have to work overtime, or two mucking shifts may be needed, obviously increasing the speed of driving. Some advantages and disadvantages of one-shift operation under ordinary conditions follow. ADVANTAGES: 1. Drilling and mucking are done on separate shifts; the heading is clear when the drill-shift comes on, so that the machines can be set up at once for the next round. Runners and helpers therefore waste no time in mucking, preparatory to mounting the drills; an important point when columns are used, because, for setting up, the debris must be cleared down to the floor. 2. During drilling, runners and helpers are not hampered by the muckers, avoiding the waste of time due to both crews working together. 3. Starting promptly, the round can usually be completed within the allotted time. But, in any case, sufficient extra time is available without delaying the following shift. 4. Drilling and mucking shifts can be arranged to avoid loss of time in waiting for smoke to clear away; a serious consideration where ventilation is poor. DISADVANTAGES: 1. Since daily progress is limited by the advance from a single round the total speed is slower. As most tunnels are useless until completed, if work is not pushed the capital invested in equipment is tied up too long, whence the charge for interest and depreciation is increased. 2. Realization of benefits

Bl, blowing; *Ex*, exhausting; *Ex-Bl*, exhaust, then blow; *PBl*, pressure blower. (*t*) 21 × 21-ft tunnel; cost includes heavy expense for road construction and other preparatory work; (*u*), includes proportion of construction and equipment costs and other capital charges; (*v*), dry sections, excavation only; (*w*) one month only; (*x*) based on £1 = $4.65; (*y*) cost of 2 759.5 ft for year ended Aug 31, 1900; (*z*) portal heading. * West portal. † East portal.

to be derived from the tunnel is delayed. In case of a drainage adit the extraction of ore below water level is delayed; or, if the adit is intended to lower the cost of underground transport, loss on the added tonnage handled in the old way should be charged against the slower driving of the tunnel. With an irrigation tunnel, an entire season's crops may be lost because of the increased time required by the one-shift system. 3. Overhead charges are operative during full period of construction; these charges per ft of tunnel are smallest when the max number of hours per day are employed in driving. Finally, although one-shift work is cheaper in wages, this may be offset by losses due to delay in completing the tunnel.

Two shifts will obviously make faster progress than one shift, the direct cost per ft being the same or more or less, depending upon organization and equipment. With hand mucking it is usually necessary to work the drilling and mucking crews simultaneously, although there is advantage in having the muckers start an hour or so before the drillers in order to make room for the latter to work over the muck pile. In this system, drills are usually mounted on a horiz bar set over the muck pile, and the top and breast holes are drilled first while the muckers are removing the rock beneath. With vert column mounting, the shift first mucks back from the face to make room for the set-up. A disadvantage of the horiz bar and drilling over the muck pile is the chance of drilling into a missed hole with a vert column set-up; time is lost unless the muckers come on ahead of the drillers; in either case, working the two crews together usually results in congestion at the face and loss of efficiency. With mechanical loading the work is usually planned for a clean set-up of the machines for each round, unless two complete cycles per shift are desired, when it may be necessary to use a horiz bar set-up. The machines may be mounted on horiz bars, vert columns, or drill carriage, and enough machines are employed to drill a deep round and shoot in 4 to 5 hrs or less. Mucking can usually be completed in 2 to 3 hrs, leaving a clean set-up

for the next shift. The mucking time varies but little with size of tunnel section, providing the mucking machine capacity is sufficient. In some tunnels two complete cycles are completed in a shift using mechanical loaders, horiz-bar drill mountings over the muck pile, or a drill carriage, with adequate ventilation for removing blasting fumes, and facilities for quickly changing cars at the face. Where two cycles are completed per shift, separate mucking-machine and loading crews are sometimes employed, each of which works two high-pressure periods, with an intervening rest period partly devoted to overhauling gear and equipment, sorting steel, preparing for blasting, etc. For one complete cycle a single crew will usually suffice, the drillers operating the mucking machine after blasting.

Three shift organization is similar to that for two shifts, except that each crew must usually be composed of men capable of taking up the work at any point in the cycle where the previous crew leaves off. Unlike 2-shift organization, if delays occur there is no time between shifts to complete unfinished work.

Table 4. Typical Time Cycles in Representative Tunnels

3. SURFACE PLANT

Aside from requirements for office, camp buildings, and power plant or transformer stations, which vary widely with size and location of job, and time required for its completion, the usual surface plant comprises: air compressors, bit sharpeners (or detachable-bit grinders), heating furnaces, blacksmithing equipment, explosives magazine, ventilating fans or blowers, and car-dumping facilities. In some cases, a small machine and electrical shop may also be required for making repairs to cars, track switches, loading and haulage equipment; but where the tunnel is driven at an established mine, most or all of these facilities may be already available.

4. DRILLING EQUIPMENT

Drills and accessories. The old piston-drill has been superseded by faster drilling hammer-type machines. The use of hollow drill steel and wet drilling has become almost universal, and with growing understanding of the danger to health from dusty air, wet drilling is advocated under all conditions. Mounted drifters with 3, 3 1/2, or 4-in pistons are commonly employed, the size depending to some extent upon hardness of rock and depth of holes. Mounted jackhammers of smaller piston diam are sometimes used in soft, easily drilled ground, and hand-held drills for vert holes in benches, where the heading-and-bench system is employed. Air pressures of 90 to 100 lb. are usual. Recently, standard makes of automatic-feed drills have come on the market and have found favor in numerous large tunnels. They are of two general types, those that feed by vibration of the machine and those with pneumatic feed. Accessories comprise rubber air and water hose, line oilers, manifolds for connecting hose from several drills to the mains, and drill mountings.

Drill Mountings comprise horiz bars and clamps, or vert columns with arms and clamps, or drill carriages. If drilling and mucking are carried on simultaneously, the horiz bar is preferable, since it can be set up over the muck-pile as soon as the back has been trimmed of loose rock and made safe. With vert columns, some muck must be shoveled back from the face before the set-up can be made, involving loss of time and rehandling of part of the muck by hand. Vert set-up behind a muck-pile interferes with efficient drilling; water from the drills dams up behind the muck and the hose must be carried over the pile and down to the drills. Horiz bar is sometimes preferred to carriage mounting, because muckers and drillers can work simultaneously.

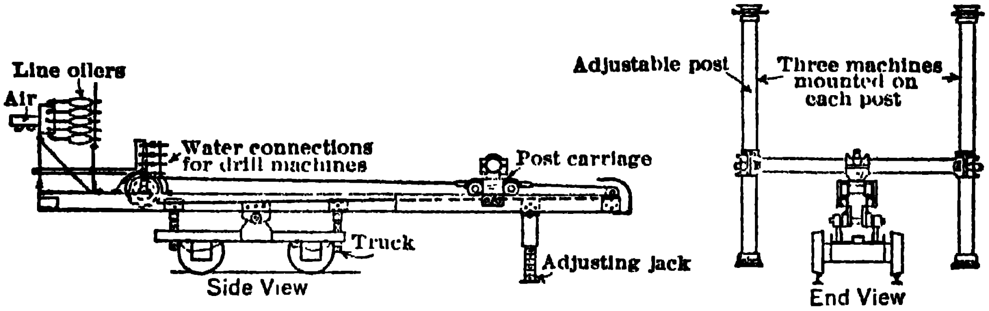

Fig 1. Drill Carriage, Montreal Mine

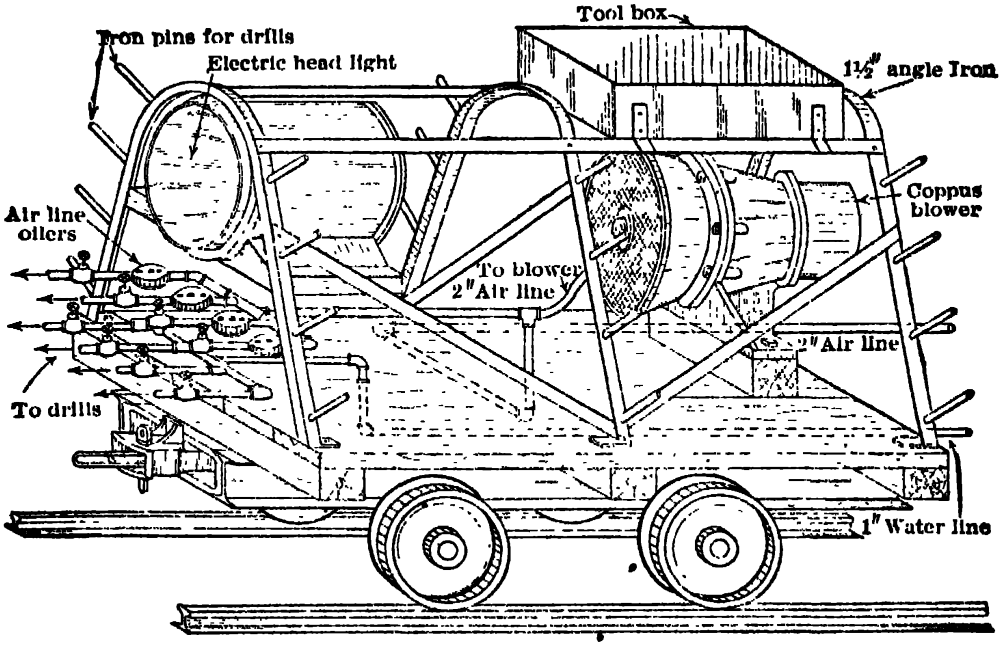

Fig 2. Hezzlewood Drill Tender

In the east portal of the Cascade tunnel, the superintendent was satisfied that he could make better time with a bar than with a carriage (4). 0.5 hr was allowed after blasting to clear the heading, and 20 min were required to bar loose rock, during which time the bar, 4 drills and 160 steels were brought up and some mucking was done where dirt lay against the face. Finally the set-up was made, the entire preparations requiring about 1.5 hr. Drillers stood on the muck pile. Mucking started with the "fly rock" and proceeded to the face. "By the time the shovel loader is close up and ready to dig into the last of the pile, the drillers have finished all but 5 or 7 bottom holes. . . . We manage to pick up a round in the course of 48 hr by this work cycle. We count on 3 rounds a day and try to make or save enough time to gain an extra round every 2 days." While it is probable that extra speed can be gained with a bar, it is questionable whether as good direct costs can be secured as with a carriage.

Drill carriage or "Jumbo" has gained favor in recent years, but its use is limited to clean set-ups where it can be run right to the face. It usually runs on the tunnel track, but may be mounted on a caterpillar crawler. It is variously designed and constructed, but consists essentially of the carriage proper upon which are mounted the columns, bars, arms and drills, with individual air and water hoses attached. Manifolds and line oilers may be mounted on the carriage (Fig 1) or carried on a tender (Fig 2). The manifolds are connected to the mains by large hose. Drill steel is carried on the carriage or on a tender as the case may be. The tender in Fig 2 was used in the Ojuela tunnel (19) and in addition to carrying steel, air and water manifolds and a tool box, was equipped with a Coppus blower. Drill carriages permit a quick set-up, as the mounted machines, equipped for drilling, are run to the face with drill steel sorted and conveniently racked. When drilling is finished, the equipment is readily and quickly removed.

Drill steel. In American tunnels, hollow, 1 $^1/_4$-in round, lugged-shank steel is commonly employed for 3 $^1/_2$ or 4-in drifter drills; 1-in quarter-octagon or $^7/_8$-in octagon steel is often used with lighter machines in easy drilling ground, or for vert down holes in benches. Machines with anvil-block chucks and plain shanks without lugs are seldom used in the U S, but are standard in many Canadian mines. Steels are commonly made up in lengths for 24-in changes; sometimes for 18, 20, 30-in changes, with corresponding gage changes of $^1/_8$, $^3/_{16}$, or $^1/_4$-in. Here the standard U S practice of using a starter of 2 $^1/_2$ or 2 $^3/_4$-in or even 3-in gage might be improved, for it has been found in some mines that deep holes can be drilled in hard, abrasive ground, with 1 $^5/_8$ or 1 $^3/_4$-in starters and $^1/_{16}$ to $^3/_{32}$-in gage changes for a 24-in run, by exercising proper care in forming, gaging and heat treatment of the steel. Drilling speed increases rapidly with decrease in size of hole, and with corresponding decreases in steel loss, air consumption and time required to complete the round. A cross bit with full reaming edges (that is, having all 12 points in the same circumference) has been successful; gage loss is usually less, whence gage changes and bit size can be smaller to finish with same diam of hole. Detachable bits have come into favor in recent years. For tunnel work their chief advantages are: perfect forming of each bit, uniformity of gage and uniform results of heat treatment, which are attainable in the factory to a degree rarely possible on any but large tunnel jobs, where the best equipment and expert steel sharpeners can be had. Capital investment for regrinding bits is considerably less than for sharpening equipment and the amount of money tied up in steel is less.

5. DRILLING

Tunnels of the sizes under consideration are driven by carrying forward the full cross-section, or by heading and bench. In most long tunnels, drill rounds are fairly well standardised for each job, although ground conditions sometimes change so frequently and abruptly that standardization is impossible. The principle upon which standard rounds are based is the drilling of cut-holes, which, when blasted, will break out a wedge of rock, thus providing free faces to which relief and square-up holes will break, being timed to go slightly later. It is axiomatic that if the cut-holes fail to break to bottom, the others will also fail to do so and a short round will result.

Principal types of rounds are: The V OR WEDGE-CUT (Fig 3); PYRAMID-CUT (Fig 4), which pulls a pyramid or cone-shaped block in the center of the face; the MICHIGAN OR "BURNT"-CUT (Fig 5) which pulls a cylindrical core in the center; and the "SWING" OR SLABBING-CUT (Fig 6). In the DRAW-CUT, a variation of the wedge cut, holes are drilled at a steep angle to pull wedge *W*, Fig 7. The cut holes may be drilled steeply downward, as in Fig 7, to form a bottom-draw or "toe"-cut, or toward one side to form a side-draw cut. The bottom draw-cut is used in narrow headings, with insufficient room to swing the drill at the angle required for a regular V- or pyramid-cut. The burnt-cut is used for tough, tight ground, and is especially applicable to small headings, where there is not room to swing the machines for drilling conventional cut holes. The two center holes (marked black in Fig 5) are drilled normal to the face, and are not loaded; they merely form lines of weakness for the surrounding cut holes to break to and some space for the rock to expand into. The slabbing-round (Fig 6), as used in an 8 by 12-ft heading, consists of 28 holes in 4 rows of 7 holes each, one above the other; 3 or 4 holes of each row at the right can be drilled from a single column set-up by using a long arm. The 4 shortest holes (4 $^1/_2$ ft) are blasted first, followed in succession by the 5 $^1/_2$ and 6 $^1/_2$-ft holes, etc, each tier breaking in turn to the free face provided by the breaking of the preceding tier. The pyramid-cut ordinarily comprises from 3 to 6 holes, although 4 holes will break in most ground. Fig 8 shows a double pyramid-cut in the Ojuela tunnel for pulling a long round; 4 short holes, 14–12 and 27–28, are blasted first, pulling a shallow pyramid or cone, followed by the long cuts 15–16 and 19–22, and then for enlarging the opening; the two relief holes 13–11. In the diagram the circled numbers indicate order of firing, and boxed figures the number of cartridges of 40% gelatin dynamite used in average limestone rock. All holes were spaced so that after the cut had been fired no charge carried more than 2.5 ft of burden. Each top machine on the carriage drilled 8 holes from two settings; each bottom machine, 6 holes. Fig 9 shows a heading-and-bench round, with a vert V-cut in the heading and flat lifter holes in the bench, while Fig 10 shows one with a

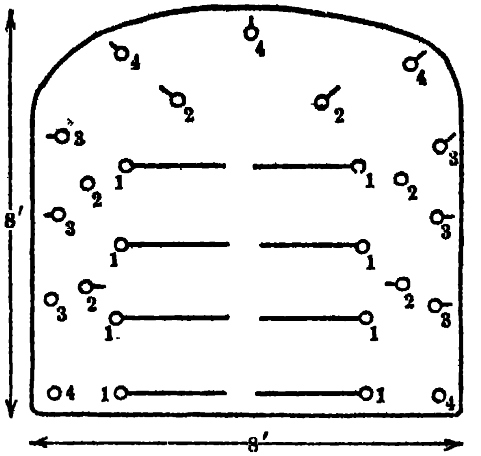

Fig 3. V-cut Round. In trap rock, this round proved effective with 12–14 cartridges of 60% gelatin dynamite in each cut hole. From 10 to 12 cartridges of 60% special dynamite in other holes completes the charge. Advance by each round averaged 11–13 ft, using 13-ft holes. Figures in diagram indicate order of firing electric blasting caps. In easier ground, as sandstone, 2 easers and 2 side holes are not used; the 60% special dynamite also is replaced by 40% special dynamite.

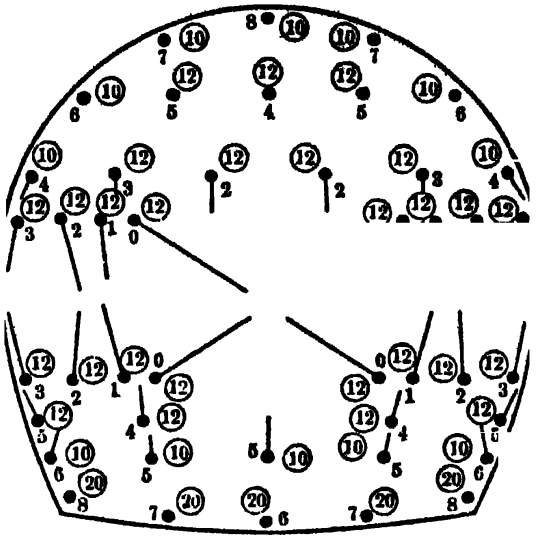

Fig 4. Pyramid-cut Round. Drill round used in Colorado River and in Copper Basin No 1 tunnels was built around a pyramid cut, using 11.5-ft holes. Circled figures indicate cartridges of 1 1/4 by 8-in. 40% or 60% ammonia gelatin, and uncircled figures, the firing order. This typical round could be easily modified to conform to changing conditions.

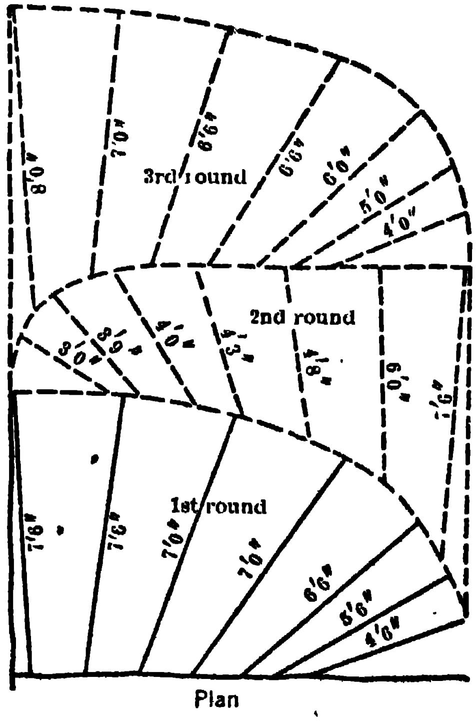

Fig 6. "Swing" or Slabbing Round

vert V-cut in the heading and nearly vert "plugger" holes in the bench. The total number of cut, relief and square-up holes required for any type of round obviously varies with toughness of rock, the position, number, and direction of fracture or bedding planes, and with size of heading. With V- and pyramid-cuts, the cut holes should be drilled to connect at bottom, especially if blasting with fuse and cap. It is virtually impossible to cut fuse so that the several charges will explode simultaneously, but if the holes connect or are very close together the first charge to go will detonate the others.

Drilling speed varies between wide limits, depending on "drillability" of rock, size of drill piston, air press, diam and depth of holes, amount and press of drilling water (affecting the rapidity of removal of cuttings), and sharpness of bits. Drillability of rock, while largely a function of hardness or abrasiveness and toughness, may sometimes be influenced more by fracture and bedding planes, stickiness of drill cuttings and presence or absence of vugs; that is, by homogeneity or its lack. Table 5 gives typical data on drilling speeds in a number of tunnels.

6. CHARGING AND BLASTING

Charging. Rules prescribed for transport, handling, and use of explosives should be observed, and primers prepared as recommended by the explosives manufacturers. The approved methods of inserting the detonator in the cartridge (Sec 4) insure against its being accidentally pulled out when charging and prevent kinking the fuze and consequent breaks in the powder train, or abrasion of the insulation on leg wires. The detonator should lie in the axis of the cartridge and be pointed in the direction of bulk of charge. Before charging, holes are blown clean with compressed air. The cartridges are then pushed in, one at a time, and pressed firmly with a wooden tamping bar. To insure filling the entire area of the hole, the cartridges are often slit, so that the explosive will be pressed out against the walls of the hole. Care should be used to avoid breaking the fuse or damaging leg wires. Explosive manufacturers usually advocate placing the primer last (on top of charge), or next to last in the hole. There is no accepted rule that gives best results under all conditions. Thus in tunnel work, if the primers are near the top, the cut holes, which go first, may cut off the primers in one or more relief or square-up holes, especially in seamy or schistose ground. If the primers are at or near the bottom, a cut-off hole will throw unexploded dynamite into the the muck pile. Table 6 gives data from

a number of tunnels and indicates in each case the preference as to the primer position. Fuse or leg-wires are brought out along one side of the hole, pulled straight but not tight, and the rest of the hole filled with stemming (tamping). Though sometimes omitted, stemming is advocated by all makers of explosives; it increases the work done, and by confining the explosive causes more complete detonation and less fume. Paper tamping bags different in color from the explosive cartridges are in general use and are convenient. They are preferably filled with dry sand, fine rock screenings, or clay (see Sec 4).

Order of firing, with fuse blasting, is controlled by cutting fuse in different lengths, and to some extent by the order of "spitting"; with bunch blasting the order of firing is determined by the length of fuse only, since all fuses are spit at almost the same instant. Electric detonators are especially effective for cut holes, by insuring simultaneous detonation of all the charges even though the bottoms of the holes do not connect, a result virtually impossible with fuse. Order of firing is usually: (1) cuts, (2) relievers, (3) breast, side and top square-ups, and (4) lifters. The lifters go last to throw the muck away from the face (Fig 3 to 10).

Fuse vs electric blasting. Elec detonators for tunnel rounds are now generally preferred, and are advocated by the Bur of Mines for safety. With delay detonators, one closing of the firing switch causes the holes to go in proper rotation, and since there are no men at the face when firing, the danger (with fuse) of overstaying the safe time limit is avoided. However, modern fuse is almost uniform in rate of burning, and the use of igniters or "spitter" fuses to give warning has greatly reduced this danger. Some operators consider fuse safer than electric blasting, contending that danger from stray currents is greater than the hazards with fuse. "Bunch blasting" (32), as developed by the Anaconda Copper Mining Co, might be applied to tunnel work with good results as to both timing and safety. In wet tunnels good waterproofing of both fuse (or wires) and caps is essential. Here, electric blasting has a decided advantage, because of the difficulty of keeping fuse ends dry Burning fuse adds to the smoke, which must be cleared before recharging cut holes (if that be necessary), or preparing the remaining holes. Also, if fuse "side-spits," due to imperfections or abrasion of the tape while loading, the charges will explode by ignition instead of by detonation, reducing effectiveness and increasing the quantity of noxious fume (see Sec 4).

Firing. When blasting with fuse, there should be at least two men at the face and precautions taken against leaving them in the dark. After all holes are charged, fuses are cut to the lengths for proper order of firing, and their ends slit to expose a short train of powder for lighting. Carbide lamps are often used for lighting, but may be blown out by the "spit" of a fuse. Igniters, now on the market, or notched "spitter fuses" (Sec 4) are better, and are advantageous in warning the miner when his safe time is up. For successful electric firing care must be taken in connecting leg wires together and to the leads; wires should be twisted together, not merely looped or hooked. Bare connections must be protected against short-circuiting, especially under wet or damp conditions, by being raised off the ground and preferably taped. With a blasting machine, the holes must be connected in series, but either series or parallel connection may be used when firing from a lighting or power circuit. For a blasting machine, leg wires should be connected first, then connections made to the lead wires, and lastly, after everyone has retired from the face, the lead wires are connected to the machine. With power-circuit firing, connections are made in the same order, but a locked safety firing switch should be used, so that the power connection can not be made until the box is unlocked and opened. As an additional precaution, a second switch, kept open until ready to blast, may be placed across the leads between firing switch and face, well back from the latter. The chief precautions in electric firing are to keep the detonators short-circuited until the moment of connecting them to the blasting circuit and to keep the lead wires short-circuited until they are connected to the source of current. In some ground it is necessary to load and blast the cut holes, then return to the face and, if they have not broken to bottom, reload them and other holes, and blast a second time. Although this involves waiting for smoke from the first blast to clear, with loss of time if ventilation is poor, it may save time in the long run when the ground is such that the cuts fail to bottom up.

Misfires result in lost or short rounds, loss of time for refiring, and hazards in drilling and mucking. Unexploded powder in the bottom of a hole may be drilled into or, if in the muck pile, may be struck with a pick and exploded. After every round, missed holes and unexploded powder must be looked for. Various methods are advocated for dealing with missed holes. If elec firing has been used the lead wires should be disconnected from the source of power, short-circuited and wound back out of the way. With fuse, men should not return to the face for at least one half hr, preferably longer. Having uncovered the missed hole, many prefer to remove the stemming (a method condemned by the Bureau of Mines), exposing the top cartridge and then reblast with a fresh primer. If the stemming is picked out, great care is necessary and no metal tools are permissible. It is safer to blow out the stemming with compressed air, or wash it out with water. A still safer, but more time-consuming method, is to drill and blast a parallel hole close enough to detonate the missed hole, taking care not to drill into the latter.

7. MUCKING EQUIPMENT

Hand mucking requires no special comment. Some hand work is necessary even with mechanical loading, for cleaning up, handling fly rock, and, where drilling and mucking go on simultaneously, shoveling back from the set-up. Mechanical loading depends for its success upon continuous operation during the mucking period. Mechanical loaders are of 2 kinds: drag scrapers and shoveling machines. See Sec 27 for details.

Scrapers. Scraping equipment for tunnel headings comprises a double-drum elec or comp-air hoist, mounted on a movable slide; a scraper of the hoe, semi-hoe, or box type; pull and tail ropes; tail sheaves, and a scraper slide, or ramp. The latter is mobile and is usually on trucks running on the mine track, but can be mounted on a caterpillar crawler. Fig 11 shows a common type of slide with hoist mounted on top. For low headings, the slide may be built with the hoist mounted underneath the ramp. The loading boom extends back over the car and has an opening in the bottom through which the rock falls. Fig 12 shows a loading unit used at the Montreal mine, Wis (33). The slide and boom are mounted on 2 large cars, coupled to a locomotive tender on which is mounted the slusher hoist. When the cars are filled, the entire unit moves under its own power to the dump. The use of 2 large cars, together holding 380 cu ft, minimizes loading delays due to waiting for cars. The usual types of scrapers, many of which are suited to tunnel work, are illustrated and described in Sec 27. Their advantages are: flexibility, low first cost, and small power consumption (especially if the hoist is elec driven). Aside from labor, rope renewals are the largest single item of expense. Scrapers usually show no direct cost saving over hand loading in tunnels of less than 7 by 7 or 8 by 8-ft cross-sec.

Shovel loaders in a number of successful types are on the market, ranging from low machines suited to tunnels of moderate height, to converted power-shovels, like those for surface excavation. They are usually mounted on wheeled trucks and run on the tunnel track, but may be mounted on crawlers. Among these, the Conway shovel (Sec 27), which requires little headroom, is especially suited to mine tunnels of large cross-sec. A machine of this type requires tractive effort to force the dipper into the muck pile, and the dipper loads onto a short conveyer extending back over the car. For smaller headings, small shovel-type loaders are popular; that shown in Fig 13 uses traction to force the dipper into the pile; it is close-coupled to a mine car, into which the dipper discharges. For headings larger than about 9 or 10 by 12 ft, the larger loaders compete with scraper and slide.

8. MUCKING OPERATIONS

Hand shoveling. With modern high-speed drills, rounds can be completed in less time than they can be mucked by hand, hence, the depth of round that can be pulled economically is often limited by the rate at which muck can be removed. In 3-shift work, mucking must be finished when the drillers are ready to lower the bar for drilling the lifters, else they may be unable to complete the round by the end of the shift. With 2 shifts, drilling and mucking on both, there is some leeway and the muckers can start an hour or two before the drillers. But, if the rounds are too deep, more than 1 shift may be needed for mucking, involving overtime and increasing cost. With hand-mucking, shallow rounds are often found to give max rate of advance. Thus, at the Kerber Creek (Rawley) Tunnel (12), max progress with two 8-hr shifts, drilling 8-ft rounds, was 414 ft in a month, or 15.5 ft per day. In good drilling ground 2 rounds of 4.5 to 5.5 ft could be made in 1 shift, giving an advance of 18 to 22 ft per day. "Mucking by this method would be much facilitated, because fully 25% more could be landed on the muck-plates, and, if necessary, a third shift of muckers could be used." The number of muckers that can work around a car is limited; if too many, they interfere with one another. Analyses at a number of tunnels show that a shoveler requires a $2^1/_2$ to 3-ft width of floor space, so that in a 10-ft tunnel there should not be more than 4 shovelers; in a 6-ft tunnel, only 2 shovelers. For speed work, extra muckers may be required to relieve one another. Their time need not be lost, since, when not actually shoveling, they can switch and handle cars, pick down the muck pile, etc, the change in working position affording physical relief.

In the Laramie-Poudre tunnel (13), 6 muckers worked as follows:

When car 1 was filled, 2 shovelers (A and B) took it to the rear, while 2 others (C, D) took empty car 2, previously thrown on its side off the track, set it on the track and pushed it into position for loading. Meantime the remaining men (E, F) stopped picking down the rock pile, took the shovels

left by A and B and assisted C and D in filling car 2. Car 3 was then brought up by A and B close to where car 2 was being filled, and was thrown on its side in the position formerly occupied by car 2. A and B then picked for the other 4 men, while car 2 was being loaded. When filled, car 2 was removed by C and D, while E and F set up the third car and loaded it with help of A and B. A fourth empty car was meanwhile brought up by C and D, who then took their turn at picking. The cycle was completed when E and F took the third loaded car to the rear, brought back an empty and resumed their original position on the muck pile. Thus, each man spent two-thirds of the time in tramming or picking muck, either of which is easier than loading, and relieves the monotony of shoveling. In this methodical procedure there is no lost motion. Cars of 16-cu ft capacity were filled in an aver of 3 or 4 min. At the Rawley tunnel (12) where a similar system was used with 4 shovelers, 25 17-cu ft cars were loaded in 2 hr; in another case, 20 cars in 1.75 hr, including all delays in making up trains.

Fig 13. Shovel-type Loader Close-coupled to Mine Car for Small Headings

Mechanical loading is not well adapted for drilling and mucking simultaneously, although with small dipper loaders this may be done as at the B. C. Nickel Co's tunnel (3). The routine for driving the long Eureka crosscut at the Burra-Burra mine, Ducktown, Tenn, is typical. The crosscut is in schist and graywacke, 8 by 8 ft in section. As a speed of 500 ft per month was all that was required to reach the objective on the desired date, only 2 shifts were worked, as follows (34):

A scraper operated by a double-drum, 25-hp elec hoist was mounted on a portable frame of mine-track gage, upon which was supported a steel incline for loading into 4-ton cars, spotted by a cable-reel locomotive. Sidings for empty cars were kept within 700 ft of the face. The few minutes needed for switching cars caused no delay, as this time was employed in preparing the muck pile for easy loading. The drill crew began at 7 a m, and, with a clean set-up, started drilling with two 144-lb drifters mounted on columns. At 9 a m the round was about finished, and was usually shot and smoke blown out by 10 o'clock. As the ground broke well, the entire heading was generally shot in one operation. The mucking crew, coming on at 9, oiled and overhauled the equipment, to be ready by 10 o'clock to begin mucking. While mucking out, the drillers overhauled their equipment, sent out dull steel, brought in and sorted fresh steel, and took a short rest period. Mucking was usually done by noon, and a second round drilled and shot by 3 p m. Two shifts each of drillers and muckers completed 4 rounds, making an aver advance of 18 ft per day of about 20 hrs. Each drill crew consisted of 2 drill runners (one acting as shift leader), 2 drill helpers, and 1 steel nipper. The nipper helped the muckers on his shift, besides keeping the drillers supplied with steel. The mucking crew comprised a hoist man, helper at the face, and motorman who spotted and changed cars, hauling and dumping the loaded cars, while the drillers were at work. A foreman had charge of both shifts. The job was organized on basis of 2 high-pressure work periods for each crew, with an intervening period of rest. For completing two rounds per shift, wages were: shift leaders, $8.16; drillers, $7.16; scraper man, $7.16; drill helpers, $6.16; steel nipper, $5.16; scraper helper, $5.16; motorman, $4.08. Except the motorman's wage, these rates were 40 to 90% above the standard. If the 2 rounds were not completed, the men received only the regular daily rate.

The 4 100-ft haulage tunnel at the Britannia mine (2) is 10 × 12 ft. Low cost was more important than speed, the aim being to attain max effic with small crews. The heading crew per shift comprised 1 shift boss, 4 miners, 2 muckers, 1 motorman and 1 brakeman; also 1 trackman and helper and 1 ditchman on day shift, and 1 steel sharpener and helper. The cycle of operations was as follows:

After blasting, 2 miners bar down, 2 rig equipment for drilling holes for "Lewis wedges," 2 muckers clean out for the scraper slide, and the train crew bring in cars and slide. A hole is drilled in each wall at the face, wedges are driven in, a chain is stretched across, on which the tail sheave is hung; the mucking machine is meanwhile clamped to the rails and connected to the 440-volt 3-phase a c power line, and mucking begins. While a 120-cu ft or 6-ton car is being filled the train crew hang an empty on the car switcher, the full car is pulled back, and the empty dropped on the rails and pushed to the mucker. Filling cars averages 3 to 4 min, and switching 1 to 3 min, according to distance. The car switcher is moved up about every 500 ft. One side of heading is scraped out first; when the tail sheave is switched to the other side, 2 or 3 men clean up along the wall with shovels and hand scrapers. The permanent rail is kept 30 ft from the face, so that the scraper can dig to bottom of the ties over the whole area.

After mucking is completed, a light rail extension is laid, over which the drill carriage is run to the face and set up, the staging is erected, and drilling begins. Some side holes and relievers can be drilled as well from one machine as another; the order of drilling being such that these holes are drilled last. If one machine gets into trouble, another can take an extra hole and save delay. While drilling is in progress, 1 man cuts powder and prepares primers; 2 men blow out the holes while the drill carriage is being taken out; the round is loaded, the blasting circuit tested, and the connecting wires strung out; holes connected in series.

A drainage ditch, 3 ft wide and 3 ft below bottom of ties, is carried with the heading. For this the necessary plugging and blasting are done while drilling is in progress in the face, and mucking is done by hand at all points of the cycle. The ground ranges from very hard and blocky to very soft and highly schistose. Hard ground is often wet, and at times water pressure is so great that plugs must be driven into the holes to keep the powder from being forced out. Drilling time ranges from $1^1/_4$ to $5^1/_2$ hr, but 2 to $2^1/_2$ hr is usually sufficient. Timbering was necessary in one place only for about 40 ft.

Aver advance is one 6-ft round per shift, which can be maintained in any but the hardest ground. Total cost of this work to the present time has been $25.83 per ft, including a proper proportion of all constructional and equipment expenses, such as purchase and installation of compressor, erection of steel shop, etc, and of capital charges necessary to equip the completed tunnel with 100-lb track and trolley wire for haulage of ore.

With shovel loading the routine is similar to that with scrapers, as shown by the following examples.

1. Ojuela Tunnel (18). Mucking was done by an air-operated Nordberg-Butler underground shovel, Model 109, which loaded into 40-cu ft cars. The cycle of operations was:

Beginning with a clean set-up, the power shovel was pulled back to the passing switch and the drill carriage pushed to the face. Each of the 4 machines drilled a prescribed number of holes. During drilling the shovel runner overhauled and oiled the shovel and the track crew cleaned up along the side to prepare for laying track and pipe. When drilling was completed, the motor pulled the drill carriage back to the portable turnout and the round was blasted. After waiting 10 min after the last shot, about 1 000 ft back from the face, the entire crew cleaned up the track to the point at which the muck pile was about 1 ft high. The shovel followed the crew and necessary connections were made when the muck pile was reached. Three men pushed one 40-cu ft car from a group of 6 empties from the portable turnout switch to the shovel, after which another empty was placed on the passing switch to be exchanged as soon as the first was filled. Loaded cars were returned to the loaded side of the portable turnout, and the train hauled out. Empties were kept on opposite side of the switch.

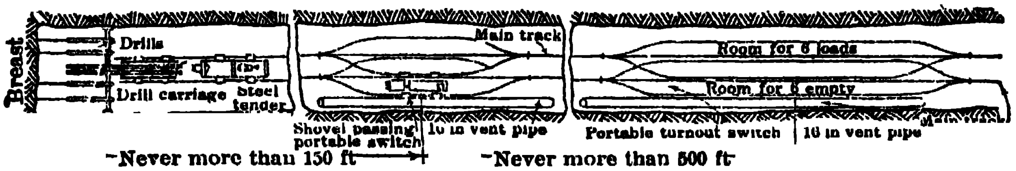

Fig 14. Movable Switches and Passing Track, Ojuela Tunnel

Considerable time was saved by keeping the passing switch (Fig 14) within 150 ft of the face; when the distance between the turnout and passing switches became so great that an empty could not be returned while the mechanical shovel was filling a car, the turnout switch was moved ahead. While loading was in progress, one machine man and the drill-carriage boss inspected the drills, replaced dull with sharp steel, filled the oilers and prepared for drilling the next round. The table shows time consumed in the various operations.

	Hr : min			Hr : min	
	Aver	Best		Aver	Best
Taking drill carriage to face and setting up	0 : 30	0 : 15	Cleaning up ahead of shovel	0 : 15	0 : 07
Total drilling time	1 : 50	0 : 55	Loading: (aver of 20 cars @ 40 cu ft per round)	2 : 00	1 : 45
Tearing down, blowing, charging, blasting	0 : 35	0 : 25	Interval, end of loading to start of setting up	0 : 15	0 : 07
Waiting for smoke	0 : 12	0 : 05	Total time	5 : 37	3 : 39

2. Owyhee Tunnel No 5 (19). General procedure was as follows: the blower exhausted powder smoke from the face for 10 min aver; it was then reversed, blowing in fresh air. A train of 81-cu ft cars, with mucking machine at head end and locomotive at rear, proceeded from nearest passing track to the face; the shovel (Conway, Type 50) started loading on reaching the first fly-dirt and continued until the face was clean. 3 miners and helpers then rigged up 3 machines on a horiz bar, and, working from a staging, put in the upper holes; one miner and helper, drilling from a horiz bar, put in the lifters; the drilling completed, the miners tore down and blew out the holes. The holes were wired by the shift boss or powder man, and fired with delays from a switch, the compressor-house attendant reversing the blower on hearing the shots. Aver time for each operation during 3 good months, 3 283 ft being driven in 212 shifts, 15 shifts of which were devoted to timbering, was: ventilating, 10 min; shoveling, 1 hr 18 min; setting up, 31 min; drilling, 1 hr 19 min; tearing down, blowing holes, loading and blasting, $^1/_2$ hr; total time, complete round, 3 hr 48 min. Per round: ft advance, 7.82; no of holes, 19.2; ft drilled, 172; no of cars, 16.9; lb powder, 146.6 (18.6 per ft advance). Per shift: rounds, 2.12; ft advance, 16.6. Depth of holes, 9 ft.

9. TRAMMING AND HAULAGE

Mucking by hand. Any delay in tramming or prompt replacement of loaded with empty cars affects mucking efficiency and may upset the entire cycle of operations. There are various methods for minimizing the time required to handle the cars. Due to the extra effort for hand shoveling into high cars, or throwing muck to the back of long ones, small light cars are usually preferable, although they involve more shifting per yd handled. Light cars are changed quickly, as empties can simply be tipped off the track, to allow loaded cars to pass, and replaced for pushing them to the face. Another method for light cars is to use a "slick-sheet," beside the track and close to the face, on which an empty is kept always ready. When a car is loaded, it is pushed past the slick-sheet, an empty brought to the face, and another empty placed on the sheet. At the Sheep Creek tunnel (21) the slick-sheet was never more than 50 ft from the face; another sheet, a few hundred ft farther back, held a train of empties. The loaded cars were run back past the empties, made up into a train and hauled out. The empties were then run singly to the sheet at the face. As the sheets were set at same height as top of the rail, cars had only to be lifted the height of the flange.

Mechanical loading has brought about the use of larger cars, which are loaded by machine as quickly as small cars by hand. To reduce switching delays, thus increasing actual loading time, special methods and equipment have been developed. The commonest are movable switches and passing track, and the crane car-lift ("cherry picker"). Fig 14 shows switches and tracks in the Ojuela tunnel (18); for details of car changing routine, see Art 8. Fig 15 shows a form of "cherry picker" employed in the Wachusett-Coldbrook tunnels (35).

It is an air-lift hoist, traveling on a transverse beam or bar near roof of tunnel. An empty car is raised by the hoist, transferred to one side, the loaded car switched back, and the empty then returned to the track ahead of the train and pushed alongside the loader. Thus, for each car switched, the train moves its complete train length, backward and forward; plus any distance greater than normal between the cherry picker and the face; plus the working clearance for car and shovel at the face. Time studies at the Moffat tunnel, where a cherry picker and 50-cu ft cars were used, showed that actual loading consumed 28% of total loading time, and switching 24%. At the Owyhee tunnels (19) with same equipment, except that cars were of 81 cu ft capac, the number of cars to be switched was reduced by 60%, thus saving 13 to 19 minutes per round. When loading by scraper and slide, a large car can be used, although its height must be limited to allow room for the loading boom above it and clearance for the scraper as it passes over the boom. Fig 12 shows the equipment devised at a Wisconsin mine (33), where 2 cars (190 cu ft each) and a locomotive comprise a loading and haulage unit. With this, an aver round of 6.1 ft in a 9 × 14-ft crosscut was mucked out in 3 hr 9 min aver. The entire unit goes out to the dump, 3 or 4 trips being required to clean up a round. Other devices for saving time in switching are the "grasshopper" and the conveyer (Sec 27). The former, applicable only to a high tunnel, consists of a steel frame straddling the tunnel track and traveling on a wide-gage track. A hinged ramp at each end is lowered to permit running a string of empty cars on and off the deck of the frame which is high enough to allow cars to pass through under it. The empties are pulled up the rear ramp by an air hoist, and lowered singly on the front ramp, as required by the loader. The conveyer may be used where headroom is less; it consists of a belt mounted on a framework straddling the tunnel track. The mucking machine loads through a hopper onto the conveyer, which is long enough to cover a string of cars. Table 7 gives data on tramming and haulage time, which are virtually the same as mucking time, the operations being concurrent.

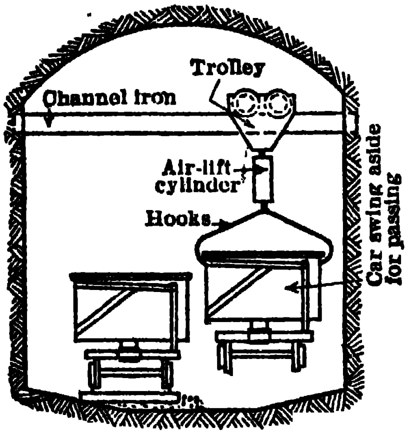

Fig 15. "Cherry Picker"

Type of car used will depend largely upon dumping facilities. Solid-body cars may be of large capac, yet low. Their first cost and repair costs are comparatively small, and spillage along the track is a minimum, due to the absence of doors around which leakage may occur. These cars require a rotary dump, and involve rehandling the muck in another car or skip for final disposition; the extra cost of plant may not be warranted. Granby-type cars (Sec 11) have certain advantages, especially for fast dumping, but require a fixed dumping ramp. In most tunnel jobs the muck is spread over a considerable area near the portal, simply by fanning out the pile, and for this side-dump cars are ideal, although they may be too high for easy hand loading, and even for mechanical loading if the tunnel headroom is small. Gable- or rocker-bottom cars are commonly employed in the smaller tunnels. (For different types of cars, see Sec 11.)

Haulage is usually by locomotives, which are also used for switching at the face and for moving drill carriages, mucking plant, timber, and supplies. Storage-battery locomotives are ideal for short hauls, and have the advantage of eliminating trolley wires, especially important at and near the tunnel face. Combination trolley-battery locos, often used in long tunnels, run on the batteries for spotting and switching cars near the face, and operate as trolley locos for the long haul out to the dump. Cable-reel trolley locos are employed similarly. On some jobs a small battery-loco is used at the face for spotting and switching, and a separate trolley-loco for the long hauls.

10. VENTILATION (see Sec 14)

Adequate ventilation is a requisite for rapid and economical tunnel driving and to protect workmen against dust and gas hazards. In tunnel work it usually implies mechanical ventilation, for prompt removal of gases after blasting and supplying fresh air at the face. Good ventilation is required during drilling and mucking, for diluting and sweeping out harmful dusts; under high-temp conditions, for immediate physical relief of the men; and, under explosive-gas conditions, for diluting and removing gas.

During drilling, or the operation of air-driven shovels or scrapers, exhaust air affords some ventilation and cooling effect. Just before firing around, the comp-air line is usually opened to blow against the face, diluting the powder gases and gradually moving them back from the face. At velocities up to about 30 ft per min, the gases move back as a cloud; higher velocities result in churning and dilution, without materially hastening this movement. Removal is therefore very slow unless a blower or fan is installed at the tunnel portal; it is connected to a pipeline which is suspended in an upper corner of the tunnel and extends as close to the face as possible without danger of its being injured by blasting.

Blowing vs exhaust systems. The relative merits of continuous blowing, continuous exhausting, and blowing followed by exhausting, are still debated. Local conditions may influence results obtained by different methods. Data in Table 3 indicate a majority preference for the exhaust system. Arguments for and against may be summarized as follows. With blowing only, the gases are churned about at the face, but are eventually caught in an outgoing current of air through the tunnel. Thus even if they are quickly removed from the face, men returning to work must pass through a gassy zone unless they wait long enough for the gas to discharge at the portal. The ventilating pipe can not be carried close to the face, because of flying rock from the blast; but, when blowing, flexible tubing can be attached to the pipe to carry air to the face, and is quickly rolled back a safe distance before the blast. While with non-collapsible tubing the same practice is possible when exhausting, it is seldom attempted. Blowing at the face causes a rapid cooling effect on the men; whereas, when exhausting, movement of air at the face is hardly felt, although the volume of fresh air may be the same. With straight exhaust, the movement of fresh air from the portal is usually along the floor near the face, thence upward, and out through the ventilating pipe. Due to the necessary distance from end of the pipe to face, the gas may take some time to reach the pull of the exhaust; but, when caught, it is immediately sucked out of the pipe, and the tunnel is clear to the portal, so that men can return to the face in fresh air. During drilling and mucking, blowing dilutes concentrations of dust (or strata gases, like methane), and sweeps them from the face, whereas exhausting often fails to reach the greatest concentrations. When drilling, the drill exhaust aids somewhat in driving the dust back to the ventilating pipe.

In general, it would appear that max results can be obtained under normal temperature conditions by the following sequence: (1) blow from compressed-air line at the face during and immediately after blasting, thus driving the gases back to the end of the exhaust pipe, whence they are drawn out; (2) as soon as gases are removed by the fan or blower at the portal, extend flexible tubing to near the face and reverse the current, blowing fresh air in; (3) continue blowing during mucking and drilling. On some jobs the system is operated *blowing* for 10 or 15 min following the blast, supplementing the effect of the compressed air jet, and is then reversed, operating *exhausting* during the rest of the cycle. Under high-temp or explosive-gas conditions, continuously blowing systems are preferable.

Blowers. The high-pressure mechanical ventilation required for long tunnels may be produced by positive-pressure blowers, low-pressure centrifugal or propeller fans installed in series, or centrifugal compressors (see Sec 14). Tunnel contractors usually prefer positive-pressure blowers, although some centrifugal compressors have been employed in recent years.

11. TUNNEL SUPPORT

Support for the tunnel roof and sides may be required while driving. If it must be kept close to the face, the rate of advance is retarded, and the cycles of operation already outlined may have to be changed to include a timbering period. Placing timbers after blasting each round may require as much or more time than drilling or mucking. Some ground stands well when freshly broken, though after continued exposure it may slack, crack or slab off. In such cases the placing of supports may safely lag some distance behind the face, causing little if any hindrance to driving operations. Temporary timbering is often used during driving and replaced later by permanent supports or lining. Permanent supports are of timber, structural steel, or concrete; brick or masonry was often used in the earlier R R tunnels. Concrete may be poured around forms, where a strong lining is needed to support heavy broken ground; or, where there is no great weight

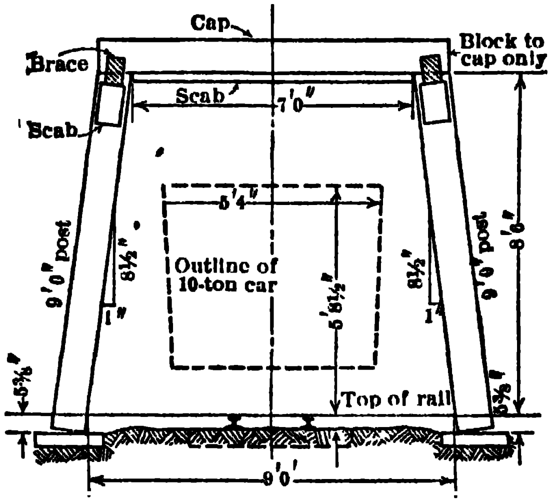

Fig 16. Three-piece Tunnel Set

and it is only necessary to prevent air-slacking, a thin layer of "gunite" suffices. For permanent support, timber should be well seasoned and treated with preservative. It is easily framed on the job and quickly erected without use of special tools or equipment. For temporary support, in local stretches of bad ground while advancing the heading, timbers are readily cut and framed to suit requirements.

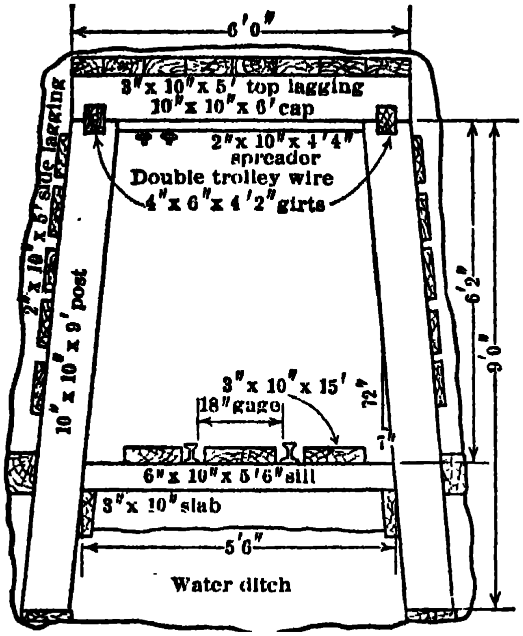

Fig 17. Drainage Tunnel Set with Ditch under Track

Timber sets comprise several timbers forming a framework across the tunnel section. The commonest form for narrow tunnels is the 3-piece set, consisting of a cap and two posts. Fig 16 shows a typical 3-piece set, with posts battered to resist side pressure. Fig 17 is a set used in the Park-Utah drainage tunnel, where a water ditch of large capacity was required (36). Posts may be dapped into the ends of the cap, or held apart at the top by a "scab" piece spiked to under side of the cap. Collar and toe braces between adjoining sets resist longitudinal movement of the sets. The batter of the posts is 1 to 1.5 in per ft, which is usually sufficient to prevent the bottoms of the posts from pushing inward unless side pressure is excessive and the bottom soft. The set in Fig 18 has "batter blocks" to prevent displacement of the posts by swelling ground. The back of the tunnel often stands better if arched (Fig 3 and 4), especially in wide headings. Similarly, arched sets (Fig 19) are customary in wide tunnels. Where only the back requires support and the walls are strong, posts may be omitted and the arch timbers set in hitches cut at the break-line of the arch (Fig 20). In swelling ground, where the bottom tends to heave, an inverted arch set (Fig 21) may be used. Size of timbers and interval between sets depend upon size of tunnel, and pressures to be withstood. The back and walls between sets may or may not require support by lagging. Swelling ground should not be close-lagged, but spaces left between adjacent pieces of lagging, through which pressure can be relieved.

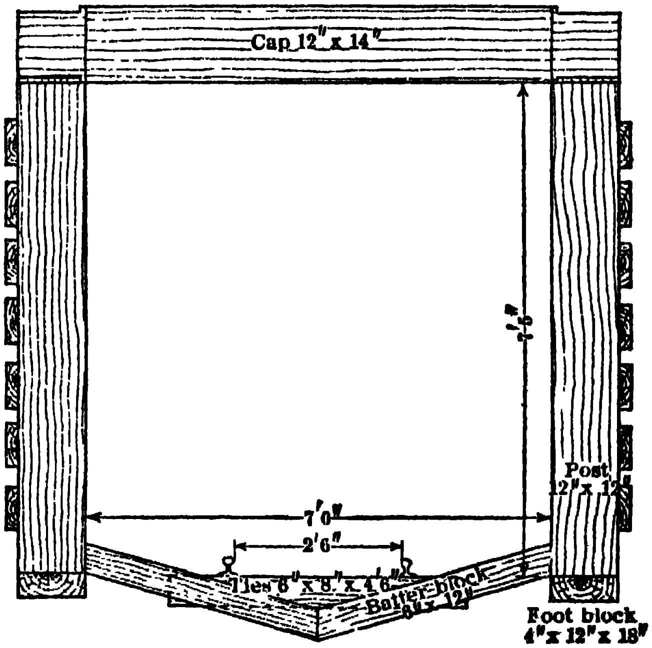

Fig 18. Set with Batter-blocks in Swelling Ground

Routine and speed of timbering depend largely on how close the timbering must be kept behind the face. If each round of advance must be supported at once, timbering becomes a part of the driving cycle. The first step after blasting is to scale the back; and, in loose ground, to hold the back ahead of the last set by forepoling, sliding booms (Fig 22) or similar means, to protect men while mucking. After the round is mucked, the new set is erected, blocked in place and lagged if necessary, and the drills are set up for the next round. This procedure obviously slows the rate of advance, but unless the ground is very bad, requiring spiling or other special methods, timbers can be standardized and a regular routine followed. Speed is gained by having all materials and supplies at the face before work begins; timber for a complete set, blocks, wedges, lagging and tools, should be brought in

with the crew. Where the timbering lags a considerable distance behind the face, a special timber crew is usually employed. With suitable scaffolding, work can proceed without interfering with driving operations. A movable scaffold, with a working deck several sets long and high enough to allow the tunnel cars to pass under it, may be advantageous.

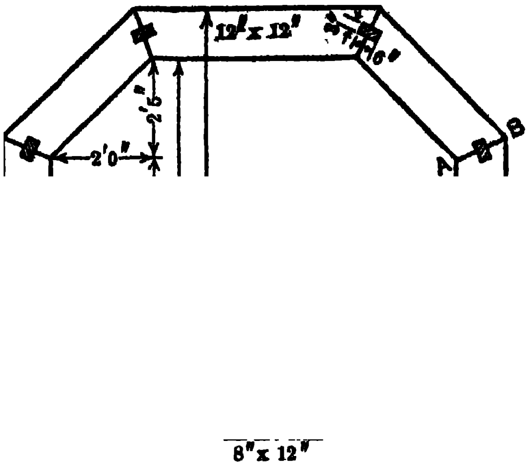

Fig 19. Arch Tunnel Set

In the Claremont tunnel (37), sequence of operations was: (1) excavation and timbering, interrupted from time to time to construct the concrete invert; (2) placing forms and pouring the concrete arch. Tunnel sets were 5-piece (arch), with 6-ft posts and were 4, 5 or 6 ft apart, depending on the ground. Timbers were 8 by 8 in, later changed to 8 by 12 in. Drilling and blasting averaged 2 1/2 hr; mucking, with a Conway machine, 3 hr. After blasting, the top lagging boards were driven forward and mucking was started. After clearing out the face the timber set was erected and blocked in place, side lagging being placed where necessary. Advance per round, 4 to 8 ft and 24 ft total advance was often made in a day. About 5.5 hr were required for drilling, blasting and mucking, leaving some 2.5 hr for timbering; thus it was possible to complete a round and timber it in an 8-hr shift. However, timbering close to the face usually precludes completing two rounds per shift, though it may not do so where the ground is not bad and the work is highly systematized.

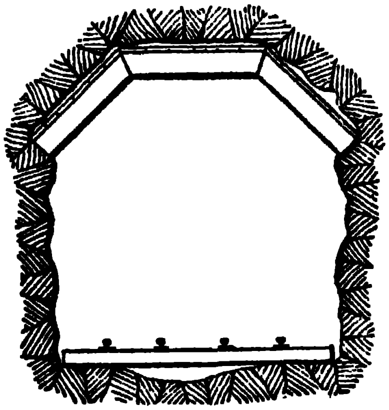

Fig 20. Arch Set without Posts

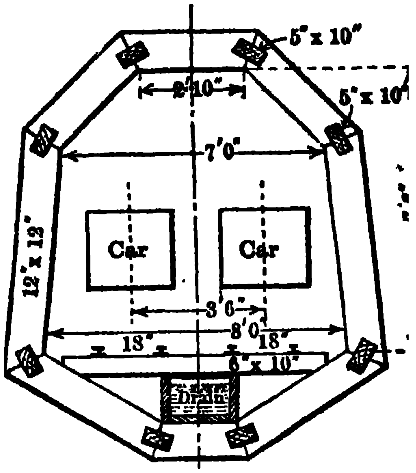

Fig 21. Inverted Arch Set for Swelling Ground

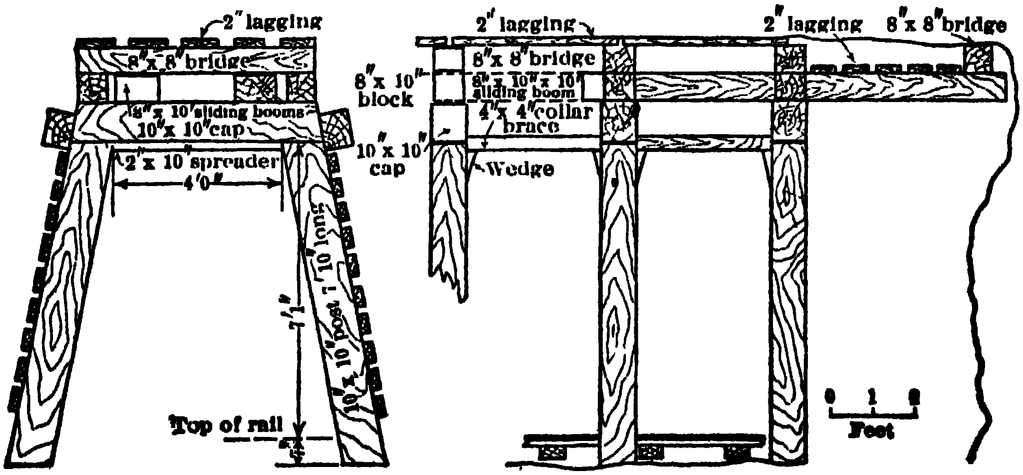

Fig 22. Sliding Boom for holding the Back ahead of Last Set]

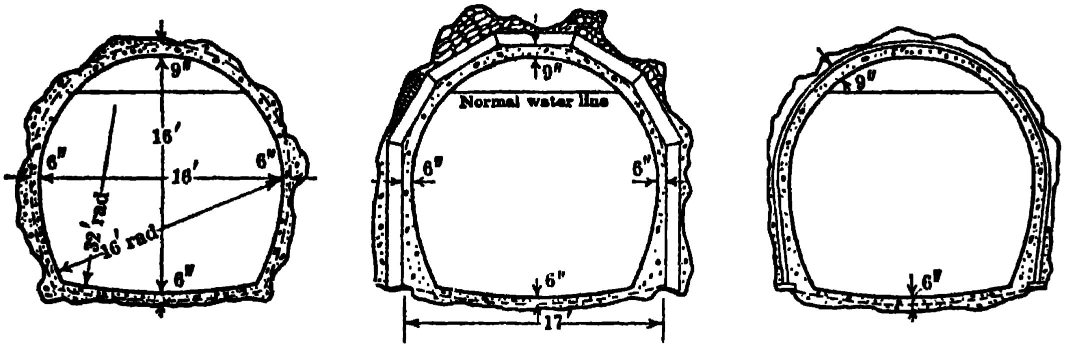
In the B. C. Nickel tunnel, where little timbering was required, the timbers were set by the muckers under direction of the shift boss while the machinemen were drilling the lifters. At the Big Creek tunnel (1) it is stated that "bad sections of ground were timbered as broken, which threw the cycle out of gear and cut down progress." Much of the Rawley tunnel (12) had to be timbered during Sept and Oct, 1912, when the advance was 390 and 185.5 ft, respectively; during June, July and Aug, when little timbering was required, the advance was respectively 488, 555 and 421 ft.

Concrete lining is now used in many tunnels, especially aqueducts, designed for long life, irrespective of immediate need for support; in the course of time many rocks disintegrate to some extent and some slabbing occurs if they are not sealed off. In most mine tunnels and some others which have to be timbered during driving, the concrete is poured around the timbers without disturbing them, the tunnel having been driven oversize, to leave the desired clear section inside the timbers. Sometimes 2 or 3 in of concrete over the face of the timbers is considered sufficient, the thickness of course being much greater between the sets.

In the Colorado River aqueduct a 6-in thickness of concrete was maintained inside timbers (Fig 23*b*). Fig 23*a* shows the lining in untimbered sections of this tunnel and Fig 23*c*, a steel-lined section. Concrete is placed in separate sections after excavation has been completed. The curbs *A* (Fig 24) are poured first, then the arch *B* and last the invert *C* (7). "The forms used in placing the arch lining are made in 30-ft lengths and constructed so they may easily be collapsed on a carriage to such dimensions that they may pass under other forms in place in the tunnel. . . . The carriage is equipped with hydraulic jacks, used to expand the forms into position, where they are braced and held between the curbs by screw jacks placed between the forms and the haulage track. . . . About 8 30-ft sections are required at each concrete pouring operation. The batches are proportioned by weight in quantities of 1 cu yd each, at batching plants outside the tunnel, placed in specially designed batch cars and pushed into the tunnel and up to the mixer by a locomotive. . . . The mix is dumped from the cylinder into an ingenious pump, which forces the concrete through an 8-in pipe-line up over the tops of the forms to the advancing arch of fresh concrete. . . . Another method is to wet-mix the concrete outside the tunnel and transport it to the placing machine inside in batch buckets carried on special cars. These buckets are elevated by an air hoist and dumped into the cylinder of the placing gun. The cylinder is then closed and compressed air introduced at a pressure of 80–125 lb per sq in. . . . As much as 735 cu yd have been placed in one tunnel in one day. In a month of 27 working days, 14 400 cu yd of concrete were placed; an aver of 535 cu yd per day." Where ground conditions permit, concreting follows some distance behind the heading, else it must be done intermittently and at greater cost, since (unless more than one heading is in progress) the concreting crew will be busy only part of the time. Minimum thickness of concrete is gen-



a-Untimbered section *b*-Timber-supported section *c*-Steel-lined section

Fig 23. Typical Sections of Concrete Tunnel Lining, Colorado River Aqueduct

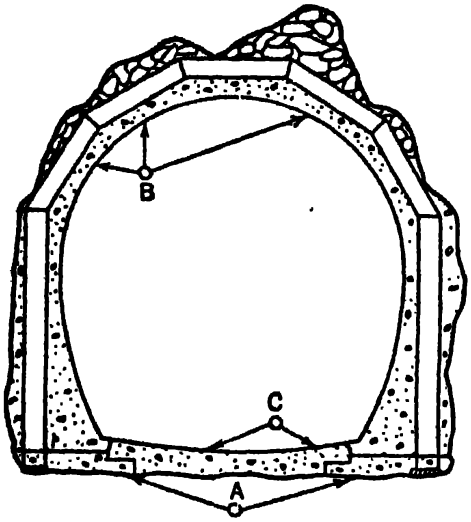


Fig 24. Order of Concreting, Colorado River Aqueduct

erally from 6 in upward, the arch usually thicker than the walls. The forms are of wood, steel, or wood on steel. Concrete is placed by hand, gravity, pump, or pneumatic cylinder. Gravity is common for sides and invert; pneumatic cylinder for the arch, even on same job.

Gunite. Where no great weight is expected, slabbing is often prevented by a $^1/_4$ to $^3/_4$-in coating of gunite (mixture of about 2.5 to 3 parts sand to 1 cement), applied to the rock walls with a cement gun. The fresh rock should be coated as soon as broken, all loose rock being first removed and the walls cleaned thoroughly. In the United Verde Ext tunnel gunite was used successfully in a 4 090 ft section, and in 1930 had held for over 10 years (38). The tunnel is 10 by 10 ft; a 3 : 1 sand-cement mix was applied in 2 coats. Total cost of labor, materials, machinery repairs and supplies, was $5,772.23, or $1.40 per lin ft of tunnel treated, or 46c per sq ft.

12. DRIVING THROUGH LOOSE OR RUNNING GROUND

Conditions range from ground which is merely loose and heavy to those where water under pressure may force soft-material into the heading. For the first condition, forepoling with or without breast boards usually suffices. Methods differ in detail, but in general involve the driving of spiling over the last set of timbers, so that room is left below or (with side spiling) inside, for erecting the next regular set (Fig 25).

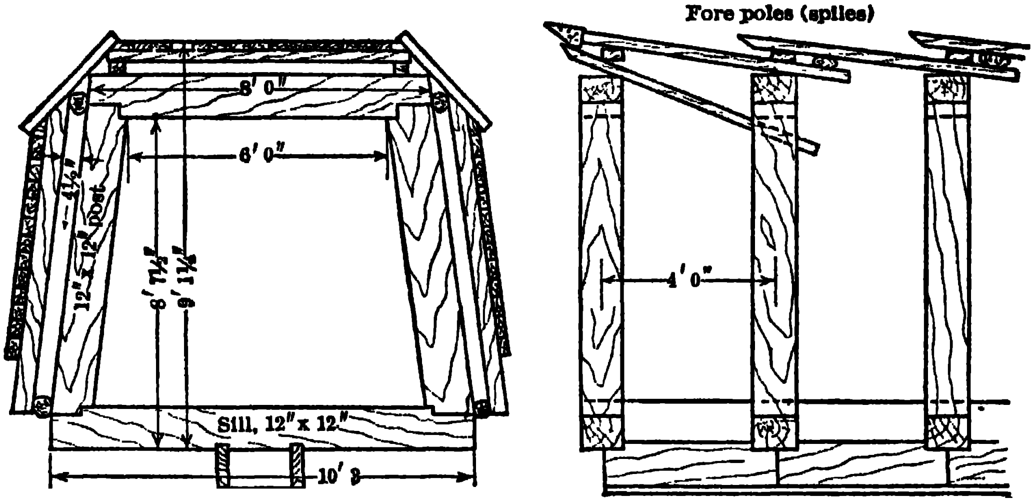

Fig 25. Forepoling with Regular and Bridging Sets

Fig 26 shows the swinging false set with a 3-piece arch cap for very heavy ground. It can be applied with even greater facility to the ordinary horiz cap. There are no tail blocks, nor does the spiling have to be driven across 3 sets of timbers, as in Fig 25. The weight on front ends of spiles is carried by the swinging false set, and the spiling can be driven with less hammering than is required with the tail blocks. The posts of the false

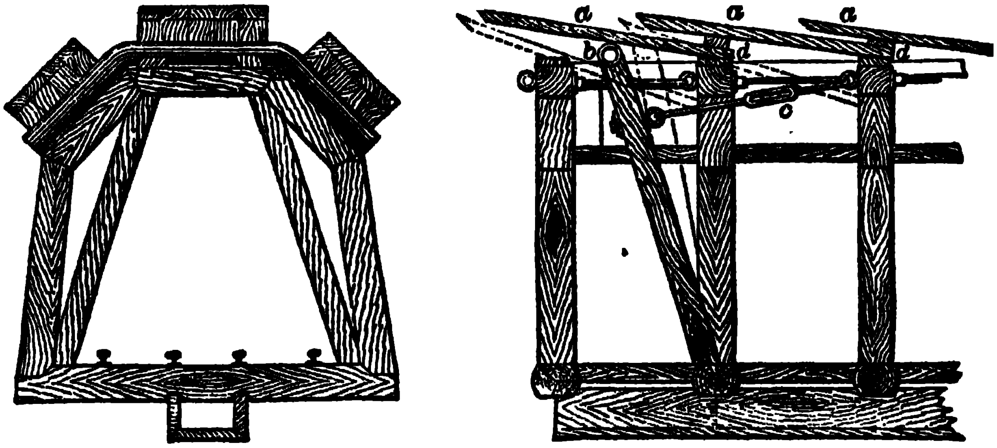

Fig 26. Swinging False Set

set rest and rotate on the sill of permanent set, and when first erected occupy the position shown by dotted lines. They carry a cap of heavy steel pipe *b*, which supports front end of spiles *a*. While driving, the only pressure to be sustained is that of the rock above and in front of *a*; whereas, with tail blocks, a few pounds weight on front end of a spile brings 4 or 5 times as much weight on its supports. As the spiling is driven, turnbuckle *c* is slowly unscrewed, allowing the false set to fall forward, until the spiles are nearly horiz. When all spiles have been driven home, and the supporting block *d* placed under them, the turnbuckle is slacked still farther, until the swinging set loosens. Then the hanging rods are unhooked from the eye-bolts and the false set is advanced to its next forward position.

This system requires that the timbers for at least 5 or 6 sets from the face shall be connected by tie rods, as shown. This is an advantage, because, by screwing the timbers up tightly against the braces, they can be more easily blocked in position. Also, the timbers are held in place so rigidly that, if hard ground occurs in any part of face, heavier charges of explosive can safely be used than if timbers were held in place only by blocks and wedges.

Where there is water pressure, special methods sometimes have to be adopted, such as drilling holes ahead of the face and pumping in cement grout to seal off the water (see Sec 8). The liquid cement is drawn from mixing tanks into a pump chamber and discharged through pipes into the drill holes. Pumps have been used capable of developing pressures up to 3 000 lb per sq in. Freezing methods (see Sec 8) and working with a shield behind compressed air locks are special methods seldom if ever employed in mines.

13. COSTS

Table 3 (Art 1) gives typical costs of tunnel excavation, but except for tunnel No 1, these do not cover cost of concrete linings. Concreting may cost as much as excavation or more. The following cost data are typical.

B. C. Nickel tunnel (3). Section 8 1/2 by 10 ft; length, 4 629 ft; little timbering; Nordberg-Butler "shuveloader;" progress best month, 630 ft.

Table 8. British Columbia Nickel Tunnel (1934)

	Cost per ft	
	505 ft	4 563 ft
Drilling and mucking:		
Wages	$ 8.02	
Machine shop	.24	
Drill steel loss	1.30	
Machine drill parts	.97

SHAFT SINKING IN ROCK

1. CROSS-SECTION OF SHAFTS

Rectangular section divides naturally into rectangular compartments, requires least excavation for given hoisting area, is adapted to framed timber or steel support and is most widely used in metal mining for sinking in rock. Inclined shafts are almost always rectangular, though if concrete-lined they may have arched roof. ROUNDED SECTION (circular, elliptical, oval) better resists lateral pressure, involves less air friction per unit of area, requires some form of lining other than framed support, and is adapted to rectangular hoisting compartments by using the surplus segmental areas for ventilating, pipe and ladder spaces. Circular section has max strength and for air shafts requires least excavation for a given air volume. Oval or elliptical section is stronger than rectangular and shares its space economy, but is difficult to keep plumb during sinking. In U S colliery shafts, straight sides and rounded ends (Fig 3) combine convenience of dividing into compartments with efficient air passages.

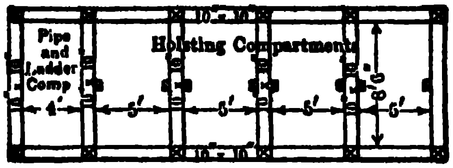

Fig 1. Rectangular Shaft

Compartments of a vert shaft may be side by side (rectangular or oval form), or in pairs across the shaft (all forms). Cage compts are best in line (Fig 1), to simplify trackage at stations, but large modern shafts often combine cage compts of full shaft width with paired skip compts (Fig 2; also applied to rectangular form, Fig 25). Inclined shafts usually have compts side by side, though "double-deck" slopes have been sunk; they are said to be cheaper than shafts of like capac but of 2-compt width.

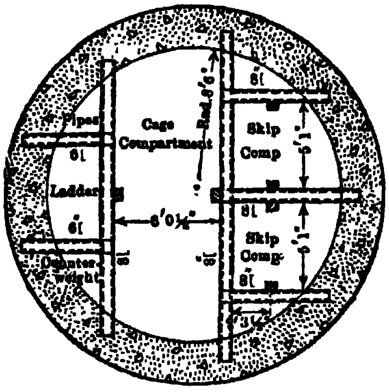

Fig 2. Circular Shaft

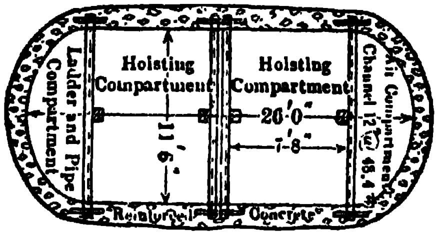

Fig 3. Modified Elliptical Shaft

In heavy ground the oblong section (Fig 1) can be more effectively supported than the square; the long axes of compts should lie across the shaft, to reduce distance between dividers and give better support to wall plates. Oblong section favors a wide collar between cut holes, with economy of powder (Art 6). In steep strata the short axis of vert shaft should follow the strike, to minimize the unsupported rock span and so guard against movement along the dip during sinking. Forman shaft (Comstock lode) was L-shaped, with 3 compts in line and a service compt offset at one end; it invited unequal ground pressures, was costly to maintain and proved unsatisfactory.

2. SIZE OF SHAFTS

Sectional dimensions depend on: purpose, required capac (in terms of product, mine supplies and men transported, or vol of air passed); amount of water to be raised; hoisting method (cage or skip); character of ground; and unit costs of sinking and operating. Sinking cost per ft of depth is minimum for a section of approx 4 or 5 by 6 ft; smaller sections impose cramped positions on miners and preclude the most effective placing of drill holes; hence cost more.

Prospect shafts are often of minimum size, and may have but 1 compt, for both hoisting and ladderway.

Air shafts may have 1 or 2 compts, the second being a small ladderway with fireproof curtain wall. Single-compt shafts in solid rock are often circular and unlined, though smooth lining reduces air friction. Davis-Daly shaft (Butte) has an octagonal section, circumscribed about a circle of 6.5 ft diam inside a smooth timber lining; its coeff of air friction for 1 800 ft depth was 1.29×10^{-9} at 90 000 cu ft per min, compared to 8.8×10^{-9} for a rectangular unlined shaft of like depth and capac. Boring a shaft full-size by shot drill (Sec 9, Art 23) implies circular section and smooth walls, ideal for passing air; an air shaft of 5 ft diam was bored at Grass Valley, Calif, to 1 125-ft depth. That section is most economical, for which interest on first cost, plus cost of forcing air against the shaft resistance, is minimum.

Working shafts. For general service, design becomes more elaborate with depth and capacity. Shafts used solely for hoisting water often have no ladderway and operate automatically. Two-compartment shaft (one compartment for unbalanced hoisting, with pipe and ladderway) is suited only to shallow mines of small production, where low sinking cost means more than power economy at the hoist. Three-compt shaft, including pipe and ladderway, permits balanced hoisting, but in 24-hr duty 30–50% of the time is spent in handling men and supplies, hence is best suited to moderate production. Time is saved for hoisting ore by adding a service compt, which may be merely part of the manway reserved for a small cage (to transport mine officials and minor supplies), or a distinct compt with cage, often counterweighted, for entire handling of men, timber and supplies (Fig 4). In wet shafts it is convenient in handling pumps; and in firm ground may be long enough to handle timber laid sidewise on trucks (Fig 25); it may serve also for further sinking. Four-compt shaft usually comprises 1 service and 2 (balanced) hoisting compts, with pipe and ladderway. In a five-compartment shaft, the service compt develops into 2 balanced cageways, with 40–60% spare time available for hoisting ore; there are also 2 regular hoisting compts (often skipways), and a pipe and ladderway. Sometimes ladderway and pipeway are separate compts. In this way, or by multiplying hoisting compts, six- and seven-compt shafts are developed; on the Rand a 6-compt shaft with 2 main hoists and 1 auxiliary for miscellaneous service has ample capac for the working area conveniently reached from one shaft, but time lost in frequent inspection of a deep single-lift shaft may make a 7th compt advisable. The 6-compt Vlakfontein No 1 shaft is 43 × 14.5 ft, the 7-compt Wolhuter shaft 46 × 9 ft rock section.

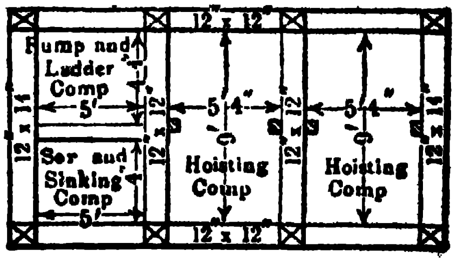

Fig 4. Shaft with Service or Sinking Compartment

Size of compartment for hoisting depends upon the horiz area of cage or skip, with clearances (Sec 12). In U S metal mines, for cage carrying 0.75 to 1-ton cars, cageways may be 4 by 5 to 5 by 7 ft inside timbers; in coal mines, with larger cars, 6 by 10 or 7.5 by 12 ft. In a service compt, the cage may be proportioned to size of loaded timber truck, not of ore car.

Rock section for framed steel or timber support is cut to allow 3 or 4 in outside of shaft sets, for blocking and wedging; a greater clearance involves needless expense. For monolithic concrete linings, shaft walls are dressed to allow a minimum thickness of concrete.

3. SINKING PLANT

Temporary sinking plant at a new site comprises: hoisting apparatus (windlass, whim or engine, with rope and buckets, skips or cages); tripod, derrick or headframe; provision for waste disposal; equipment for removing water (bailing tanks or sinking pumps); boiler plant or elec power substation; air compressor; and housing and accessories. At a working mine the existing power supply is available, and (for deepening a shaft in use) hoisting service also. Temporary plant should be designed not to interfere with installation of permanent plant; the sinking hoist is placed away (often on opposite side) from site of permanent engine, unless opposite a service compt for later use as a service hoist; the sinking headframe is designed to permit erection of permanent frame and placing of shaft collar while sinking. Use of permanent hoist when ready promotes sinking effic.

Windlass and whim (Sec 12) are often used in starting a shaft and in sinking through surface soil before the power hoist is installed. Amount of water influences depth to which their use is

practicable; for depths over 20 to 30 ft their application is mainly to new work in remote regions, or where mechanical power is not available.

Sinking engines should be strongly built, of duplex type; many lives depend on their reliability. For depths to say 500 ft, and hoisting with ordinary bucket (Sec 12), a friction-gear engine of 12 to 30 rated hp is ample, depending on size of shaft. A single deep-flanged drum of 14-in diam, gear-driven by air or steam cyls 6.5 by 8 or 7 by 9-in, or by 25-hp elec motor, will handle 0.5-ton bucket at 300 ft per min. Greater depth requires a larger hoist, preferably of reversing type. A 5-ft drum geared to a 200-hp a c or 150-hp d c motor will hoist a 2-ton bucket or a cage with 1.5-ton car at 600 ft per min; suitable for a 12 by 16-ft rectangular or 17-ft circular shaft to 1 000 ft depth. In deep Rand shafts, two drums 8-ft diam, 2-ft face, geared at 3 : 1 to 2 steam engines, cyls 16.5 by 33 in, hoist 2-ton skip or 3-ton bucket at 1 500 ft per min; deep circular shafts have been sunk with two 3-ton buckets in balance (6). For a 2 500-ft shaft at Kirkland Lake, Ont, a 72 by 36-in double-drum hoist was used, with a 150-hp a c motor, overall capac (single line), 7.5 ton at 1 000 ft per min; for cost, see below.

Tripod of timbers bolted together at top, where sheave is suspended, forms a simple sinking headframe. A second sheave may be fastened to bottom of tripod leg nearest the hoist, to lead rope off horizontally.

Stiff-leg derrick is often used for sinking through surface soil; it does not exert pressure on ground immediately surrounding shaft, nor interfere with placing timbering or masonry of permanent shaft collar. Donaldson (1) recommends for colliery shafts a derrick with 40-ft boom and 30-ft mast of 12 by 12-in timber. Where derrick is used for sinking to depths of 100 ft or more, provision should be made to prevent it from swinging when bucket is in the shaft.

Sinking headframe design is the same in principle as for permanent frame (Sec 12). It is smaller; usually has one sheave; and distance between sheave and crosshead in the dumping position is small. Sinking frame should embody features for dumping buckets or skips; for protecting workmen on surface and in the shaft from falling pieces of rock while dumping; and minimizing work of topmen, in dumping buckets and removing broken rock. A contractor's sinking frame is portable, easily erected and dismantled.

Water to approx 1 000 gal per hr may be hoisted, much of it filling voids in bucket-loads of rock; larger volumes require sinking pumps. With increase of water, cost of sinking rises, speed decreases. Ample capac of boiler plant is more important than steam economy, especially if there is danger of sudden inflows of water that may drown the pumps.

Cost of plant. For 500-ft depth, handling 30–40 gal per min, cost in 1910 was given as follows (1): present costs are roughly 50–75% higher:

Hoisting engine	$1 000	2 buckets	$150
Two 80-hp boilers and setting	1 800	Rope	150
Pipe and accessories	500	Buildings	500
150-hp feed-water heater	300	Dump cars and rails	300
14-in compressor	1 750	Electric lighting plant, 10 kw	750
3 drills and steel	1 000	2 sinking pumps	500
Shaft bar and clamps	100	Small tools and sundries	500
Derrick	400		
Headframe	500	Total	$10 200

Cost of erecting and dismantling plant, $1 000 to $2 000.

For 2 500-ft depth at Kirkland Lake, Ont, a shaft 17 by 9 ft rock see required the following in 1931 (30); costs include installation:

Road to site, 0 5 mile	$ 2 297	Blacksmith shop	$ 3 360
Hoist (see above)	26 823	Office and equipment	1 420
Compressor, 1 000 cu ft per min	8 494	Misc surface plant	3 265
Hoist and compressor house	1 960	Drills and accessories	2 282
Headframe, A-type, wood, 60 ft high	2 938	Drill steel, 4.5 ton	1 095
Cars, 2 of 1.5 ton, and trackage	510	Buckets, 3 of 1.5 ton	300
Elec power substation	7 086	Sinking pumps, motors	3 137
Surface pumps, motors, pipe lines	1 269	Total	$66 236

4. SINKING ORGANIZATION

Two general systems of organizing underground work in sinking: (*a*) Machine men drill and blast the round, and lower-priced men handle the muck. The two crews may work together or on separate shifts; if together, good management is needed to prevent interference, and if on separate shifts, to maintain a rigid schedule. When well organized, this is usually the cheaper system. (*b*) Labor is used indiscriminately to drill and muck.

No interference is possible, and no rigid schedule necessary; each shift takes up the work as left by preceding shift. With 3 shifts, this system makes for speed, but at slightly greater cost per ft of shaft, because skilled labor is used for mucking. It is usual with hand drilling and hammer drills, both of which can be adapted to local variations in the rock and therefore tend toward a flexible drilling schedule. Shaft raising, and breaking ground by moiling present special problems.

Examples of system 1: No 5 TAMARACK shaft, Mich (18); 2 drilling and 2 mucking shifts per 24 hr with minimum interference; the former drilled and blasted a center cut and one side; muckers first cleared the remaining bench, and then the side already blasted; second drilling shift, beginning in middle of the mucking shift, then drilled and blasted the remaining bench, ready for second mucking shift. CENTRAL 3-compt shaft, North Star mine, Calif; day shift, 8 drillers, 1 mechanic, 1 tool nipper, 1 hoistman, drilled round of 40 holes for 5-ft advance, removed extension skip guides, and blasted; afternoon shift, 5 muckers, 2 timbermen, 1 hoistman, lowered extension guides to bottom, lowered the sinking bulkhead and placed next set of timbers, wedged guides in place and mucked about 25 skiploads of 2.5 ton per load; night shift, 5 muckers, 1 hoistman, mucked same amount; rock was mucked into loading pans and handled to skip by air hoists; any delay on day shift meant loss of 24 hr. MCPHERSON shaft, Ducktown, Tenn, 8.5 by 19 ft; deepened while in regular daytime service, hence the sinking routine: day shift underground, 4 timbermen, 1 hoistman, on surface 1 hoistman, 1 laborer, kept timbering within 20 ft of bottom, took down loose ground and left bottom safe for mucking; afternoon shift underground, 4 muckers, 1 lander, 1 hoistman, loaded 393 cu ft rock with 8-cu ft bucket, hoisted by 25-hp elec hoist; night shift underground, 4 drillers, 1 hoistman, drilled and blasted half-round of 20–24 holes, total 140 ft; other half-round was drilled and blasted next night.

Examples of system 2: PABST H shaft, Ironwood, Mich; sunk with 12 hammer drills in slate and granite; a round of 50–53 holes was fired in 2 relays, as follows: drilling entire round, 6 hr; blasting first relay, 2 hr; blowing out smoke, 1.5 hr; mucking first relay, 8 hr; blasting second relay, 0.5 hr; blowing smoke, 1.5 hr; mucking second relay 6 hr. This cycle, with timbering and bailing, overlapped the shifts, and the shaft crews performed all functions as required. Advance per round 9 ft. COPPER MOUNTAIN, B C; 3-compt shaft; shift comprised 1 boss, 7 miners, 1 hoistman, 1 dumping bucket, 1 trammer; 18 holes per 6-ft round. Cycle as follows: cleaning and barring down, 1.2 hr; mucking, 11.6 hr; picking and cleaning bottom, 1.1 hr; setting up and drilling, 4.9 hr; charging and blasting, 0.5 hr; blowing smoke, 1 hr; placing shaft set, 4 hr; backfill behind sets, lagging and extending pipe lines, 2.5 hr; lost time, 2 hr; total, 28.8 hr. See also Table 1.

Special cases: DAVIS-DALY air shaft, Butte (11) (Art 2), was raised simultaneously from 9 levels; each raise required 2 miners and one man at a small hoist in the level. MIAMI No 5 shaft, Ariz, was chiefly in fissured conglomerate, which retained powder fumes and was therefore MOILED without blasting; 3 men using hammer drills with bull-bits broke enough rock for 4 muckers; monthly advance, 100 ft. VAN DYKE No 1 shaft (same district) traversed 760 ft of conglomerate, MOILED as above with hammer drills and bull-bits; a V-cut 12 in deep was made across the shaft, then enlarged to a depth of 18 in and width sufficient to receive bucket; 1 driller on each bench then loosened rock in "bites" 8 in wide, using the drill to pry toward the cut; 1 mucker followed each drill.

Delays are due to: removing drills, etc from shaft bottom preparatory to blasting; clearing bottom of smoke; clearing shaft walls and timbers of loose pieces of rock and securing bad ground after blasting; lowering timbers, which may be put in place during drilling.

Where pumps are used, the suction is removed from bottom and pump stopped before blasting; in very wet shafts, this may result in several feet of water accumulating at the time of blast, which acts as a cushion to protect timber and pumps, and absorbs much of the powder smoke. This water must be pumped or bailed before miners can go down.

With 2 shifts per day, much of the above work may be done between shifts; there is also time to make up for unusual delays. With 3 shifts, no such opportunity exists; speed is increased, but at slightly greater cost per ft than with 2 shifts.

Bonus system lends itself readily to shaft sinking, and in many cases has increased speed and reduced cost per ft. Bonus is paid (as a percentage of wages or fixed sum) per ft of advance in excess of a given standard; thus, at McPherson shaft (see above), men on drilling and mucking crews received $2 per ft of excess over a monthly aver advance of 2 ft per day.

Safety precautions (3). No other operations should be carried on, nor tools nor material raised or lowered to or from other points in shaft, while men are at work in bottom, unless they are protected from falling material by a well constructed TIMBER PENTICE extending over nearly the entire area of shaft, with closable openings for passage of buckets. In deepening a working shaft, an ample ROCK PENTICE should be left, or timber bulkhead built before sinking begins.

Trap doors, normally in closed position, should be provided at collar to cover shaft opening, with added set of trap doors when dump point is above collar, to prevent possibility of falling rock breaking through the collar doors. At Woodbury shaft every man in the shaft was provided with a felt hat stiffened with resin and shellac; these are hard and will resist severe blows from fragments of falling rock.

Buckets or skips should stop at least 15 ft above bottom, until rung down by shaft crew. Ladderways should be provided to within such distance from bottom as will prevent injury to them from blasting; from end of these, chain, wire rope or wooden extension ladders, should go to bottom of shaft to assure safety of men against failure of hoisting engine, fire or inrush of water.

When elec hoists are used, elec lights in shaft bottom advise sinkers of interruptions in current In some districts the law provides that all blasting in shaft sinking shall be done by electricity.

Table 1. Month's Labor Record and Time Cycle, Creighton No 3 Shaft

	Max	Min	Aver		Max	Min	Aver
Advance, ft	164	112	136	Drill shifts	308.3	267.8	294.7
per drill shift	0.54	0.39	0.46	Rounds	21	16	18

Timbermen	112.7	76.9	98 1		1.0	0.5	0.7

Creighton No 3 shaft, Canadian Copper Co, 5-compt, rock section 35 by 9 ft, inclined 55°; sunk with 12 $3^1/_8$-in piston drills on 6 columns, 2 men per drill; powder, 40% Forcite, with elec delay-action fuses; little timbering required; crew drilled, mucked and timbered as required.

5. DRILLING

Drills used in shaft sinking are: hand-churn, single or double hammer, and piston or hammer machine drills. HAND-CHURN DRILL in the hands of energetic workmen may be advantageous in soft rock. Hole is usually started with hammer and drill. More care must be taken in shaping the bit than for hammer drilling, and a low temper is desirable. HAND-HAMMER DRILLING is best applicable with low-priced unskilled labor. A large number of shallow holes, approx 3–4 ft, are drilled per round.

Advantages of hand work: (*a*) Saving in plant, especially in beginning small operations. (*b*) Flexibility in placing holes to take full advantage of peculiarities in the face, thus saving powder. (*c*) Use of lighter charges per hole than customary with machine-drilled holes, with less shattering of shaft walls, less injury to timbering and less over-breakage (beyond desired rock section); therefore greater ease in setting timber. (*d*) Effectiveness when blasting the bottom in benches, for which machine drilling is less advantageous. This system lightens the burden on each hole, thus saving powder, but interferes somewhat with mucking, especially when only one hoist is used. (*e*) Avoidance of delays incident to setting up drills and removing them before blasting.

Hammer drills (Sec 15), which work best in down holes, are almost always used for shaft sinking. Advantages: (*a*) flexibility in placing holes, almost equal to that of hand work; (*b*) effic with high-priced labor; (*c*) rapidity of set-up and transfer from one set-up to another, as compared with piston drills.

Piston drills (Sec 15) were long used in heavy shaft work, and are best suited to a fixed plan of locating holes, though here as elsewhere they have been largely superseded by the hammer drill.

Mounting. In rectangular shafts drills maybe on SHAFT BARS, placed across the longer axis of shaft. Tripods are sometimes used in U S colliery practice, but are less rigid and more cumbersome than bars, and for rectangular shafts have little to recommend them

Table 2. Examples of Drills and Bits Used in Sinking

* Down to 2 000-ft depth. † Beyond 2 000 ft, harder rock.

for circular or elliptical shafts they are preferable to bars, which are then harder to set up. In Europe sinking frames have been devised for circular shafts, on which drills are mounted so as to command entire shaft section. The frame with drills attached is raised to the surface before blasting (22).

Machine drill repairs. The practice of overhauling machine drills at the shop after each round has resulted in very low repair costs: at Pyne shaft (Birmingham, Ala, 1918–19), $1.14 per ft of shaft; at Pabst H shaft (Ironwood, Mich, 1917–19), $2.51 per machine-month, or 0.5¢ per ft of hole.

6. LOCATION AND DEPTH OF DRILL HOLES

For max effic of explosive (Sec 4, 5) drill holes are located so that most of them break to 2 free faces. One or more key or cut holes, drilled at an angle to the face, are blasted before the others, which are placed to utilize the additional face thus formed. In general, hand-drilled holes take advantage of rock cleavages, cracks and shape of face, rather than follow a rigid plan; the shaft bottom is then sometimes carried in benches stepped upward on either side of the cut holes. Machine-drilled holes are usually located by a definite plan, which makes for systematic work, though it may sacrifice some economy in powder. If a shaft-bar is used, symmetrical location enables several holes to be drilled from one set-up (Sec 6, Art 4).

"V," center or wedge cut is commonest. In simplest form it consists of pairs of holes inclined so as to bottom close together, and forming 2 rows parallel to shorter axis of shaft.

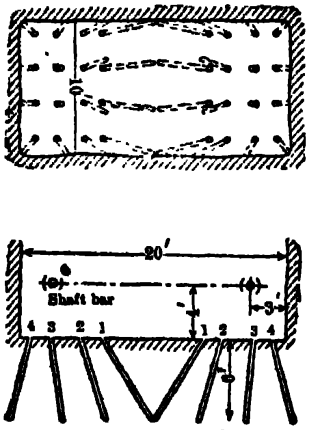

Fig 5. "V," Center or Wedge Cut for Shaft Sinking

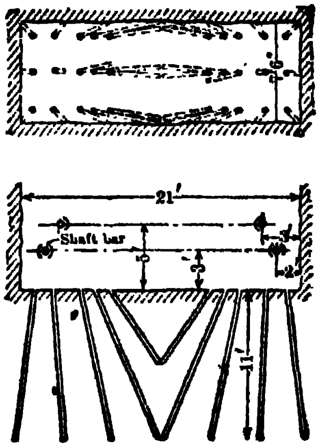

Fig 6. Double "V" or Wedge Cut

In Fig 5, rows 1 are cut holes and are blasted first; rows 2, 3 and 4 are then fired in order. Fig 6 shows a double V-cut for greater depth; in hard ground this may be supplemented by a few shallow vert holes along the center-line of the V; in soft ground one hole of each pair may be drilled only to half depth. The cut is usually midway between shaft ends, though in large shafts some engineers place it near one end and fire the remaining holes in order, retreating toward the other end. This tends to throw the muck toward the cut and facilitates clearing the other end for the drills, which can resume work while the cut end is being mucked. Local conditions, as rock cleavages, reentrant angles, and position of hoisting compartment, sometimes influence position of cut. Dynamite is most effective when pairs of cut holes meet at the bottom and are fired simultaneously. The angle of the V should be as great as good results permit.

Pyramid cut comprises a ring of holes inclined so as to bottom close together and blast out a sump in center of shaft. It is typical of circular shafts (Fig 7), though applied also to rectangular shafts of approx equal axes (Fig 8; numbers show order of firing). Davis-Daly octagonal shaft (Art 2) was raised with a 4-hole pyramid cut at center and 8 corner holes per round. In small shafts and favorable rock one center hole may suffice to blast the sump. In any case the cut is blasted first, then side and corner holes in order.

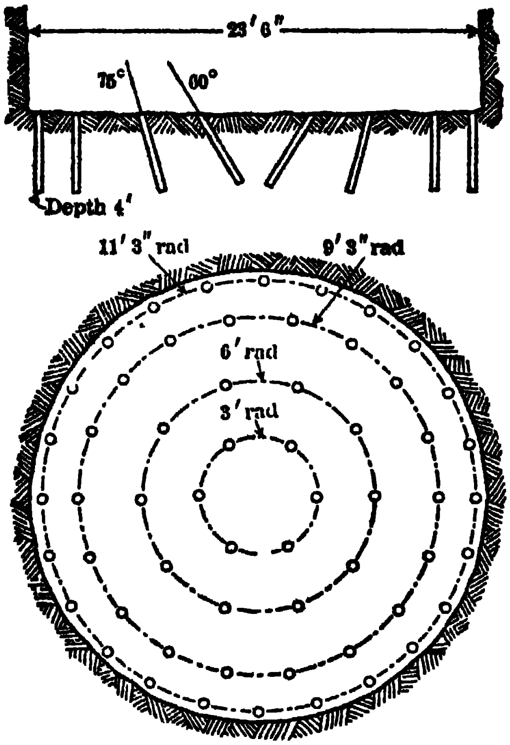

Fig 7. Pyramid Cut for Circular Shaft (Randfontein)

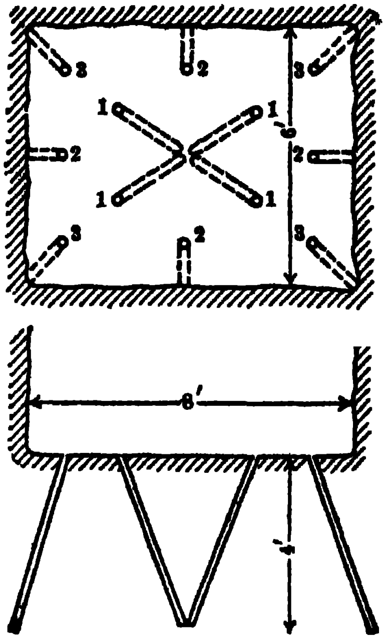

Fig 8. Pyramid Cut for Rectangular Shaft

Wedge and pyramid cuts are sometimes combined by pointing the middle pairs of V holes toward a common center, the outlying V holes taking their usual position. At Newport mine, Mich, a 4-in hole was drilled at shaft center with a heavy drill, 4.75-in starting bit, the hole (about 1 ft deeper than the regular round) being left uncharged, to provide a free break for 8 surrounding pyramid-cut holes, 4 on 6-in radius (instantaneous firing) and 4 alternately spaced on 18-in radius (first delay).

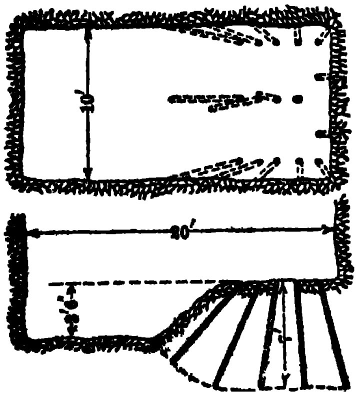

Fig 9. Bench or Stope Cut

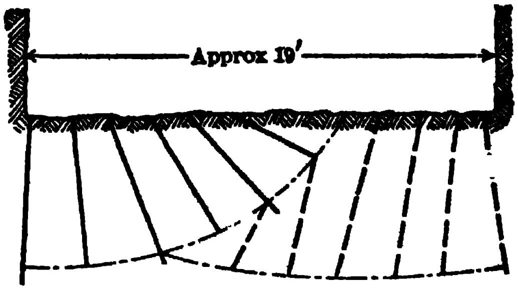

Fig 10. Bench Cut at McPherson Shaft

Bench or stope cut is sometimes used in tight ground (Fig 9). The cut alternates from side to side of shaft, always leaving 2 more or less free faces and thus saving powder. Broken rock is thrown, not upward as with wedge and pyramid cuts, but toward opposite end of shaft, with less risk of damage to timber and pumps. The bottom is always lower at one end or the other, facilitating mucking and drainage. A modification, in McPherson shaft, Tenn, is shown in Fig 10; the holes in solid lines were drilled and blasted first, then those shown dotted.

Bottom cut, like that for tunnel work (Sec 6, Art 5), is sometimes useful for flat, inclined shafts (Fig 11).

Depth of hole depends on type of drill, character of rock and shape and size of shaft. As holes are deepened, the width of V cut ("collar") is increased, reducing the number of side holes and total footage per round; but to secure sufficient diam at bottom, holes 10 or 12 ft or more in depth require very heavy drill steel, in lengths inconvenient to handle in the bucket. Usual depth of HAND-DRILLED holes is 2-5 ft. With PISTON DRILLS, depth should be the max consistent with powder economy, to reduce percentage of time lost in setting up, and in hoisting and lowering drills between rounds. For each case this max should be determined by test; roughly, depth of hole may be assumed at one-half, in soft rock three-fourths the width of shaft. Practice of drilling deep holes and blasting them 2 or even 3 times is wasteful of powder unless, before charging, they are partly filled with sand or other easily removable material. With HAMMER DRILLS, ease of set-up makes the factor of lost time less important, but the steel is smaller than that of reciprocating drills, and holes more quickly taper to a diam too small to hold enough powder for good results; max depth of hole then depends on ability of steel to keep its gage.

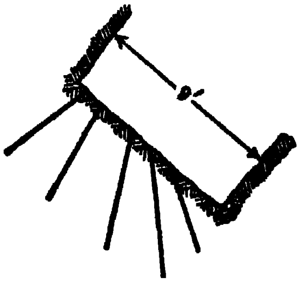

Fig 11. Bottom Cut for Inclined Shaft

At Woodbury shaft, Mich, 10-ft holes were possible in soft slates, but in granites and quartzites, with 2 1/4-in starting bit, 8 ft was maximum. In very hard rock at Gordon shaft, Tenn, piston machines drilled 5 to 7-ft holes and made approx 5 ft advance per round, the hammer type drilled 2 to 4-ft holes with approx 2 ft advance per round, but greater sinking speed.

7. EXPLOSIVES AND BLASTING

Explosives (Sec 4). In American practice, 40% gelatin dynamite is generally used for sinking where holes are drilled by hand or reciprocating drills. For shallow rounds in easy ground, 30% may serve; for aver rounds in difficult ground, 50 or 60%; for deep rounds, 60 or 80% in cut holes (used at Morenci to break an 8-ft round in easy ground), in some districts, 2 sticks of 60% are placed on bottom of hole, remainder 40%; sometimes 2 or more sticks of "100% gelatin" are placed at the bottom. On the Rand, 60-74% gelignite has been used in recent sinkings. Proper amount and strength of charge should be found by trial. Where timbering must be carried close to the bottom, the higher strengths may damage timber; a factor in proportioning charge and depth of round.

Table 3. Consumption of Explosive in Shaft Sinking. (Examples from practice)

Rock sec, ft	Dip	Ground	Gelatin		Rock sec, ft	Dip	Ground	Gelatin	
			%	Lb per cu yd*				%	Lb per cu yd*
9 × 7	60°	hard	40	10.0	8 × 21	vert	medium	40	5.3

8 × 17	"	medium	40	5.5	17 × 24	"	. . .	40, 50	3.3
7 × 17	"	sheared	40	5.5	8 1/2 × 28	"	slabby	40	2.6
8 × 16 1/2	"	firm	40	5.3					

* Solid measure.

Table 3 indicates that consumption of explosive per cu yd tends to decrease with increasing size of shaft section, but depends chiefly on breaking characteristics of the rock.

Blasting may be done with ordinary cap and fuse, elec fuse igniters or elec caps, preferably of the delay-action type (Sec 4, Art 10). In some districts the law requires elec firing in sinking. Firing a round of holes in proper order lightens the burden on all except the cut holes and lessens danger of injury to timbering. For ordinary fuse, some engineers advise 2 equal lengths of fuse and 2 detonators in each hole. Fuse wound around 2 properly placed nails or hooks and cut at one nail, with caps crimped on the severed ends, will show by the mark of the other nail where it should be cut and spit at blasting time.

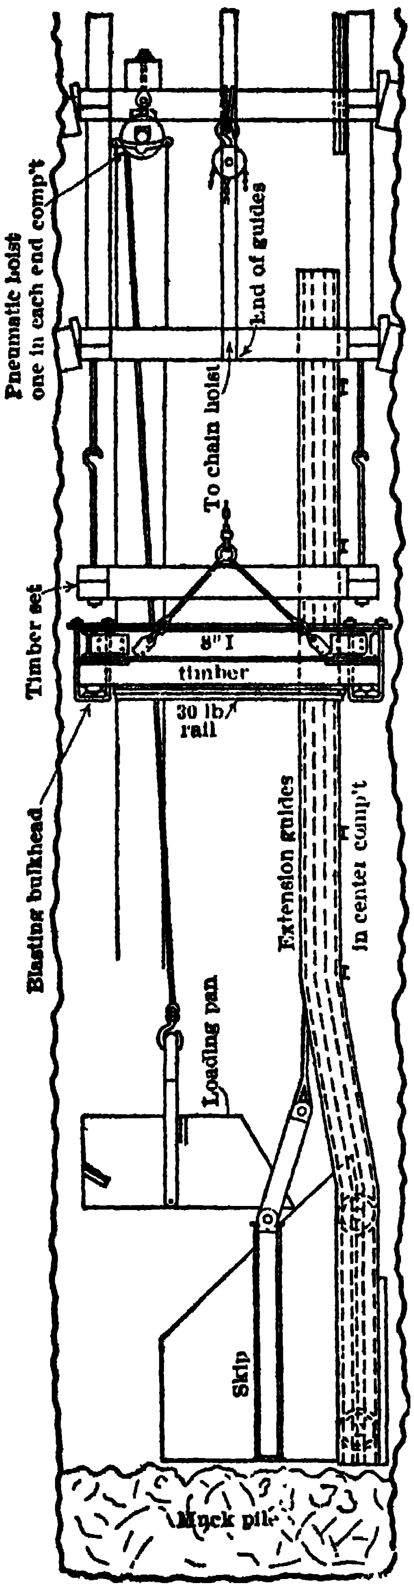

Fig 12. Use of Loading Pan for Mucking (AIME, *Tech Pub* No 324)

If shot-firers begin spitting (lighting fuse) at ends of the shaft, and work toward the middle, they finish near the bucket and avoid danger of stepping on lighted fuse and putting it out. This method involves cutting fuse to different lengths, because the cut holes are then the last to be spit and should be the first to explode. When spitting begins at the cut, fuses of uniform length insure proper order of firing; and if for any reason the entire round is not spit, at least the cut and neighboring holes will explode. A time-keeper fuse, cut to burn out about 2 min before the first explosion is due, serves as a warning. In wet shafts on the Rand, fuse is spit by torch, or "cheesa stick," made by splitting blasting gelatin, wrapping it around a pine stick 18 in long and covering with clay. The resulting fumes are absorbed by the water without bad effect.

8. MUCKING

Mucking, or loading broken rock into hoisting conveyance, occupies 40–60% of sinking time. Methods: (1) hand shoveling direct into bucket or skip, or (2) into loading pans, dumped into bucket or skip by mechanical means; (3) mechanical loading in large shafts with scraper or (rarely) caterpillar shovel.

Hand shoveling loads 9–13 cu ft per man-hr (measured in place), depending on character of muck, conditions at shaft bottom and promptness of hoisting service. Rock in 20 to 200-lb pieces can be loaded by hand faster than an equal wt of fines can be shoveled. Shoveling in a shaft bottom is difficult, though when the 2 ends are blasted alternately, it is facilitated by laying steel plates to receive the muck in the end not blasted. Empty bucket should always be ready at bottom, to avoid delays. In large shafts, where more shovelers are employed than can crowd around the bucket or skip, 2 compartments may be used for hoisting.

For vertical shafts, a bucket or skip may be suspended from bottom of sinking cage, which has long guide shoes to permit lowering below the last set of timber. In other cases, sinking crossheads (Sec 12) are used to prevent the bucket from swinging. Double cross-head (Marquette Range) comprises (*a*) upper head clamped to hoisting rope, (*b*) lower head loose on rope and resting on bucket; the latter is kept from rotating by 2 additional ropes extending from upper head through the lower head to the bail. Blocks at lower end of guides stop the lower head and release the catches that attach it to the bucket, which, with the upper head, then continues down until bucket is on bottom (6). Skips loaded by hand are made low at the back, to reduce lift of shovel. Guide shoes are either long enough to engage lower ends of guides when skip is on bottom, or extension guides are provided, which may reach 45-ft length and are removed when blasting (Fig 12 shows special form at North Star mine, Calif, for offsetting skip to one side of bottom). For inclined shafts, buckets sliding on skids, or sus-

pended from a carriage running on a cableway, and skips running on regular track, are in general use. Temporary track, capable of being raised on blasting, reaches from end of timbering to shaft bottom.

Loading pans (Fig 12) are shallow and open at one end or side to facilitate filling by shovel. For dumping into skip, they are lifted by 7 to 10-hp air hoist mounted on timbering above or on sinking stage. They are loaded while skip is being hoisted and lowered, and save time; at the Colorado shaft, Cananea, they increased sinking speed 20%.

Scraper (Fig 13) is suited to long, narrow shaft section. At Champion mine, Mich, it first scraped the muck to the end opposite loading end; a slide was then clamped to a horiz bar across the shaft, the hinged apron of slide resting on the bucket; scraper was then reversed for loading, after which the hinged apron was turned back, scraper rope pulled aside and bucket hoisted. Two full scraper loads filled a 0.5-ton bucket in 20 sec; round trip of bucket, 2.5 min. In one case a small Butler shovel was used to muck the shaft bottom.

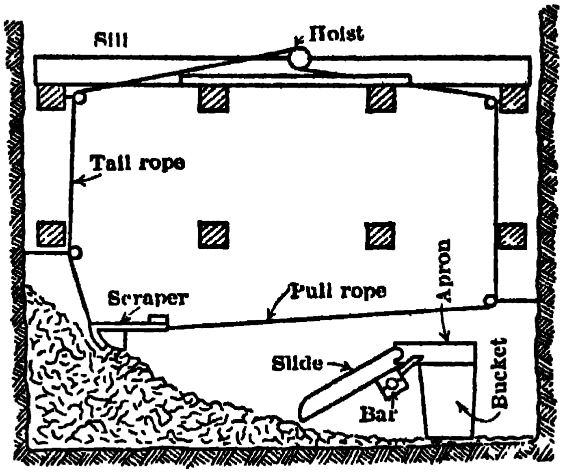

Fig 13. Scraper in Shaft Bottom, Champion Mine, Mich

9. VENTILATION (See also Sec 14)

While sinking, enough air must be delivered at shaft bottom to remove powder smoke and rock dust, and enable sinkers to work in reasonably pure atmosphere.

Natural ventilation, set up automatically, may serve to great depths; in some cases, mechanical ventilation must be adopted at the outset. Some of the factors governing natural ventilation are: character and temp of surface atmos, temp of strata penetrated, and amount of water falling in shaft. Natural ventilation may be aided in several ways. If a small portion of shaft area is partitioned off by a brattice, and this compartment carried up into the headframe by a chimney, difference of air head will cause circulation. Where steam sinking pumps are used, the warmth usually suffices to establish a rising current; a steam jet directed upward from shaft bottom will accomplish same result. It often happens that, even with no brattice, the space around the steam pipes is upcast, while the opposite side is downcast.

Fan or blower on surface, connected to a wooden or sheet-iron pipe 12–18 in diam, reaching close to shaft bottom, may be used to force down fresh or exhaust foul air. A fan may be used to exhaust blasting fumes promptly; it is then reversed to supply fresh air. If the pipe or chimney be of wood, the boards should be matched and painted to reduce leakage.

Where compressed-air drills are used, the exhaust generally removes dust and prevents vitiation of air. Powder smoke is readily blown out by opening the air valve at the bottom after blasting. Spraying water down the shaft facilitates clearing powder smoke.

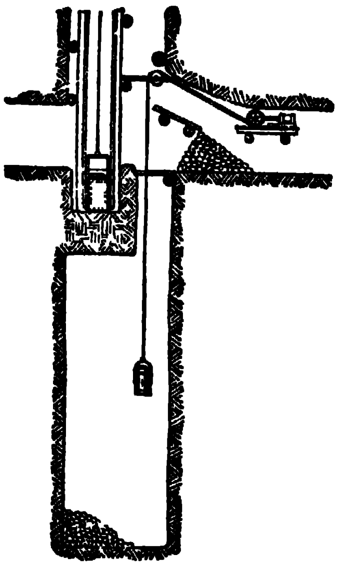

Fig 14. Sinking Under Rock Pentice

10. SINKING IN A WORKING SHAFT

Working shafts are frequently deepened while regular mining operations are being carried on above. Sinkers should be protected from falling objects by a rock pentice (Fig 14); or by a heavy timber bulkhead, sometimes loaded with 10 or 15 ft of waste rock.

There are two general methods; (*a*) rock is hoisted direct to surface through special sinking compartment; (*b*) rock is hoisted to the lowermost working level, by a small elec or compressed-air hoist, whence it is raised to surface by regular hoisting plant. The pentice may be left across entire shaft area, in which case a short incline must be sunk from the level above before the shaft is widened to full section. If the pentice is left across bottom of hoisting compartments only, a small opening may be cut in line with the ladderway, through which sinking is carried on (Fig 14). In large shafts, special means of transferring muck from the small underground sinking hoist to main hoisting system are common: in extending No 5 United Verde shaft, the shaft was first bulkheaded above the lowest existing level, then sunk full size for 20 ft, and 2 skip pockets of 70-ton capac excavated for muck; then a pentice was formed by sinking only the manway for the next 30 ft, after which the shaft was widened to full size, the bulkhead removed and regular sinking resumed.

11. SHAFT RAISING

When an additional opening is needed for existing workings, a shaft may be raised instead of sunk. This presupposes a final plan of underground connections between shaft and workings, because some or all of these connections must be driven before raising begins. Raising in moderate lifts is faster and cheaper than sinking, because it avoids mucking and pumping; but 200–300 ft lifts may be difficult and costly, involve ventilation troubles, and in some formations (as at Magma) lead to serious overbreak when raises are enlarged to full section. It is chargeable with cost of tramming muck to the hoist (unless the muck is used for filling), but profits by lower cost of hoisting with permanent plant instead of a small uneconomical sinking hoist.

Methods. For speed, raising may proceed from several levels simultaneously. The raise may be made of the smallest section consistent with effic, and enlarged to full shaft section after holing through. If raising is done in sections, errors of alinement can be corrected while enlarging. Temporary timbering in the pilot raise may be partly salvaged. Shafts are also raised at full section, especially if made in only one lift.

Shaft No 2, Harold Mine, Minn, was raised 90 ft at full rock section of 18.5 by 8.5 ft, using the shrinkage system (as in stoping) for support, except in 2 cribbed manways at shaft corners. Normal cycle: (*a*) wedge-cut in center and pyramid-cut over each manway; (*b*) manways cribbed to within 3 or 4 ft of back and wedge-cut blasted; (*c*) remainder of 1 end drilled, its manway cribbed close to back and covered with rails and lagging, and the entire end blasted; (*e*) manway cleared for access and other end drilled and blasted. Only enough muck was removed to provide working space until, when excavation was complete, it was slowly drawn down to keep pace with permanent timbering (17).

For its Pilares shaft, Moctesuma Copper Co drifted to line of shaft at the 1 600, 1 700 and 1 800 levels and drove 4 by 7-ft pilot raises on shaft center-line from the 1 600 and 1 800, the former holing through to the sump on the 1 400, 167 ft above. In each raise, shrinkage stoping to full section was started 20 ft above the bottom and carried up the full lift; the shaft was then timbered downward as in preceding example.

12. DESIGN OF GROUND SUPPORT

Types of support: (*a*) timber, steel or pre-cast concrete frames ("sets"), or concrete rings poured in place, spaced at intervals with or without lagging; (*b*) continuous linings of brick, stone, C-I tubbing or concrete poured in place designed to exclude water, as well as to resist ground pressure. In the U S, brick, stone and C-I linings are rare; formerly, timbering was almost universal but concreting and steel framing are increasing in use.

Choice of support depends on ground and water conditions, shape of shaft and cost of materials. Timbering is increasingly costly and (unless proofed) involves fire hazard; in swelling ground it fails slowly and with ample warning. Steel sets are often lagged with wood, thus incurring some fire hazard. Both timber and steel framing are typically suited to rectangular sections. Concrete avoids fire hazard and when poured in place will fit any section; used chiefly in shafts of long, life, except where loose ground, or surface soil, requires close lining in any case. In the U S, it is the usual material for watertight linings.

Design for strength. There are no exact rules for computing pressures. In very wet ground some engineers assume full hydrostatic head, but this assumption has been criticised as too severe. Lining must withstand impact of a falling cage or skip, if hoisting rope breaks; otherwise it is proportioned by experience, allowing for bad ground or excessive water, which may increase the pressure.

Anchorage to shaft walls. Continuous concrete linings are usually poured to the rock at many or all points, keying into the shaft walls. Tubbing, masonry linings, and all framed support require special anchorage; by means of wedging cribs or bearer sets, resting on hitches in the shaft walls at intervals of say 30–100 ft.

Shaft collar is raised far enough above surrounding surface to exclude surface drainage and facilitate disposal of waste rock; on level ground it may be 15–20 ft high, inclosed by waste fill. Incidentally, it often provides foundations for the headframe. When the collar is in solid rock, framed support begins with a collar set, of heavy members extended on firm ground beyond the excavation; this is virtually the first bearer set, from which regular sets are hung by hanging bolts, until the next bearer is placed below. When the collar is raised above the surface, the collar set may rest at ground level on timbers or concrete piers, and carry the superstructure; or it may be supported on posts and bracing until waste has been dumped beneath it.

In traversing soft overburden the shaft may be cribbed (Art 13), or preferably concrete-lined. Concrete lining should be sealed in bedrock to exclude water, and timbering may be built up inside the lining or connected to guide bolts embedded in the concrete. In shallow overburden, a conical pit, dug to bedrock, facilitates building the collar; it is refilled when collar is in place.

Water rings are placed at intervals in vert shafts to intercept falling water, which is then led to a sump and pumped to surface. A groove is cut around the shaft to a depth of 1.5 or 2 ft, on the edge of which a dam is made of timber embedded in clay or concrete, or of clay or concrete alone, to form a channel behind which water is collected and led thence to a sump. In timbered shafts, water is guided into the ring by short planks placed in an inclined position to intercept its fall (Fig 15). In concrete-lined shafts (Fig 16), the rings are placed behind the lining, water being led to them by lines of tile pipe, placed vertically in or behind the concrete; a small projection on inside of lining serves to catch the water falling in shaft. The ring should have sufficient grade to the outlet pipe.

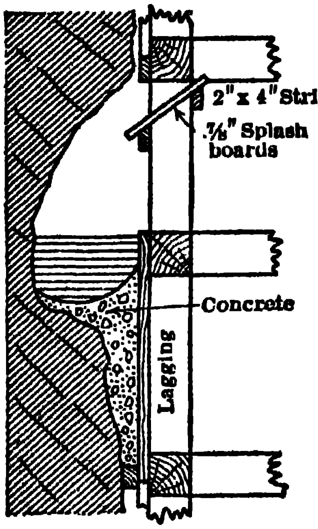

Fig 15. Water Ring for Timbered Shaft

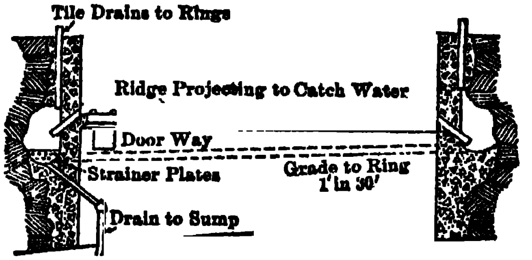

Fig 16. Water Ring for Concrete-lined Shaft (*Mines & Min*)

Grouting behind a continuous lining is often effective in checking inflow of water. For grouting in advance of sinking, see Bib 8.

13. TIMBERING

Cribbing consists of timber, round, hewn on 2 sides or squared, built crib-fashion against the shaft walls. In large shafts it is used chiefly in traversing soft overburden, though in heavy ground it is sometimes carried to depth. Small shafts are often cribbed throughout.

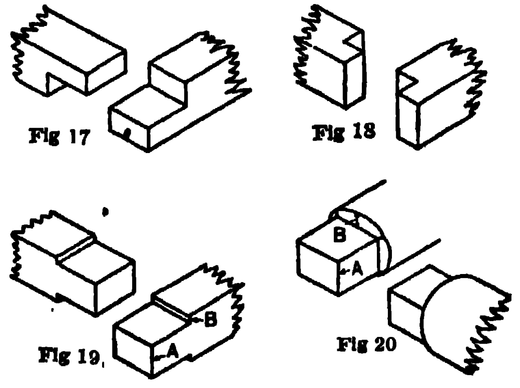

Fig 17, 18, 19, 20. Cribbing Joints

In simplest form cribbing is of undressed timber, cut to length but not framed, held in place skin to skin by vert strips nailed inside the crib corners; or plank is set edge to edge, with ends halved into each other, or cut square and held by nailed strips. In close cribbing, timbers, skin to skin, are framed as in Fig 17, 18, 19, 20, where A = half the thickness of piece; that is, $A = 2B$. In open cribbing, A exceeds half the thickness, and some space is left between crib timbers (Fig 19); that is, A is greater than $2B$.

If ground permits, several feet of cribbing are placed at a time, each section being built up from a set wedged in place at bottom; otherwise, sets are placed singly as sinking proceeds.

Vertical-shaft sets. Each set (Fig 21) comprises 2 wall plates and 2 end plates, respectively on the longer and shorter sides of shaft section, and 4 corner posts or

studdles, to preserve spacing and support the sets. All members are usually of same timber size. Compartments are separated by **dividers** (buntons), usually of same depth as plates, but narrower. Posts are also generally placed opposite the ends of each divider, of same size as the divider, or smaller.

Guides are bolted to end plates and dividers, into which guide backing posts are sometimes framed (16) just behind the guides, to stiffen and support them; or guide girts (16) may be framed into studdles between sets, like extra end plates or dividers. Sometimes space is provided for a 2 or 3-in filler between guide and end plate or divider; then, if the set is distorted by ground pressure, alinement of guides can be preserved by varying the thickness of filler.

For shaft sets, sawed timber is preferable to round, in permitting more accurate framing of joints. Timber sizes: 6 by 6-in for small shafts in firm ground; to 14 by 14-in for large shafts in heavy ground; under aver conditions, 10 by 10-in plates are common. Vert spacing of sets varies with character of ground, often in the same shaft; 6–7 ft clear is max for solid rock; 4–6 ft is usual; in bad ground, intervals are smaller.

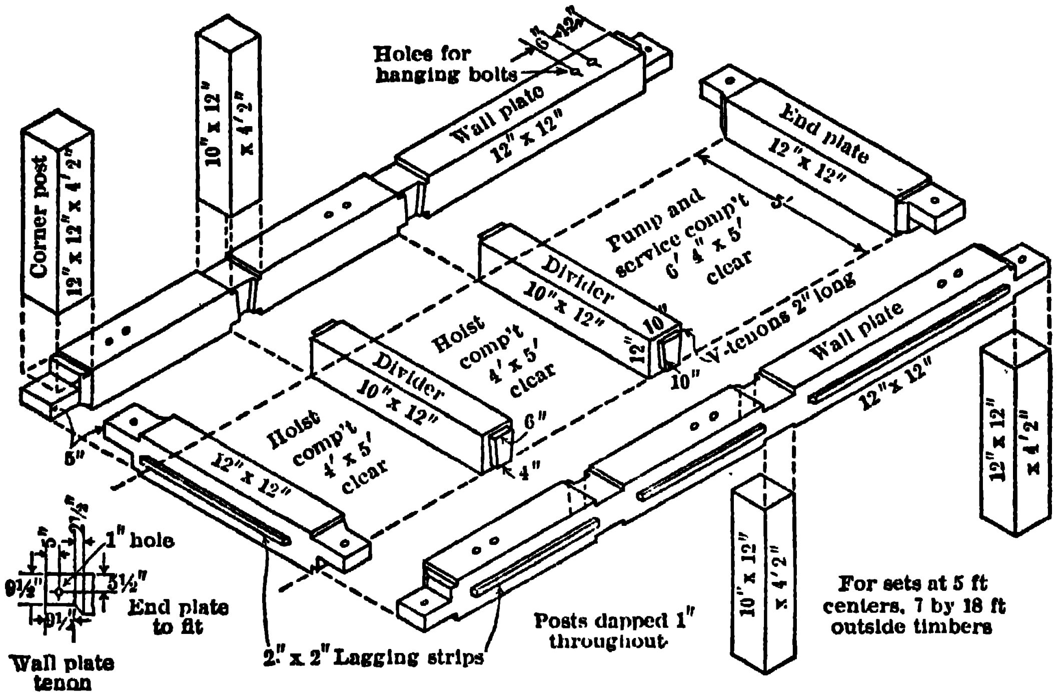

Fig 21. Shaft Set

Details. For plates, **tenons** (horns) are 0.5 the thickness of piece. Wall plates are always mortised in the upper half, end plates in the lower; whence the former carry the latter when assembled. A 1-in hole may be bored in center of tenon, with a wooden pin to hold plates together during assembly. To bring wall and end plates in contact for their full depth, they are sometimes given a 45° bevel at base of each tenon (Fig 21); at Butte, tenons are shortened by 0.25–0.5 in, to assure full contact between beveled surfaces when sets are wedged in place. Dividers are usually framed with a V-tenon at each end (Fig 21), so that the wt of the piece tends to hold it in place. Sometimes only one side of tenon is sloped, the other side being vert. Shoulders on either side of tenon provide bearing against the wall plate for its full depth. If a long wall plate must be spliced, the splice is best made at the divider separating ladderway from hoisting compartment (Fig 22). Posts are squared at the ends and brought to a true bearing on the plates. Plates and dividers are usually gained to receive ends of posts, which thus resist side press. If gains are omitted, posts are blocked and wedged.

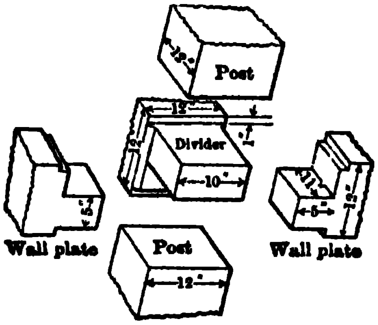

Fig 22. Framing for Spliced Wall Plate (16)

Framing must be accurate, to avoid cutting and trimming underground. Accuracy is secured by using a timber-framing machine or carefully made template; or failing these, by first drawing a center line lengthwise on the best of the 4 faces of a timber and referring all framing measurements to this line as a base. If no face is true, one may be trued for the purpose. The side on which base line is drawn should face inward after assembly.

Hanging bolts (Fig 23) are chiefly to facilitate assembly. A bolt consists of 2 duplicate parts; threaded ends are passed through the respective wall plates and secured by washers and nuts; the other ends are hooked to each other. For adjustment, the bolts are 3-4 in longer than required by the exact spacing of sets when in final position. Diam of bolts varies from 0.75 to 1.25 or 1 3/8 in. Large C-I washers prevent nuts from cutting into timber; 2 or 3 bolts per wall plate are required, depending on length of plate.

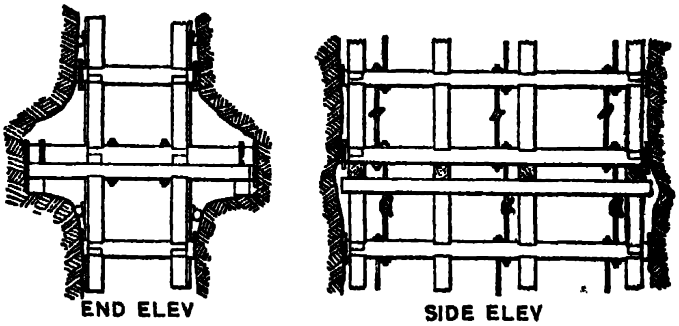

Fig 23. Bearing Timbers (16)

Assembly. Shaft bottom is carried as far as possible in advance of timbering, to minimize injury to timbers by blasting and permit timber and drill crews (if separate) to work simultaneously, under precautions for safety of the men below.

Details. Temporary staging at proper height is placed across shaft section, hung from timbering above, or laid on special stulls; or blasting set (see below), if decked; in large work a sinking stage or platform (with opening for bucket) may hang constantly above the bottom, and serves for placing sets. The right- or left-hand wall plate is lowered into horiz position on the staging, usually by timber clevis or rope sling. Hanging bolts having been put in both the new plate and the corresponding plate in set above, the hooks are engaged. When both wall plates are in position, the end plates are put in, their tenons resting on tenons of wall plates (temporary wooden pins sometimes used). Dividers and posts are then placed, and hanging bolts screwed up until the new set is in accurate position. The set is blocked and wedged against the rock walls until proper alinement is secured. Wedging is done at corners and opposite ends of dividers.

In bad ground timbering is carried close to bottom, timbermen sometimes standing on the muck pile. If there is no room for swinging a long wall plate into horiz position under sets already placed, the plate is spliced, or dividers are temporarily omitted from the last few sets; but since the tenon of a divider extends under the post above, the divider can be placed subsequently only by cutting a recess in the post just above its base. This recess is later filled by a block spiked in place.

Bearing sets, or bearers (Fig 23), placed at intervals of 50-100 ft of depth, furnish anchorage for the entire shaft structure and carry its wt if the blocking and wedging of regular sets become loose. Normally, wedging should hold the regular sets as solid as bearers, but alternate wet and dry periods may loosen them. Bearers may be regular sets, with end plates extended and wedged into hitches in the shaft walls; or (preferably) extra timbers, of same breadth as plates but deeper as desired, hitched into the walls directly beneath certain timbers (usually end plates) of regular sets, which rest on them. In the latter case, plates are framed as usual, but the gain or dap on lower face of wall plate, instead of receiving top of post, now fits a similar gain in the bearer, which is also gained on its lower face to receive top of post. With heavy timbering, or in ground where it is difficult to cut a reliable hitch, extra bearers may be placed under the dividers. Sometimes bearer and end plate or divider are bolted together. Bearers may possibly carry the full wt of timber to the next bearing set above, and if necessary are built 2 and even 3 timbers deep. Instead of individual hitches, a continuous hitch may be cut all along the shaft wall to carry a sill (Fig 23), on which the bearers are seated and wedged.

Lagging is necessary except in solid rock free from tendency to spall off. **Materials:** round poles placed skin to skin, saw-mill slabs, or ordinary 2-in plank; galvanized corrugated steel and buckled plates have been tried.

Where ground permits, lagging is cut to lengths spanning 2 or more sets, and put behind wall and end plates after several sets have been placed. If each set must be lagged as soon as placed, 2 by 2-in LAGGING STRIPS (Fig 21) are nailed to outer faces of plates, and lagging in single lengths is placed with ends abutting on these strips. Space between lagging and shaft walls is packed with filling to prevents walls from "starting." CLEATS may be spiked to upper and lower faces of plates, and lagging placed behind these cleats, standing between instead of behind the sets. Cleats facilitate renewal of lagging, but are structurally weak and unfit for heavy ground.

Vertical-shaft alinement of timbering. Shaft sets are first alined roughly with a straight-edge placed on inside faces of 2 sets above; final alinement is by at least 2 plumb

lines, set by permanent reference points in timbering above. Vert marks are made in selected places on timbers by saw or scratch awl, and, by carpenter's square and wedging, the marks are brought into same vert plane as the plumb line. Blocks are sometimes used as gages where lines are hung near shaft corners.

In timbering a large Mich shaft, one pair of plumb lines was hung 3 in from wall plates on the shorter center line of shaft, and another pair 3 in from end plates on a line parallel to long center line, but 6 in to one side of it, to prevent interference with guides. After the 4 corners had been blocked, a horis line touching second pair of plumb lines was stretched lengthwise of shaft and just above the dividers, measurements were taken to midpoint of dividers, and wedges driven opposite divider ends to aline them.

Inclined-shaft timbering. Where hanging wall requires no special support, single posts or stulls are used as needed, with toe set in footwall hitch and the head wedged against a head board on hanging wall. Stringers or cross ties are always added to support skip track, pipes and ladders. Where hanging wall tends to spall, but sides are firm, horis timbers are set close to roof and hitched into sidewalls; for long spans, they may be supported at midpoints by posts between compts. Where both hanging wall and sides are weak, or both require lagging, 3-piece tunnel sets are used (Sec 6). Compartments are formed by placing additional posts as required. Where footwall is bad, the 4-piece tunnel set is sometimes used.

In heavy ground, inclined shafts are timbered like vert shafts, with sets placed approx normal to dip of shaft. If end plates are inclined more steeply than the true normal, movement of hanging wall along the dip wedges them more tightly in place; in general (9), head of plate may be raised above normal position $^1/_8$–$^1/_4$ in (30°–45° dips), or $^1/_4$–$^3/_8$ in (50°–75° dips), per ft of plate length. For dips greater than 70°–75°, framing differs from that of vert-shaft sets. Cap and sill (corresponding to wall plates) usually extend beyond end plates, which may be framed with V-tenons (Fig 24) or, if studdles are used, with square tenons; end plates are thus held in position during blocking and wedging. For strength, cap is often of deeper section than sill. Cap, sill and end plates may be gained or mortised to receive square ends or tenons of studdles, which in a flat shaft are lightly loaded and small. A collar set and bearers are used, the latter generally spaced at longer intervals than in vert shafts. Hanging bolts are used only for steep dips.

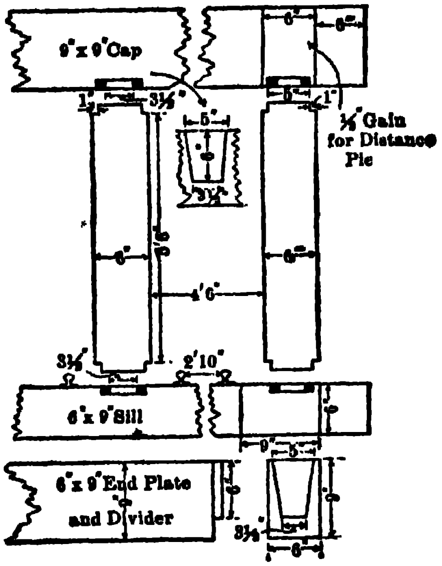

Fig 24. Inclined-shaft Timbering (after Truscott)

Inclined-shaft alinement of timbering. Azimuth and dip of an existing shaft are found by setting a transit at shaft collar and sighting a target at the bottom (or some intermediate) set, with target and telescope offset at fixed distances from sill and end plate. New timbering is often alined with spirit level, carpenter's square, plumb line and straight edge, checked every few days by transit.

In each cap and sill, before assembly, a tack is driven at the same relative point; then, tacks on the new sill, the sill last preceding, and a third several sets above, are alined with a stretched string, the new sill being wedged to alinement and leveled with spirit level. For the cap a second string is stretched as before, with plumb line attached at the last preceding set; the cap is wedged until plumb line touches the sill string. Dip is maintained with straight edge, which should span 3 sets and is often triangular, with its top horis when the bearing edge is at required dip. To aline new timbering with transit, the instrument is set over or under a tack some distance above, backsighted for azimuth and sighted on new timber, which is shifted by wedging until its tack is cut by the vert cross-hair. Telescope is then set at established dip, its height measured and slant height to plane of sills calculated, target of leveling rod is set at this slant height, the rod grounded on the new sill and rested against new cap (thus lying normal to line of sight), and the set wedged up or down until the horiz cross-hair bisects target. Corners of set are then tested with square, and sill with spirit level, corrected if necessary, and again checked by transit. In deep shafts this method permits slight errors in the compt farthest from transit; hence, a set-up is made and tacks driven in the end hoisting compt, usually 1–2 ft from shoulder of cap or sill, errors being thrown to ladderway. Steep dips require an auxiliary telescope; the tripod is often replaced by a bracket screwed to timbers, or by a stretcher bar (Sec 18, Art 3).

Swelling ground is difficult to hold unless provision is made for cutting away protruding rock and easing the timbering. This is best done, without interrupting hoisting, by making the shaft opening large enough to allow a 2.5 to 3-ft space outside of the shaft sets. Auxiliary or jacket sets (16) are then placed and wedged around the regular sets. Floors may be laid on jacket sets and lagging placed outside of them in the usual way; occasionally, regular sets are also boxed in with plank. In the space thus provided, work of easing timbers proceeds as required.

Cylindrical shafts may be lined during sinking by lagging driven behind wooden or steel rings placed at vert intervals of 4–6 ft (23), which in turn are kept in place by wood or steel distance pieces. Steel plates are also used. Such linings afford temporary support before placing permanent metal or masonry lining.

Timber preservatives are sometimes used to combat decay and fire hazard. Timber for an Alaskan shaft was pressure-treated with zinc chloride against decay; specified retention, 1 lb dry chloride per cu ft of wood. Timber for the Capote shaft, Cananea, was treated against decay and fire hazard with a hot solution of 27% triolith (90% NaF, 6–7% potassium or sodium bichromate, and phenol) and 73% sea salt; max temp in treating tank, 190–200° F; wood preheated for 12 hr, and soaked in solution 24 hr. Timber may be fireproofed by coating with gunite; for details (Tramway shaft), see Art 15.

Protection during blasting is required when timbering must be carried within 20–30 ft of shaft bottom. Logs swung by loops of chain close under timbers of lowest set are often enough. For better protection, a BLASTING SET is hung below the lowest shaft set and lowered as needed, *e g* by chain blocks; it may be of green timber, sometimes half-round, or (at Macassa mine, Ont) 8-in channels, framed to match the shaft sets in plan. At Copper Mountain, B C, a blasting set of H-beams was used, open in center compt, covered over end compts with 2 thicknesses of $^3/_8$-in punched plate. For blasting set at North Star mine, Calif, see Fig 12; end compts solidly covered, center compt with iron door.

14. STEEL SHAFT-SETS

Steel sets are of structural shapes, arranged and named like the members of timber sets. Shapes are selected that furnish convenient riveted or bolted connections (Fig 25).

Wall and end plates act as beams under lateral press, and as columns under axial press of ground. Normally, dividers in vert shafts act as columns, but in moving ground, or inclines subject to creep of hanging wall, they may also resist bending, due to rigid connection. Posts act as columns, unless distortion of shaft support produces bending stress. Plates and dividers must therefore have relatively large least radii of gyration (Sec 43, Art 28), and for heavy duty are often H-beams, placed with flanges vert^{y} for max resistance to lateral ground press. Angle posts permit easy connection (Fig 25) and eliminate permanent hanging bolts. I-beams are common for bearers. Steel cross ties, and T-rails alone or reinforced by angles, have been used as plates, I-beams, paired channels and Z-bars as buntons, and rails as posts where wt of shaft framing is carried by lower bearers. Composite sections involve a shop cost that single shapes avoid. Guides are often of wood, though steel has been used; cast-steel racks, sometimes bolted on steel guides to engage safety dogs, seem of doubtful value, as they must function under heavy impact. If size of compartments and space under the previous set permit, a steel set is framed at surface and lowered intact; otherwise it is shop-riveted in parts and assembled underground, with bolted connections. Chain blocks are used to swing the framing into place.

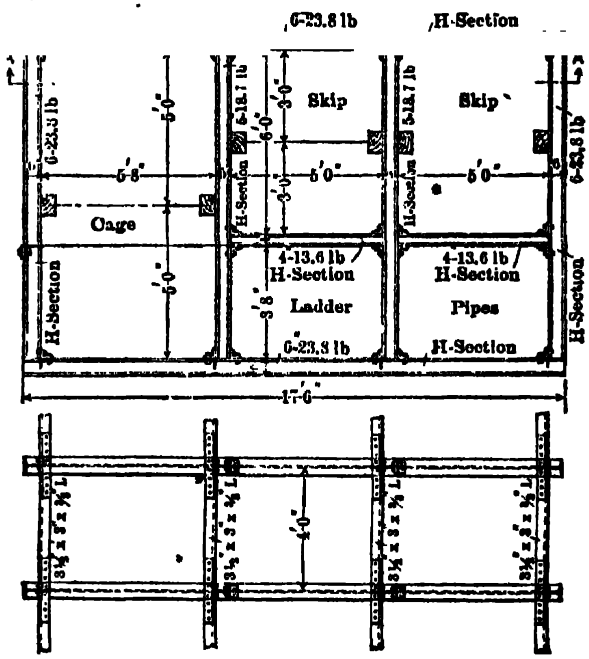

Fig 25. Steel Timbering for o-compartment Shaft

Preservation. Shaft steel may be painted with a mixture of 8 parts coal tar, 1 kerosene and 1 portland cement, applied hot to cleaned surface. Steel has been coated with gunite (Art 15); first cleaned and covered with chicken wire for reinforcement. Troughed shapes, as H- and I-beams, placed with flanges vert, should be concrete-filled between upper flanges, to prevent collection of water.

15. CONCRETE FRAMING AND LINING

Concrete may be pre-cast above ground in reinforced members like those of a timber set and similarly put in place; or poured underground in a succession of rings around the shaft (with bare rock between) virtually as monolithic sets; or poured in a continuous lining; or used in the form of pre-cast blocks for walling. Linings poured underground or walled are equipped with wood, steel, or pre-cast or monolithic concrete dividers. Gunite, or sand concrete applied by air jet, is used as protective coating on timber and steel (Art 14), and even as shaft lining in firm ground.

Pre-cast shaft sets, with members corresponding to those of timber sets, have been successfully used in both vert and inclined shafts.

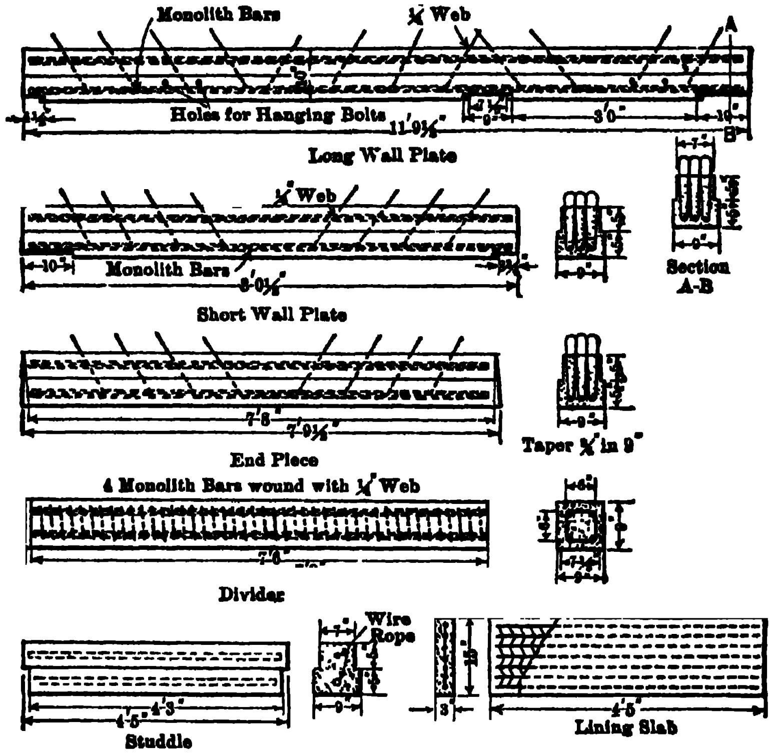

Fig 26. Reinforced-concrete Shaft Sets (34)

Oliver Iron Mining Co, Mich, used a 1 : 2 : 3 mixture, poured wet, in molding sets for vert shafts; Ahmeek Mining Co, Mich, a 1 : 3 : 5 mixture for plates and dividers, and 1 : 2 : 4 mixture for studdles of an 80° inclined shaft. After removing forms, members were allowed to harden for several weeks before placing. Reinforced concrete slabs, of a 1 : 2 : 3 or 1 : 2 : 4 mixture, were molded for lining between successive sets and as partitions between compartments. Where used as lagging between sets, the slabs generally rest on offsets on the plates, space between slabs and rock walls being filled with broken rock or other material. Slabs used as compt partitions may be bolted to dividers.

After blocking a set into alinement, it is sometimes bonded to the rock by placing a wooden bottom and filling around the set with fresh concrete, thus approaching the RING method. Members may be molded with reinforcement protruding from ends or outer faces, to be embedded in the fresh concrete bond; Fig 26 shows stirrups of web reinforcement (Sec 43, Art 14), protruding thus from wall plates. Holes are cored for assembling and hanging bolts. Due to their wt, concrete sets require more labor for assembly than timber sets, and long wall plates may be cast in 2 or more sections.

In a 3-compt shaft of Ahmeek mine (20), concrete sets (Fig 26) replaced 12 by 12-in timbers. Costs (prewar) per set delivered at shaft mouth: timber, $37.60; concrete, $22.50. Unit costs: timber, $28 per M; crushed stone, 35¢ per cu yd; sand, 60¢ per cu yd; cement, $1.15 per bbl; reinforcement, $12 per shaft set. 7 men placed 1 set per 9-hr shift. At American shaft, Zaruma, Ecuador, with cement at $2.85 per 94-lb sack and reinforcing (0.5-in deformed bars) at 4.5¢ per lb, cost of casting 2-compt set (reported 1925) was $15; 3-compt, $22. Cost per ft of shaft, including removal of old timber: labor, $23.57, supplies, $34.09; members were placed crib-fashion, 6 in apart.

Ring method provides monolithic concrete lining in horiz bands, separated by intervals of bare rock. In the cylindrical City Deep shaft, Rand, rings 18 in high at 10-ft intervals furnish entire support in firm rock and serve as anchorage for continuous brick or concrete lining in heavier ground; each ring is bonded with 20 steel pins sunk in the rock.

A square shaft at Jerome, Ariz, 13 by 13 ft in clear section, was continuously lined for 1 550 ft and ringed for 450 ft below. Rings 30 in high on 6-ft centers were each reinforced with 5 $^{3}/_{4}$-in horiz and 10 $^{3}/_{8}$-in vert bars, spot-welded at shop. Bottom form was a wooden sill with projecting pieces of ship-lap shaped to rock profile; forms for inner face were of steel, well braced. Concrete was poured to rock, not less than 8 in thick. I-beam and channel dividers (flanges up) and angle attachments for wooden guides completed the "set." Costs (1925), Table 4.

Table 4. Cost of Ring Method of Lining

	Per ft of depth		
For rings:	Excavation	Concreting	Total
Labor	$52.07	$ 16.60	$ 68.67
Supplies	7.68	26.51	34.19
Explosives	8.47	......	8.47
Comp air	2.08	......	2.08
Shop work	0.26	5.90	6.16
Repairs	6.55	......	6.55
Engineering	......	1.05	1.05
Miscellaneous	......	0.05	0.05
Total	$77.11	$ 50.11	$127.22
Continuous lining	68.17	146.84	215.01
Saving by ring method, per ft			$ 87.79
Per cu yd of concrete:			
Ring method (mix 1 : 2 : 4)			$61.30
Continuous lining (mix 1 : 3 : 5)			58.80

Continuous lining is combined with dividers of various types (5). Partition walls may be cast with the lining; they have openings at intervals to relieve suction of passing cage or skip, are equipped for attachment of guides, and designed for impact due to possible breakage of rope. Walls may be thinner if carried at intervals on steel beams. Dividers of steel, timber or pre-cast concrete are common. If seated with ends embedded in the lining, they are difficult to replace; whence, hitches are often cored for them, or they are supported on short lengths of steel beam embedded in the concrete; in either case they are bolted in place. If used to support guides, pre-cast concrete dividers are reinforced against impact and vibration.

Reinforcement of lining may be of standard structural design (Sec 43), or of old drill steel, rails or hoisting rope. Inward pressure causes compression in a circular lining, but may induce tension at inner face of a rectangular or flat oval lining; where lining of any form is exposed to local thrust, the principal factor is apt to be shear. Steel rope, resistance of which is purely tensile, thus finds its max value as horiz reinforcement near the inner face of a flat wall, but due to stretch, may not take full tension until adjacent concrete has begun to fail. Reinforcing bars are preferable.

In main portion of auxiliary shaft, Gallup American Coal Co, N M, 25 by 10 ft clear, horiz reinforcement comprised 0.75-in round bars, 10.5 and 18.5 ft long (2 ft lap) on sides, spaced on 9-in centers; and 12.5 ft long on ends, spaced 12 in apart. Vert reinforcement, 0.5-in round bars 14 ft long, spaced 24 in apart and lapped 2 ft. Horiz end and all vert bars placed alternately near inner and outer faces of wall. In concreted portion of a hoisting shaft of Lake Superior Coal Co, W Va, reinforcement comprised 0.75-in square corrugated bars, spaced 6 in apart when laid horiz and 24 in apart when placed vert.

Anchorage of lining poured to rock depends on skin friction, aided by leaving points of rock projecting into the concrete. This is usual practice, but linings have also been formed in the clear and anchored only at intervals.

In traversing a shear zone, 200 ft of the Barron shaft, Pachuca, Mex, were concrete-lined to elliptical section, with axes 14 and 10 ft inside lining. The lowest 9 ft were poured to rock as a BASE; 106 ft higher a second base was cast, 3 ft high, and 41 ft above this a third, 5 ft high; between these bases, and for 35 ft above the third, lining was formed clear of the rock and intervening space backfilled. The last 35-ft lift joined a rectangular section above. In the rectangular Chief Consolidated shaft, Utah, in heavy ground, a lining 8 in thick was formed in the clear for 1950 ft of depth, with a RING poured to rock every 10 ft and a heavy reinforced bearer-section deeply hitched every 100 ft.

Details. Mixtures range from 1 : 2 : 4 to 1 : 3 : 6. Wall thicknesses are 8-18 in. Before concrete is placed, flows of water should be stopped by grouting or vented through pipes laid in the forms, to prevent separation of cement and aggregates.

Mixing and placing. Concreting is best carried upward from below, although in a deep shaft, it may proceed in several horizons at once, to allow time for setting without delaying the crew.

On small jobs, the mixer may be located in nearest underground level; on large work it is usually at or near the surface, and if located a few feet below level of supply, can receive raw materials by chute, with convenient use of measuring-hoppers. Batches are delivered to the forms by cage or bucket, or by piping. In one case a hopper car was used, discharging through the cage floor into a short telescoping pipe erected at the forms; buckets may deliver to forms direct. In many large shafts concrete has been piped from mixer directly to place. In the 380-ft Songo shaft, Birmingham, Ala, a 4-in pipe without gaskets delivered into a 5-in Y, with bottom plugged and a branch discharging to forms through sectional spouts of 18-gage iron; concrete was thus placed for $3 less per cu yd than in the nearby Pyne shaft, where a bucket was used. The 5-compt Sacramento shaft (36), Bisbee, Ariz, was lined 1645 ft during time spared from hoisting; a mixer in the end service compt discharged into a 4-in column, composed of 10-ft lengths with flanges carefully faced; to reach farthest skip compt, an expanding elbow was inserted at pouring level and connected to a 6-in horiz pipe, which discharged through a 45° malleable elbow into 1 length of 8-in galv-iron pipe leading to the forms. Compressed air was admitted at back of expanding elbow to blow concrete through the horiz pipe. 67 lengths of 4-in column and 6 C-I elbows required renewal during the work.

Cyprus Mines concreted a circular shaft, 14.75-ft inside diam, working downward. A steel bulkhead, of diam 6 in greater, floored with wood and provided with door for bucket, was hung below lining by four 5-ton chain blocks; a 1.75-in angle, rolled to 13.75-ft diam, was bolted through washers to the deck, with 1.5-in clearance between, through which 1-in boards were extended to rock and wedged in place, as a base for concrete, the bulkhead being centered by 3 radial arms sliding in guides. Forms of flanged corrugated steel, 16 in high, in 36-in sections, were bolted in place, after which the bulkhead was pulled up snug; usually 3 tiers of forms were placed and poured at once, with steel shaft dividers placed in the middle tier of every alternate pour; concrete was piped from surface; mucking proceeded during concreting.

Forms are of wood or steel, 2.5–12 ft high; aver about 5 ft. If greased, they are easier to strip, and leave better surface. On large jobs, and where curtain walls are cast with the lining, standardized steel forms save time; they are made in sections, each sometimes comprising several hinged parts, and designed for rapid assembly.

At the Sacramento shaft (36), steel forms 5 ft 9 in high were used for a 5-ft course: bolts were embedded near upper edge of each course to engage holes along lower edges of forms when latter were placed for next course above, thus securing alinement and holding forms against pressure of wet concrete. Steel forms are much used for circular and elliptical linings. If the shaft is timbered for safety while sinking, the lagging may serve as the inside forms.

Gunite (21) is sand concrete applied by a "gun," which pipes the dry materials under air press to a movable nozzle, where water is added and the resulting paste sprayed in place as a thin coating. Uses: to preserve timber and steel (Art 12, 13), to fireproof timber, to prevent air slacking of rock, and as shaft lining in firm ground. Surface to be coated is thoroughly cleaned; to secure bond, timber and steel are covered with wire mesh, and timber may be wet before coating. Mixtures vary from 1 : 2.5 to 1 : 5 at the gun, but are enriched during placing, due to rebound of the sand; 1 : 3 mixture at the gun becomes 1 : 2.5 in place. One bag of cement yields 32 sq ft of 1 : 4.5, or 22 sq ft of 1 : 3 nominal mixture, 1 in thick in place; 0.6 cu yd of coating requires about 1 cu yd of materials. The 1 : 2.5 nominal mixture is used to waterproof; its ultimate compressive strength is 4 500, that of 1 : 3 mixture is 4 000 lb per sq in. Cement should be screened; sand should be clean, not over 0.25-in size, and not quite dry. Usual sizes of gun require 110–225 cu ft free air per min at 40–75 lb press; the air should be dry.

Tramway shaft, Butte, was fireproofed by coating to 2 000-ft depth; lagging was removed just above and below each level and coating carried to rock, thus sealing the timber in a series of air-tight sections; timber was covered with 27-gage diamond-mesh metal lath and wet just before coating. Mixture 1 : 3, applied in two 0.25-in layers; tests showed that keeping the coat damp for several days prevented shelling off under heat. 4 men with gun coated 100–150 sq ft per hr; 100 sq ft required 3.5 sacks cement, 0.85 ton sand, 94 sq ft lath, 1.5 lb staples and nails, and 23 man-hr in all (3.6 for lathing, 2.7–4 for coating).

In 1918, 900 ft of colliery slope, including timbers, were coated with 0.5 in gunite, at $3.09 per ft; 100 sq ft required 1.67 sacks cement, 5 sacks sand and 2.4 man-hr (shaft and compressor crew only). In Cary A shaft, Wis, steel sets and wood lagging were covered for 263 ft of depth with meshed reinforcement and coated 1.5 in thick, in 1 to 3 layers; total cost, $13.60 per 100 sq ft, requiring 3.8 sacks cement, 0.6 cu yd sand and 1.24 man-days labor; 1 foreman and 6 men coated 14 260 sq ft of wall and 3 750 sq ft of steel in 32 working days. A hoisting shaft of Lake Superior Coal Co, W Va, was lined for 185 ft with reinforced gunite. Gunite rings 10 in thick, were made every 10 ft and reinforced with bars 12 in apart grouted into holes in the rock; in shattered ground heavy concrete brackets were substituted for gunite rings. Between rings (or brackets) gunite walls were 3 in thick; mixture, 1 : 3. Gunite also used as facing for 55 ft of ordinary concrete lining.

Concrete-block walling, used chiefly in Europe, is adapted to circular shafts. Except for shallow depths, it is divided into lifts, each built on its own curb ring, best made of concrete poured to rock as in the ring method. Blocks are segmental, from 6 in thick, 9 in high, 12 in long on outer face, of 1 : 2 : 4 mixture (6), to 3.2 in thick, 30 in high and about 36 in long, as in a circular shaft at Charleroi, Belgium. The blocks were dowelled for alinement and reinforced; after placement, rods were passed through ring bolts protruding from the outer face, and bonded in the concrete backing; mixture, 1 : 1 : 2. An interlocking reinforced block in Z-form has been used in Belgium. Walling is built clear of the rock, and space behind filled with concrete.

16. MASONRY LINING

In Europe, circular shafts in dry or moderately wet ground are often lined with hard-burned brick or cut stone, laid in lime mortar or, in wet ground, cement mortar. Brick and stone are preferably shaped to the required curve, though for diams over 12 or 14 ft, ordinary brick may be used. Lining is backfilled with clay, sand, cinder or other fill, rammed in place. Large volumes of water, not too great for pumping, are excluded by COFFERING, which in simplest form consists of brick laid in cement and carefully backfilled, or more elaborately of concentric walls, up to 8 in number, filled between with clay or concrete; both horiz and vert joints are broken. For concrete block lining, see Art 15.

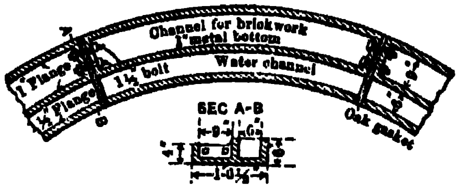

Fig 27. Walling Crib and Water Ring Combined

Anchorage is provided at intervals by a C-I WALLING CRIB (Fig 27), which is cast in segments, usually 8 to the circle, wedged or bolted together on a continuous hitch cut in the rock and dressed level. Ring is made watertight by fir sheathing driven into the joints.

Placement. Shaft is sunk with temporary wood lining (Art 13) to firm rock, and a walling crib placed, on which the wall is built to surface from a stage hung in the shaft. Correct curvature is maintained by wooden templates, and alinement by plumb lines. On resuming sinking, a shelf of rock is left under the crib until wall has been brought up from next crib below. The shelf is then cut away a little at a time and replaced by walling, using temporary props for crib above. For coffering, wedging cribs like those used in tubbing (Art 17) may be employed. Walling cribs are sometimes of wood, and in firm ground may be omitted, masonry resting directly on rock.

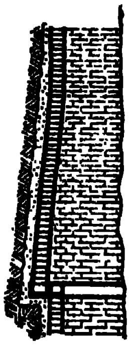

Fig 28. Walling Crib and Water Ring in Place

Walls (single) are usually 9–18 in thick; coffering may be designed (23) for hydrostatic head, and is thicker. Water rings (GARLANDS) are of wood or C-I, often cast integrally with walling cribs (Fig 27). At each ring, lining may be gradually offset as in Fig 28, to leave shaft area clear. Weep holes are left in the masonry; in coffering these may be lined with wood or C-I PLUG BOXES, sealed when masonry is completed.

Cost. For diam of 18–21 ft, Redmayne (22) in 1925 estimated cost of sinking and lining, excluding wall material, at $3.25 per ft of diam per ft of depth; for diam less than 18 ft, slightly less; for labor only, $1.65 per ft diam per ft of depth. In England before 1915, a walling crib cost $25–$50; ordinary brick lining per ft of depth, 75¢–$1 per ft of diam, with brick approx $5 per M; coffering in one shaft 18 ft diam cost $33 per ft; another, 16 ft in diam, $17 per ft.

17. TUBBING

Tubbing is a watertight lining of C-I rings for circular shafts, used in very wet rock formation underlaid by an impervious stratum, to which lining can be sealed above mineral deposit. Vol of water must not be too great to be pumped during sinking.

Rings are cast to shaft radius in flanged segments approx 4.5 ft long. If D = shaft diam (ft), P = hydrostatic head (ft), measured to outcrop of water-bearing strata (which may be above shaft collar), then thickness (in) of web or flange = $\sqrt{P}(0.05D + 0.125) \div 14.14$, minimum 0.5 in; width of flange (in) = $\sqrt[3]{P}(D + 15) \div 35.09$, increased to nearest in or half-in above; minimum up to 10-ft diam = $0.684\sqrt[3]{P}$; after Lupton (25). Acid water calls for extra thickness.

Flanges may project inward or outward; if inward, they are faced by machine and bolted together with lead gaskets (segments 18–36 in high); outside-flange segments (30–60 in high) are rough castings wedged against the rock, with pine or lead gaskets in the joints. Inside-flange tubbing is the stronger and avoids stress due to wedging, but being bolted, may incur abnormal stress in shifting ground due to its rigidity. Space between tubbing and rock is best concreted. A cored hole in each segment aids handling and vents water during placement.

Placement. Anchorage and sealing against water are provided by WEDGING CRIBS (usually ring castings, Fig 29) projecting outside the lining and seated in a continuous groove around the shaft. The seat is dressed level and covered with pine sheathing (0.5–0.75 in thick) and tarred flannel, or with fresh concrete; on this the crib segments are assembled, with pine or tarred flannel gaskets. Between crib and rock, small pieces of oak are placed and packed with dry moss, into which wooden wedges are driven; finally chisels are used to open the way for more wedges until no more can be driven, the crib having been propped down against the wedging until secured by wt of lining. Placing then proceeds upward; except with SUSPENDED TUBBING, hung from crib above, and used where ground requires support close to bottom. Air or gas trapped behind the lining may exert abnormal pressure and is carried past the sealed crib through by-pass pipes; or better, vented through a check valve in the crib itself, finally escaping at top of tubbing. Wedging cribs are usually 30–75 ft apart, or wherever rock affords an effective seal. In sinking by freezing (Sec 8), with no room outside shaft circle for hitches, tubbing has been anchored by a few rings with deeply corrugated outer faces, concreted in place.

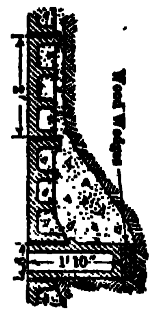

Fig 29. Wedging Crib and Outside-flange Tubbing

Costs in England before 1915 were \$40–\$100 per ft of depth, installed; castings, \$25–\$35 per ton; placing, \$6–\$10 per ton. Costs per ft for a 14-ft shaft: 0.75-in tubbing, \$44; placing, \$5; gaskets, wedges, etc, \$2. Preparing seat and placing wedging crib, \$200. Costs are now approx twice the above (22).

18. KIND-CHAUDRON PROCESS (2, 25, 27)

Conditions for use are as for tubbing (Art 17), but with inflow of water too great to be pumped during sinking. Such conditions are rare in the U S, but common in Europe.

Method. The shaft is excavated under water, by massive drop tools, called TREPANS, the method being an extension of the rod system of boring (Sec 9). The water stands at its natural level until the work is finished. A small shaft may be bored first and enlarged to full diam, or the full section bored in one operation. On completing boring, the bottom is cleaned with a special tool, and the lining (inside-flange tubbing, Art 17) is put together at the shaft mouth and lowered as rings are added. The lowest ring is the MOSS-BOX (see below), specially designed to seal the lining to the underlying impervious stratum. When lining is in place, the space between it and the shaft wall is filled with cement grouting, lowered in trip-bottom boxes, and the shaft is pumped out. An effective seal is essential.

Plant required consists of a suitable headframe (with facilities for handling the heavy boring tools), power plant, boring rods, small and large trepans, sludgers and special tools.

Trepans are massive steel frames, to the lower edge of which are attached chilled-steel bits weighing about 100 lb each. Bits are placed unsymmetrically to cover entire area of shaft bottom as trepan rotates; they are also set to slope the shaft bottom towards center, thus facilitating removal of cuttings. Trepans are inspected frequently and dull bits removed. Wt for a small bore, 2–15 ton; for large, 15–30 ton. An enlarging trepan (Fig 31) has a projection extending into advance bore, and a crosshead fitting the shaft, to preserve alinement; the crosshead may carry bits to dress the shaft wall. Strokes per min 8–25; length of stroke, 6 in to 2 ft. Tools are suspended from the walking beam by rods and temper screw (Sec 9), which feeds down as boring progresses.

Boring. Usually the shaft is started by ordinary methods, and a shallow hole, of diam of small trepan (Fig 30), is made at shaft center. In this the trepan is started, and cuts an advance bore of 4 to 10-ft diam, usually kept at least 30 ft ahead of the enlargement, sometimes cut to full depth before enlarging begins. Cuttings from the small trepan are removed by sludger (Sec 9); those from large trepan are caught in a bucket suspended in the advance bore. Where shaft walls cave badly, they may be lined temporarily with sheet-steel casing, hung from the surface or rested on a shoulder of rock left for the purpose. Diam of shaft below must then be reduced.

Permanent lining. Moss-box is a double telescoping ring with outside flanges, between which dry moss is placed and secured while lowering by means of wire netting. When seated, the wt of tubbing telescopes the rings and compresses the moss against the shaft wall, forming a watertight joint. Sometimes concreting alone (without moss-box) is depended on for sealing; special bits on the enlarging trepan then cut a level seat for bottom flange of regular tubbing.

With deep shafts and excessive wt of tubbing, the lining as a whole is made buoyant by placing above the moss-box a false bottom or diaphragm, in which a vert EQUILIBRIUM PIPE is inserted, equipped with valves for admitting water as desired and thus controlling buoyancy. When lining is finished and sealed, and shaft pumped out, wedging cribs (Art 17) are placed below the moss-box and sinking proceeds by ordinary methods.

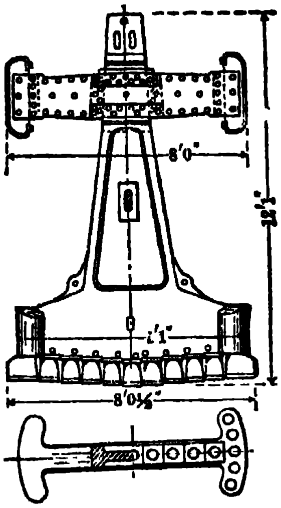

Fig 30. Small Trepan

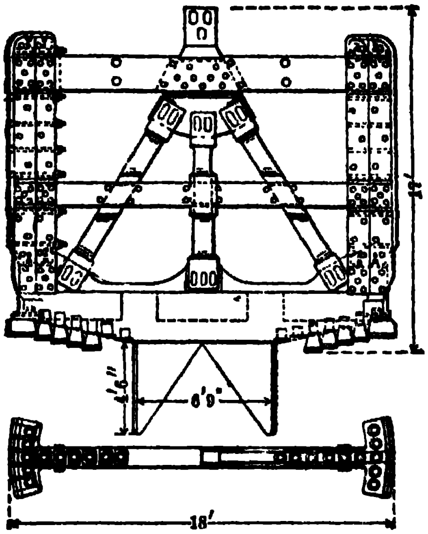

Fig 31. Large Trepan

Speed and cost. Aver rate of sinking to 600 ft depth in northern France (24), 12–33 ft per month; cost (before 1915) $66–$200 per ft.

Costs of sinking 14.5 ft diam shafts in the Ruhr district, Germany, to mean depth between 164 and 1 148 ft prior to 1915, were (27): plant and equipment, 50% of first cost, $25 000 to $35 000; miscellaneous, $12 500 to $25 000; tubbing per ft, $90 to $195; concrete per ft, $12; power and supplies per ft, $60 to $105; labor per ft, $135 to $210.

Kerr (23) gives cost of sinking only, exclusive of tubbing, at $83 to $250 per ft; ordinary rate of advance, 9–12 in per day. In general, pre-war cost of 12-ft shafts ranged from $100 to $300 per ft; 14 to 16 ft shafts, $250 to $500 per ft.

SPEED AND COST DATA

Of the following cost examples, all but three are dated 1920 or later, and fall within the period of higher wages and prices that followed the World War. Costs prior to 1916 should be increased 50–60% for use as guides to current practice. For cost examples of steel shaft support, see Ross shaft, Art 20, and Matahambre No 2 shaft, Art 21.

19. SMALL SHAFTS

201-ft prospect shaft, southwest U S, 5 by 7.5 ft, no water. Hoist and 6 by 8-in vert compressor powered by tractor engines; 25-ft headframe cost $165. Drilling and blasting 3 hr, mucking 6–7 hr, timbering 6 hr. Round, 8–13 holes, aver of 40 sticks, 1 1/8 by 8 in, 40% dynamite. Sets 5.5-ft centers, 4 by 6-in plates, 4 by 4-in posts and dividers. Sunk in 98 days. Cost (reported 1935):

	Total	Per ft		Total	Per ft
Labor	$2 267.50	$11.28	Lights	$ 6 60	$ 0.03
Insurance	135.00	0.67	Gasolene	35.00	0.17
Explosive	175.00	0.87	Oil, grease, coal *	9.65	0.05
Lumber	381.35	1.90	Pipes, bolts, nails	33.35	0.17
			Total	$3 043.45	$15.14

* For blacksmithing.

Alaska-Juneau No [illegible] prospect shaft (7), 7 by 9-ft rock section, 60° incline, sunk by contract for 300 ft through hard rock. Shaftmen earned aver of $9.28, hoistmen $4.50 per shift. Round, V-cut, 24 holes, 5–6 ft deep. Powder, 40% special gelatin, 23.5 lb per ft. Timber, 8 by 8-in plates, 6 by 8-in dividers, sets 6 ft apart, 37.5 bd ft per ft. Costs per ft (1931):

Labor:		Supplies:		Power:	
Shaftmen	$20.19	Explosive	$4.97	Drilling	$ 0.80
Pumpmen	4.27	Timber	0.98	Hoisting	0.40
Timber framing	0.69	Pipe lines	0.11	Ventilation, lights	0.05
Steel sharpening	0.42	Drill repair	0.25	Total power	$ 1.25
Miscel	0.12	Miscel	1.20	Supervision	$ 1.00
Total labor	$25.69	Total supplies	$7.51	Total direct cost	$35.45

Davis-Daly air-shaft, Butte, Mont (11): depth 1 805 ft, comprising 1 607 ft of raising, 90 ft of stations and 108 ft of sinking; timbered solid with octagonal frames circumscribing a 6.5 ft circle (1920–21). Miner's wage, $5.75; aver day's earning on contract, $6.28; explosives per lb, 20¢; timber framer, $6; timber per M, $37. Cost per ft for raising only:

Timber for shaft frames	$ 7.48	Compressed air	$ 0.86
Framing	0.76	Drill repairs	0.69
Timber for chutes, etc	1.47	Steel consumption	0.39
Cutting chute timber	0.37	Steel sharpening	0.28
Blocks, wedges, etc	0.99	All other supplies	0.33
Total cost of timbering	11.07	Labor	14.76
Explosives	2.33	Total per ft	$30.71

20. SHAFT RAISING

Bunker Hill and Sullivan No 2 shaft, Idaho (7); 3-compt, inclined about 50°, rock section 8 by 16 ft; raised 295 ft from 19th level in medium hard ground. V-cut round, 24 holes. Powder, 35% gelatin, 12.2 lb per ft of shaft. Timber, 10 by 12-in caps and sills; 10 by 10-in posts, 6 by 10-in dividers; sets at 5-ft centers; total bd ft per ft of shaft, 153.3 Man-hr and costs per ft (1927):

	Man-hr	Cost
Labor:		
Bosses @ $7 50	0.06	$ 0 47
Timbermen @ $5 50	0 61	3.30
Shaftmen @ $5 00	1 08	5 41
Helpers @ $4 50	0.11	0.41
Timber framing	0.21	0.64
Sharpening steel	0 10	0 35
Total labor	2.17	$10.58

	Cost
Supplies:	
Explosive	$ 2.05
Timber	3.68
Miscel	0.17
Total	$ 5.90
Power:	
Drilling	$ 1.11
Hoisting	0.33
Total	$ 1.44
Total direct, per ft	$17.92

Pilares shaft, Sonora, Mex (7). 345 ft of pilot raises, 4 by 7 ft; enlarged to full rock section of 12 by 20 ft; see Art 11. Total completed depth, 379.5 ft. Powder: in pilot raises, 5 lb per ft of raise; total, 10 lb per ft of shaft. Costs (1924–25):

	Per ft of raise	Per ft of full section shaft				
		Raises	Enlarging	Timbering	Miscel	Total
Labor:						
Breaking	$2.45	$2.23	....	....	....	....

Ross shaft, Homestake Mining Co, So Dak (28); 6-compt, 14 ft by 19 ft 3 in outside steel sets; designed for 5 200-ft depth; sets installed at end of 1934 for 3 242 ft. Sunk from surface, 137 ft; raised full size for 250 ft from 800 level, but wt of broken rock crushed the timbering; shaft was raised elsewhere with 6 by 6-ft pilot raises in center of shaft area then enlarged to size. Steel sets (6-ft centers): plates and dividers, 6-in 25-lb H-beams posts, 3.5 by 3 by $^3/_8$-in angles; the 2 skipways laced with 14-gage galvanized corrugated steel; ladders and sollars of steel; all steel specified to contain 0.20–0.25% copper. Upper 308 ft of shaft concreted solidly outside of sets, at cost of $46.27 per ft; total of 150 ft concreted below in sections of 1 to 3 sets; elsewhere the shaft walls were gunited. Costs per ft of 3 241.5 ft of steel-supported shaft (1933–34):

Excavation	Pilot raises	Enlarging	Total
Mining: Labor	$ 9.19	$13.77	$22.96
Explosives	2.73	3.11	5.84
Air and drills	3.20	2.54	5.74
Timbering	4.24	0.67	4.91

21. WORKING SHAFTS, METAL MINES

Typical estimate of total cost per ft, including supervision and general maintenance, of sinking a vert 3-compt shaft 8 by 17-ft section to 1 000-ft depth is given by Elsing (29):

Labor:	
Shaft	$30.00
Blacksmithing	2.00
Timber framing	2.75
Hoisting	2 75
Total labor	$37.50
Explosive	$ 5.50
Timber	7.50
Power	2.25
Insurance	2.00
Miscel supplies	7 00
General expense	3 25
Total	$65.00

Moderate flow of water will increase cost 10–15%.

United Verde No 5 shaft, Jerome, Ariz. Rectangular section 7 by 14 ft; sunk in 1925 from 2 400 to 3 150-ft level through medium quartz porphyry:

Drilling speed, in per min	10
Per round:	
Advance, ft	4.5
No of holes	32 to 35
Sticks of powder	260
Water pumped, gal per hr	5 000
Cost per ft:	
Labor (drill, muck, timber)	$31.85
Explosive (except caps and fuse)	5.26
Total cost per ft	$52.76

Butte district, Mont (15), operating more than 60 shafts, affords steady employment to specialized sinking crews. Sinking in 1920 cost approx $100 per ft, including equipment. Anselmo mine shaft, 3-compt, 19 by 6.5 ft outside timbers, was then being sunk in altered granite and rhyolite porphyry. Labor, 5 miners per shift, on contract at $40 per ft; also 1 shift boss and 1 topman per shift. Clipper drills (4, in hard rock 5) made round of 30 holes in 4 hr, in 10 rows of 3 across the shaft; V-cut holes 9.5 ft deep, pointed at 45° from 4.5–5 ft collar; side holes 5.5–6 ft deep; after finishing a round, drills were overhauled. Powder, 40% gelatin, 100–125 lb per round. Timber, 12 by 12-in; set placed in 1.5–2 hr.

Water Lily shaft (12) Eureka, Nev, 3-compt, 15.5 by 5.75 ft outside timbers, was sunk 427.5 ft in 31 days (Sept, 1920) through porphyry and 60 ft of limestone; in another month, 416 ft, all in limestone. Rock hoisted through 2 compts, partly lined to prevent buckets from catching on timbers; non-rotation ropes, no crossheads. A bonus was based on monthly advance. 3 shallow drill rounds were more effective than 1 or 2 deeper rounds. Sets of 8 by 8-in timber placed 5-ft centers; lagging, 2 by 12-in. Data for record month: aver advance per day, 13.8 ft; shaft sets placed per day, 2.8; rounds per day, 3; holes per round, 23.9; buckets (17 cu ft) per shift, 72.5; 9 hammer drills on the job; aver number in use at one time, 5; gelatin, 35% in porphyry, some 50% in limestone, lb per ft, 15.25. Regular daily wage: shaftmen, $5.25; hoistmen, $5; topmen, $3.75. Shaftmen per shift, 5.7. Timbermen per day, 4.8. Total delay for month, due to repairs and failure of power, 13 hr

Porphyry shaft, Inspiration Mine, Ariz, rock section 17 $^2/_3$ by 13 $^1/_3$ ft, timbered. 2–4 unmounted Clipper drills made aver round of 30 holes in 4 hr. Record advance for 7 months, Feb–Aug, 1922, 1 037 ft, in a total of 1 403 ft.

	Ft sunk	Cu yd rock	Man-shifts			Shifts per ft advance			Shifts per cu yd		
			Shaftmen	Topmen	Hoistmen	Shaft	Top	Hoist	Shaft	Top	Hoist
Max month	209	1823	936.6	179.0	93	7.3	1.3	0.8	0.83	0.15	0.08

Aver month	148	1292	833.4	169.2	90.7	5.6	1.1	0.6	0.64	0.13	0.07

Bisbee Queen shaft, Ariz (29), 8 by 17 ft, 3 compt, no water. Sunk 823 ft from surface; best month's advance, 235 ft. Contract price for labor and explosive, $40 per ft; contractor paid $8 per man-shift ($9 if month's advance reached 200 ft). Insurance, 5.5% of payroll; elec power, aver, 2¢ per kw-hr; powder, 16.5¢ per lb; timber, $30 per M bd ft delivered. Cost per ft (1927):

Labor:		Power	$ 2.39	Supplies:	
Shaft	$30.93	Insurance	2.15	Explosive	$ 5.49
Blacksmiths	2.07	Trucking	1.31	Timber	7.60
Timber framing	2.84	Office and general	2.06	Misc supplies	7.40
Hoistmen	2.77	Preliminary exp	2.14	Total	$20.49
Total	$38.61	Total	$10.05	Grand total	$69.15

Wisconsin zinc district (14). In 1920, 2- and 3-compt shafts, traversing 10–40 ft of overburden and varying depths of rock, with not more than 500 gal of water per min, were sunk at usual rates of 65–85 ft per month and cost $20–$50 per ft.

Ajax shaft, Cripple Creek, Colo (10), vert, 3-compt, 15 ft by 6 ft 2 in outside timbers, was deepened 502.5 ft below 1 481 ft in 1915–16. Labor: 2 8-hr shifts, each of 4 shaftmen, 1 hoistman, with topmen and skippers as needed; day shift drilled, blasted and timbered; night shift mucked and sometimes timbered; overtime as needed. 4 hammer drills made 40 holes per round; aver depth, 4 ft. Plates and corner posts, 10 by 10 in; dividers and interior posts, 8 by 10 in. Drill bits per round, aver, 126.5. Total time, 293 days; max monthly advance, 95 ft; aver ft per round, 3.03. Per ft advance, aver: machine-shifts, 1.3; sinking hoist-shifts, 0.86.

	Aver wage	Per ft		Per ft
Drillers	$5.25	$ 6.51	40 and 60% powder, 20.7 lb @ 19.42¢	$ 4.02
Muckers	4.50	6.47	Fuse, 143 ft @ 0.6¢	0.86
Timbermen	5.25	5.11	Caps, $1.75 per 100	0.24

22. WORKING SHAFTS, COAL MINES

No 261 mine, 2 hoisting shafts, Caretta, W Va (33). Skip shaft, rectangular with oval ends, 12 by 28 ft on axes of rock sec, 563 ft deep. Manway shaft, same shape, about 16 by 29 ft, 572 ft deep. Both sunk from surface through sandstones and shales, water-bearing for first 300 ft; about 200 ft in each shaft were grouted. Concrete-lined, steel buntons; no temporary timbering required except near surface. Concrete, cu yd per ft of shaft: skip shaft, 3.87; manway 4.48. Powder 40% gelatin, lb per ft: skip shaft, 15.3; manway, 19.8. Man-hr and costs (1922-23):

Man-hour per ft	Skip shaft	Manway	Man-hour per ft	Skip shaft	Manway

Total cost, per ft	$216.53

23. WITWATERSRAND SHAFTS

Shafts of large capacity on the Witwatersrand, So Africa, rectangular and timbered, were estimated (19) in 1920-21 to cost approx £40-£50 per ft, or, at aver sterling exchange of $3.75 then prevailing, $150-$190 per ft.

City Deep, Ltd. Low hoisting capac and cost of sinking and maintenance in heavy ground precluded use of inclines below 5 300-ft depth; hence, for 7 000-ft depth, a vert circular shaft of 20-ft clear diam was designed to hoist 2 000 ton ore daily, handle all men and supplies and pass 300 000 cu ft air per min. Hoisting planned in 2 stages of 2 500 and

4 500 ft, lower stage being the shorter to reduce size and heating effect of underground electric hoist. Shaft comprises 2 cageways, with pipe and cable space (no ladderway); concrete-ring supports (Art 15) carry wooden sills outside cageways, for attachment of pipes, cables and guides, the latter acting only on one side of cage, without central dividers. Sinking plant: 18 by 54-in direct-acting steam hoist, drums 7 by 3 ft; 15 by 30-in geared hoist; 18 by 48 bailing engine; 3-ton buckets; 40-in Sirocco fan. 9 water-fed sinking Leyner drills made 35–40 holes per round; aver advance, 2 ft per 8-hr shift. Water, 30 000 gal per day. First 2 950 ft (in firm rock), sunk in 1920–21, cost £29–6s per ft, or, at aver sterling exchange of $3.75 then prevailing, $110 per ft (19).

Government Gold Mining Areas. Southeast 7-compt shaft was sunk 233 ft from 1 738 to 1 971 ft, during Mch, 1912. Rock: 155 ft quartzite, 78 ft shale. 7-lb hammers used in double-hand drilling (benches drilled single-handed). Ventilation by brattice. Water was hoisted. (An example of sinking with hand drilling, now largely replaced by machine).

Labor per shift:		Depth holes	3.5 to 5 ft
1 White foreman		Aver advance per mo	194.3 ft (*b*)
1 White assistant foreman		Water, gal per min	21.0
82 Native drillers (*a*)		Timber, pitch pine:	
4 White timbermen (*a*)		Wall plates	9 by 9 in
11 Native helpers		End-plates	9 by 9 in
Size, rock sec	45 by 10 ft	Dividers	7 by 9 in
Number holes per round	40 to 45	Guides	4 by 8 in

(*a*) Timbermen worked 1 shift per day, drillers 3 8-hr shifts. (*b*) Aver of Jan, Feb, Mch, 1912.

Randfontein ventilation shaft, circular, 23.5 ft rock diam, 22 ft inside lining. Crew, white foreman and 40 natives per shift. Round, 58 holes. Lined with concrete, lowered in self-dumping buckets to sinking platform. Costs per ft (1925–27) are converted at aver sterling exchange then prevailing of $4.85.

Sinking 3 421 ft of shaft	$ 71.78
Concreting 3 071 ft of shaft	37.20
Hoisting	14.93
Shaft equipment	9.98
Surface equipment	24.05
Total cost per ft	$157.94

Simmer & Jack Mines, Ltd; 6-compt, 13.5 by 38-ft rock sec, designed for 6 350-ft depth, started 1934. Water, 400 gal per min, pumped into skips. Sinking crew, 2 whites and 60–66 natives per shift. Drilling aver round of 104 holes, 5 ft deep, with 18 drills, requires about 3.5 hr; mucking, 4.5 hr. More than 5 000 ft of shaft was sunk at aver of 204 ft per month. Timbering, 9 by 9-in pitch pine, 239 linear ft per set; interval of sets, 6 ft. Bearers of steel H-beams every 100 ft.

Vlakfontein No 1 shaft, vert, 6 compts in line; 14.5 by 43-ft rock section. Round of 100 holes: cut holes, 7 ft deep; others, 6 ft; 18–20 hand-held drifter drills; drilling time 2 hr, 46 natives at shaft bottom. Mucking crew, 80 natives; mucking time for 225 tons, usually 4 hr. Period from blast to blast, 7 to 9, usually 8 hr. Advance, 13–14 ft per day; month of Mch, 1936, 422 ft; aver for 8 months, Feb–Sept, 1936, 350 ft. Pitch pine timber: 9 by 9-in plates and dividers; 8 by 8-in corner posts; 4 by 10-in inner posts; sets 6.75 ft c-c. Steel bearers under end plates, and under dividers between compts 2 and 3, 4 and 5, and 5 and 6. Bearers for compts 4, 5 and 6 placed every 100 ft, others every 200 ft. Timbering crew, 2 timbermen and 16 natives, working during drilling period.

This is one of the most recent shafts sunk on the Rand.

24. SHAFTS WITH CONCRETE LININGS

Edith shaft, Jerome, Ariz (35), 3-compt, rock sec approx 17 by 8 ft, was concrete-lined in 1921; mixture, 1 : 2 : 5. Upper 575 ft and 2 stations (Section A, see below) lined by contract, company paying actual expenses, contractor receiving bonus of half the saving below successful bid; in lower 630 ft with 5 stations (Section B), labor received bonus based on aver daily progress for entire job. In both cases ground was practically the same, and shaftmen received current shaft wages aside from bonus. See following table for details.

Section A: 575 ft depth; 1231 cu yd concrete; aver advance per working day, 7.2 ft Section B: 630 ft depth; 1174 cu yd concrete; aver advance per working day, 9.1 ft	Labor, including supervision	Cement, sacks @ $1.10	Sand and gravel, cu yd @ $2.50	Power, kw-hr @ 2¢	Reinforcement, lb @ $0.10	Lumber for forms	Bonus	Total cost per ft
Per ft lined:								
Section A: quantity	....	11.4	2.6	44.1	10	......	......	......
cost	$15.35	12.56	6.51	0.88	1.00	1.50	5.35	43.15

cost	$ 5.78	5.86	3.05	0.45	0.50	0.75	2.13	18.52

Cost of supervision: Section A, $10 per day; Section B, $225 per month.

Sacramento shaft, Bisbee, Ariz (36). Timbering replaced by concrete lining (1915–16) for 1 645 ft of depth. 1 service, 2 skip and 2 cage compartments; concrete walls cast between skipways and between skip and cageways; pre-cast concrete dividers, 10 by 10 in and 6 ft 2 in long, between cageways. Shaft remained in service 14 hr daily, with 10 hr allowed for concreting. Aggregates were stored in special bins on top, trammed through adit to shaft at 71 ft below collar and chuted to mixer located 1 set below. For delivery to and design of forms, see Art 14. Aver wall thickness, 15 in; thin lining and all partitions reinforced. Concrete poured at 3 different horizons in rotation. Shaft crew: 2 men in each compt, 1 pipeman, 1 foreman, total 12. Mixer crew: 1 man measuring aggregates, 4 tramming, 1 helping to dump cars and measuring cement, 1 tripping to mixer and measuring water, 1 foreman discharging mixer, total 8; when mixer was idle, its crew pre-cast the dividers or handled timber. Aver time per 5-ft course: loading tools and cleaning shaft, 30 min; removing timbers, 98 min; raising and setting forms, 84 min; connecting concrete pipe, 28 min; mixing and pouring, 78 min; unloading cages and cleaning tools, 17 min; miscel, 39 min; total, 6 hr 14 min. At first, 1 course was completed in 8 hr; later 2, and once 3 courses in 10 hr. Aver wages per day: shaftmen, $5.47; pipemen, $6.22; electricians, $5.22; laborers at quarry, $2.40; laborers mixing concrete, $2.

Cost per cu yd of finished concrete (6 270 cu yd)

Lining and partitions:		Pre-cast dividers:	
Quarrying and crushing	$1.13	Aggregates	$ 1.69
Transport to bins	0.22	Cement	4.13
Cost of bins	0.34	Labor mixing	5.02
Cost of aggregate	$1.69	Reinforcement	3.12
Cement	3.44	Pipe cores	0.80
Mixing	0.56	Forms	0.39
Cost of piping	0.39	Miscel	0.58

Speculator shaft, Butte, Mont. In places, bad ground required use of jacket sets outside regular timbering (Art 13), and kept special crew constantly on shaft repair. 500-ft section of timbering replaced by concrete lining, anchored by bearer rings 6 ft high, hitched deeply into rock walls, with 15-in wall between bearers formed clear of rock and backfilled. Mixture 1 : 2 : 4. Comparative repairs: when timbered, 32 man-shifts per day, $5 833 per month (1920 equivalent); when concreted (aver of 6 months in 1920), 2.4 man-shifts per day, $389.75 per month (34).

Granite Mountain shaft, Butte, Mont (34), caved from 1 700 to 2 800-ft level after a fire in 1917. To reopen in 1918, caved section was concrete-lined for 1 340 ft, of which 813 ft were first steel-framed for immediate support. Steel sets: plates, 7 700 ft of 6-in 12.5-lb I-beams; vert members 8 130 ft of 10-in 25-lb I-beams; connections, $^3/_8$-in angles and splice bars, with $^5/_8$-in rivets. Shaft sec, 4-compt, 20 ft 9 in by 7 ft 6 in outside of sets. Concrete lining: anchored with bearers at selected points; wall, 15–20 in thick, formed clear of rock between bearers, and backfilled except for clearances of 4 in or less, where concrete was poured to rock. Solid partitions: 10 in thick between main hoist compts, 9.5 in thick between main hoist and man hoist, 9 in thick between man hoist and pipeway. Mixture 1 : 2 : 4; total cu yd in place, 6 380; cement 38 280 sacks, sand 3 190 cu yd, crushed rock 1 075 cu yd, slag 4 655 cu yd, reinforcement of 376 tons. 7 sections in progress at one time. For costs see following table:

Denn shaft, Ariz (37), 2 242 ft deep, of which 2 230 ft were concreted to replace old timbering; work done during a shutdown. Shaft has 3 compts to 1 350-ft depth, including 2 hoist and 1 large compt for piping and dinky hoist; below 1 350 ft, 4 full compts. Concrete lining: thickness 10–36 in, depending on the ground, with 8-in curtain walls reinforced in heavy ground with I-beams. Concrete placed, 9 934 cu yd, requiring 10 934 bbl cement, 5 991 ton sand, 9 052 ton crushed rock, 55 750 lb celite, which facilitated removal of forms and kept aggregate in suspension; mixture, 1 : 3 : 5. Batch, $^1/_3$ cu yd, containing 1.51 cu ft cement, 4.59 cu ft sand, 7.56 cu ft rock; total, 13.66 cu ft of materials for 9 cu ft of mix. Mixed on surface and delivered by 4-in pipe to a sinking bucket with discharge spout, thence by iron launder to the forms. Crew, 7 men and shift boss; 3 men on mixer and charging chutes at surface. Ft of shaft lined in 30 days, 455 max, 115 min (heavy ground), 234 aver. Total cost (reported 1932), $178 972, including about $30 000 due to shut-down, and with no credit for salvage, of which there was some. Following costs for concreting per overall ft of shaft do not reflect change in shaft plan below 1 350 ft; costs per cu yd are absolute.

	Total	Per ft	Per cu yd
Cement	$33 569	$15.05	$3.38
Sand	6 157	2.76	0.62
Rock	11 865	5.32	1.20

SHAFT-SINKING IN UNSTABLE AND WATERBEARING GROUND

1. DIFFICULTIES AND AVAILABLE EXPEDIENTS

Underground water is the principal cause of difficulties arising in sinking a shaft in unstable ground, as sand, gravel, clay, or silt. Even in dry soils, the removal of lateral support around an excavation may cause a fall, or flow, of the material into the excavated space, and when water is present this tendency is greatly increased. The first requisite of the shaft is, therefore, a lining or wall; but, if water is pumped out the ground-water will flow under the lining into the excavation, carrying with it the finer particles of the soil; or partially liquefied clay or silt may be forced up into the shaft by the superincumbent weight. In such case, continued excavation and pumping may cause a continued flow, with slips and falls of the ground, distortion of shaft lining, subsidence of the surface around the shaft mouth and settlement of the sinking equipment and adjacent buildings. This situation may prevent further progress, except by a change of method. Hence, sinking methods requiring pumping have been largely replaced by those in which pumping is unnecessary.

Boulders in soft ground often cause trouble and expense. They may force the shaft out of plumb, or their removal may require excavation to some depth below the lining, at the risk of flow of the surrounding ground with the consequences noted above. The presence of many boulders may cause large and unforeseen increase in cost, or even jeopardize success.

Seal to rock. The shaft having been sunk to rock, or other stable and impervious stratum, a watertight seal must be made between the shaft lining and the rock, and this, at a depth where the hydrostatic pressure of the ground-water is a maximum, may be difficult.

Lateral pressure against the shaft lining varies in different kinds of ground and increases with the depth. Pressure per sq ft above ground-water level is usually not more than 30 lb per ft of depth below surface; below ground-water level, rarely more than 60 lb per ft of depth below surface, except that in partially liquefied clay or silt it may reach 90 lb.

Borings. The success and cost of shafts are so dependent upon the nature of the ground that careful preliminary study of subsurface conditions must be made. The borings are often too few in number or too inconclusive, and a shaft is sunk under adverse conditions which might have been avoided by locating it elsewhere, or which could have been more easily and cheaply surmounted by adopting some other method. Borings in soft ground are usually of the kind known as "wash borings" (Sec 9), which may be of little value unless properly sampled in their original and undisturbed position in the ground strata.

Methods of sinking in unstable ground are now well standardized. Older methods, such as vertical poling boards (analogous to the method used for tunneling), lining the shaft by horiz timbers suspended from trusses across the shaft mouth, or vertical shields jacked down below the timber lining, have been replaced by cheaper and more reliable methods. Among these are:

(*a*) Wood or steel sheet-piling, braced by horiz timbers or steel beams; or wood lagging placed horizontally between the flanges of steel beams, which are driven in advance of the excavation. These methods may be used to depths of 50 to 75 ft, or more, in dry ground, or where the water level has been previously lowered by pumping.

(*b*) Drop-shafts, with walls of reinforced concrete built above the surface, which sink as excavation advances. This is usually the cheapest and most reliable method for depths of 50 to 200 ft, or more.

(*c*) The pneumatic method, which is generally used in connection with drop-shafts in sinking through quicksand, or strata of boulders below the ground-water level, or when the sealing of the shaft to rock may be difficult. The limit of depth attainable by this method is about 115 ft below the ground-water level.

(*d*) Forced drop-shafts, for depths not attainable by ordinary drop-shafts.

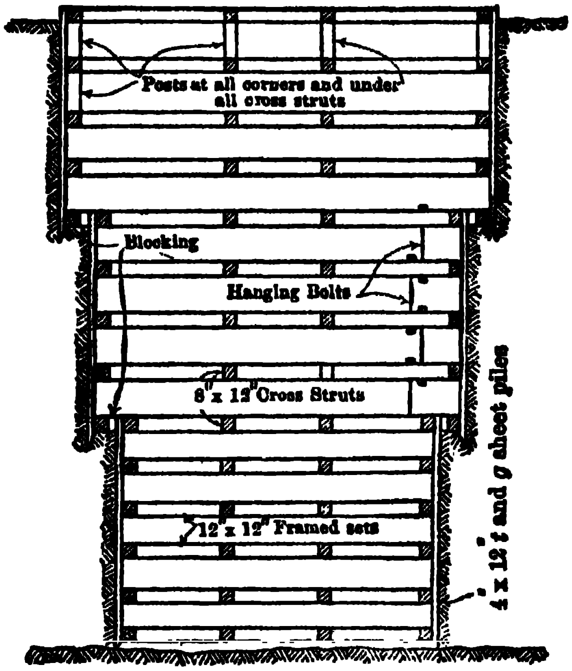
(*e*) Freezing method, which is used for very deep shafts also.

(*f*) Grouting methods.

2. SHEET-PILING

Wood sheet-piling may be used as a temporary lining for small depths above water-level (Fig 1). This consists of planks, 10 to 12 in wide and 3 to 4 in thick, driven vertically around the sides of the excavation and braced by horiz timbers. The edges of the plank are usually tongued and grooved (Fig 2), or splined (Fig 3). The piles are set up in the bottom of a preliminary pit, around two sets of horiz bracing which serve as a guide frame, and are driven by hand, or by steam or air hammers, as excavation advances. Usually the piles are not more than 24 ft long and, if this length is not sufficient, two or more drives of piles are made, successively deeper. As each drive, below the first, must be set to clear the breast timbers above, the necessary excavation is thus increased. If cross-bracing is required it will interfere with the driving of the piles below, and it is therefore desirable, when the horiz dimensions of the shaft permit, to drive the piles around octagonal frames (Fig 4).

Lowering the ground-water level, by use of well-points, is often possible with wood piling. Well-points are perforated pipes, usually 2.6 in outside diam and 3.5 ft long, connected with 1.5 to 2-in pipes and driven 3 to 5 ft apart around the space to be excavated. The tops of the pipes are joined to a header pipe, just above water-level, and a pump is connected with the header. The bottoms of the well-points should not be much more than 25 ft below the pump. Pumping should begin some time in advance of the excavation, depending upon the nature of the ground. Lowering the ground-water level is most successful in medium and coarse sand and gravel. In very fine sand, clay and silt it is rarely feasible. The location of the well-points, when used in connection with wood sheet-piles, is shown in Fig 4, 5.



Posts at all corners and under all cross struts
Blocking
Hanging Bolts
8" x 12" Cross Struts
12" x 12" Framed sets
4 x 12 t and g sheet piles

Fig 1. Vert Sheet-piling

Wood lagging is a method of temporary shaft lining, which has recently come into use (Fig 5). It consists of square-edged wood planks, 10 to 12 in wide and 3 to 5 in thick, placed as the excavation advances behind the flanges of previously driven vert steel H beams. The steel beams are braced by sets of horiz timbers or steel beams. They may be 12 in deep, 53 lb per lineal ft, or larger or smaller, as required; driven to their full length in advance of the excavation, by steam or compressed-air hammers, and may be pulled out and salvaged on completion of the permanent lining. This method is applicable to depths of 50 ft or more, in dry ground, or to about 25 ft below original ground-water level, when this can be previously lowered by well-points, as already described. But the feasibility of the method depends upon whether the steel H-beams can be driven in proper location. With many boulders this may not be possible. The ground-water level can not be lowered below the tops of the well-points, and when these are driven to rock the water level may be 4 or 5 ft above the rock; in which case it may be necessary to use vert sheet-piles, wood or steel, to complete the excavation to rock.

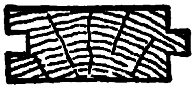


Fig 2. Tongue and Grooved Sheet Pile

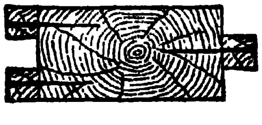

Fig 3. Splined Sheet Pile

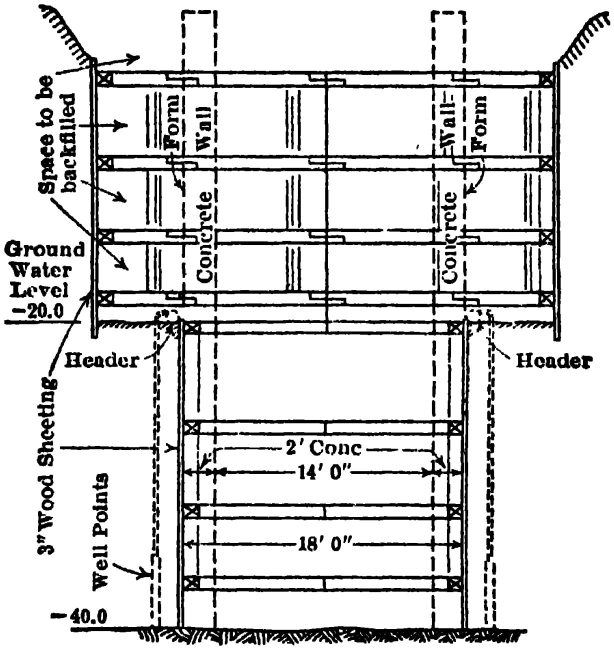
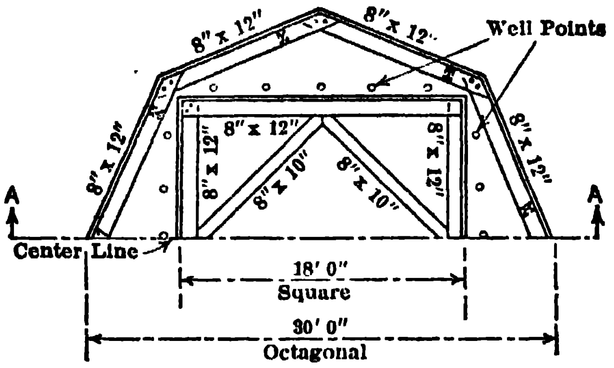
Steel sheet-piles can be used as a temporary or permanent lining. These are rolled, with edges which interlock with each other (Fig 6), in a great variety of widths and weights, and in flat, U-shaped and Z-shaped sections. Widths are from 8 1/2 to 19 5/8 in, weights per ft, from 21 to 64 lb, and the section moduli from 1.4 to 9.3-in cubed. They are rolled by Carnegie-Illinois Steel Co, Bethlehem Steel Co, Inland Steel Co, and the Jones & Laughlin Co, in the U S, and the Larsen, Kloeckner and Hoesch sections in Germany.

The special advantage of steel sheet-piles is that they are driven in advance of the excavation to their full length, down to rock or other impermeable stratum. There is thus a shield between

the surrounding ground and the excavation. Steel sheet-piles are braced by sets of horis timbers or steel beams, placed as excavation proceeds. In very soft ground the piles when exposed by excavation may be bent inward by ground pressure, to obviate which temporary bracing may be required at short vert intervals. Joints between sheet-piles are not entirely watertight and pumping is often necessary. The piles are threaded into each other and set up in a preliminary pit around two sets of the horis bracing, used as a guide frame. They are driven by steam or compressed-air hammers, 2 or 3 ft at a time, successively around the frame until all are down to their full length. A permanent concrete lining may be built inside of the sheet-piles, after which the piles may be pulled



SECTION A-A



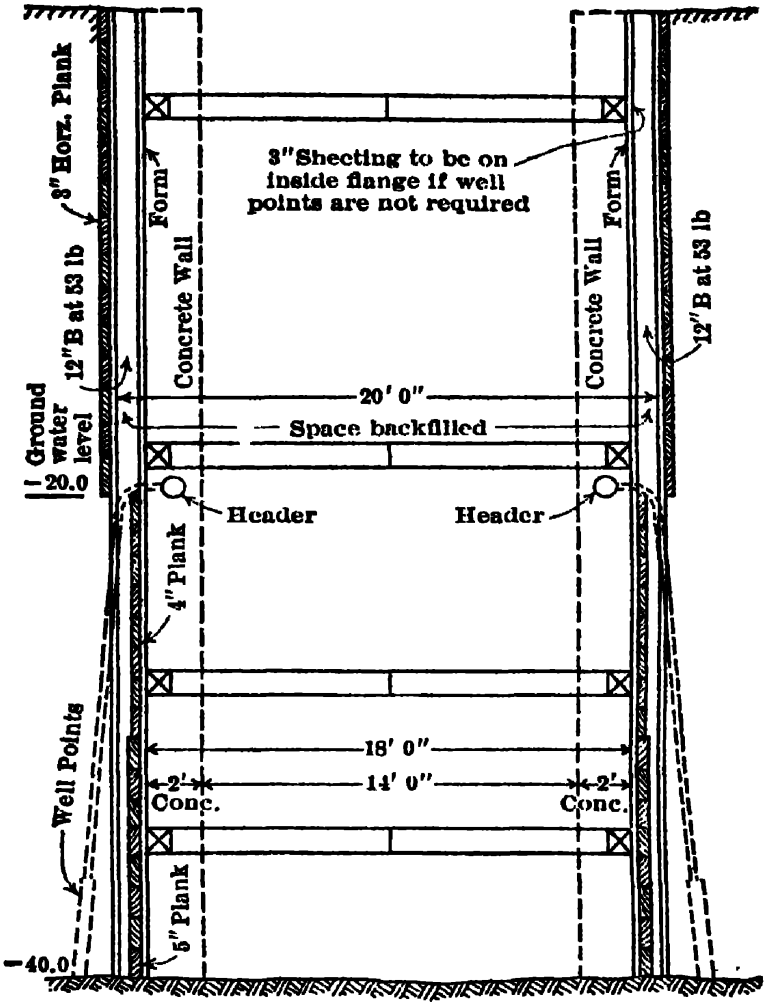
HALF PLAN

Fig 4. Sheet-piling with Octagonal Frames

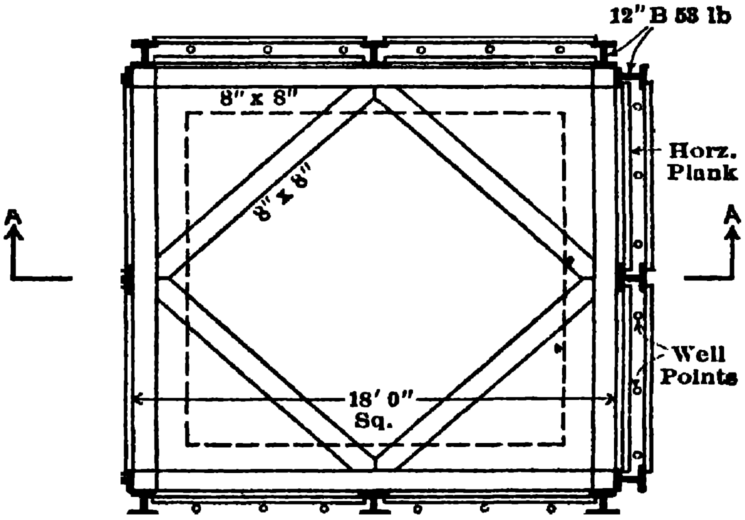
and salvaged. Shafts can be sunk to 75 ft depth by using steel piles, except in presence of many boulders.

In general, a combination of methods is used for sinking (Fig 7): wood sheet-piles, or wood lagging between vert steel beams, down to water-level, and steel sheet-piles below. Most of the excavation by any of these methods can be done by clam-shell or orange-peel buckets, operated by a stiff-leg derrick and a three-drum hoisting engine. The boom of the derrick should be at least 60 ft long, so that the mast and hoisting engine may be set far enough from the shaft mouth to be unaffected by the sinking operations.

Cost of sinking is usually least for horis wood lagging. Steel piling costs more than the other modes of support, but can be used in partially liquefied clay or silt, where other methods are not feasible. At present-day prices and hourly labor rates of 40 cts for com-



SECTION A-A



PLAN

Fig 5. Wood Lagging on Sheeting

mon labor, 75 cts for carpenters and $1 for hoisting-engineers, the cost of a 40-ft shaft, sunk by each method, is about as follows: wood sheet-piles, $13 300; wood lagging, $12 100; steel sheet-piles, $14 900. Each of these shafts would be 14 ft square in inside horiz dimensions. The cost, including a permanent lining of reinforced concrete and contractor's profit, is based on the assumption that the steel piling and steel H-beams used in the wood-lagging method, would be salvaged. The cost of a shaft with steel sheet-piling, also 14 ft square, but 75 ft deep and 55 ft below ground-water level (Fig. 7), would be about $33 600, including concrete lining and contractor's profit. In this case, however, it is assumed that the steel piling would be left in place.

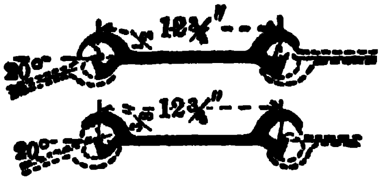


Fig 6. Lackawanna Steel Sheet Pile

3. DROP-SHAFTS

Shafts 50 to 200 ft deep, or even more, are now usually sunk by this method. The shaft walls are built above the ground surface and sink as excavation proceeds. As no pumping is required, the water press in the surrounding ground is balanced and, except in soft clay or silt, there is little tendency for outside soil to flow into the excavation.

Reinforcing. Drop-shafts are usually of reinforced concrete. The cutting edge at the bottom is usually V-shaped in section, so that it will sink into the ground below the excavation level. To prevent injury to the cutting edge by boulders or by blasting, it is shod with steel plates 1/2 in thick, or more. These plates should extend up on the outside of the walls 3 to 5 ft, and to an equal, or greater, distance along the sloping inside faces. They are connected together through the concrete by steel diaphragms placed at frequent intervals, and the whole shoe should be well anchored by steel bars to the concrete walls. The shaft walls should be reinforced horizontally throughout their height, to sustain the ground pressure and any unbalanced loads. Vertical reinforcement should also be provided for bending stresses, and for the suspension of the lower part of the shaft from the upper, in case of inflow of ground at the shaft bottom (Fig 8).

Friction. In order that a drop-shaft may sink as the excavation proceeds, and thus furnish lateral support to the surrounding ground, the friction which develops between the ground and outside surface of the walls must be overcome. Friction increases with the depth below the surface and varies in different kinds of ground: least in silt and successively greater in sand or gravel, clay and boulders. The aver friction, between the surface and bottom of a drop-shaft, may be from 100 to 1 000 lb, or more, per sq ft of contact surface. With many boulders the friction may be very great, so that the drop-shaft becomes permanently locked between them. Usually the friction is from 350 and to 700 lb per sq ft, and in most cases it is safe to estimate the aver at 500 lb per sq ft for depths of 100 ft or less, and 700 lb below 100-ft. To overcome or reduce the friction, there are several expedients. The walls are built thick enough to sustain the ground pressure and also to furnish the weight necessary to overcome friction, taking into account loss of weight due to buoyancy of the ground-water.

Drop-shafts are usually sunk from the bottom of a preliminary pit, 15 to 20 ft deep, thus reducing the area of contact between the ground and shaft walls. The pit is backfilled after the shaft is finished. If the friction is greater than anticipated, additional weight, in the form of pig iron, or sand, can be loaded upon the walls above the surface. Friction may sometimes be reduced by raising the level of the water in the shaft above that of the ground-water, thus causing a back flow under the bottom of the walls and up around them; or, the water in the shaft may be pumped down below ground-water level, thus causing a flow of ground-water into the shaft. This must be carefully done because of the danger of an inflow of soft ground.

Jetting around a drop-shaft by water or compressed air is often effective in reducing friction. Piping for this purpose must be installed in the walls as the drop-shaft is built. Jetting nozzles are usually placed at two levels, one 5 to 8 ft above the bottom of the walls, the other 8 to 12 ft above the first. The nozzles are 1-in diam and discharge horizontally, or upwards at an angle of 22 1/2 degrees from the vert. Each set of nozzles is connected by 2-in pipes with a horiz header 2 1/2 to 4-in diam, and each header is connected with the top of the shaft by a 4-in riser. The nozzles should be about 6 to 7 ft apart horizontally; sometimes an additional set, discharging vertically downwards, is placed in the shaft walls.

When other means are not effective, light charges of dynamite, exploded in the shaft bottom, may start downward movement. This may be done in combination with the other expedients.

Sinking. Excavation is done by orange-peel or clam-shell buckets, operated by the equipment described in Art 2. The shaft must be kept vertical and, in uniform ground, this can be done by excavating uniformly around the cutting edge. Deviation from the vertical may be remedied by excavating on the high side, or placing additional weight

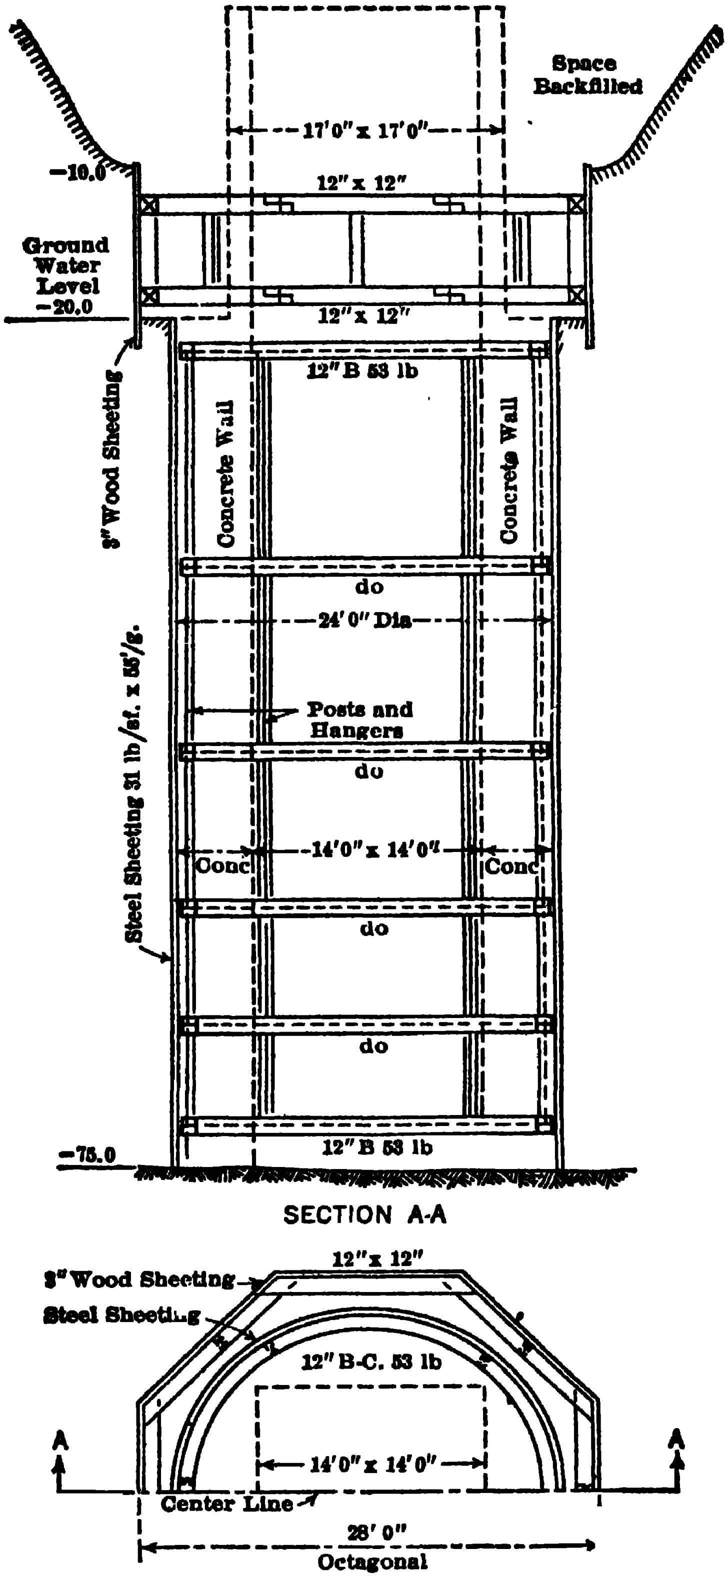

Fig 7. Combination Method of Sinking

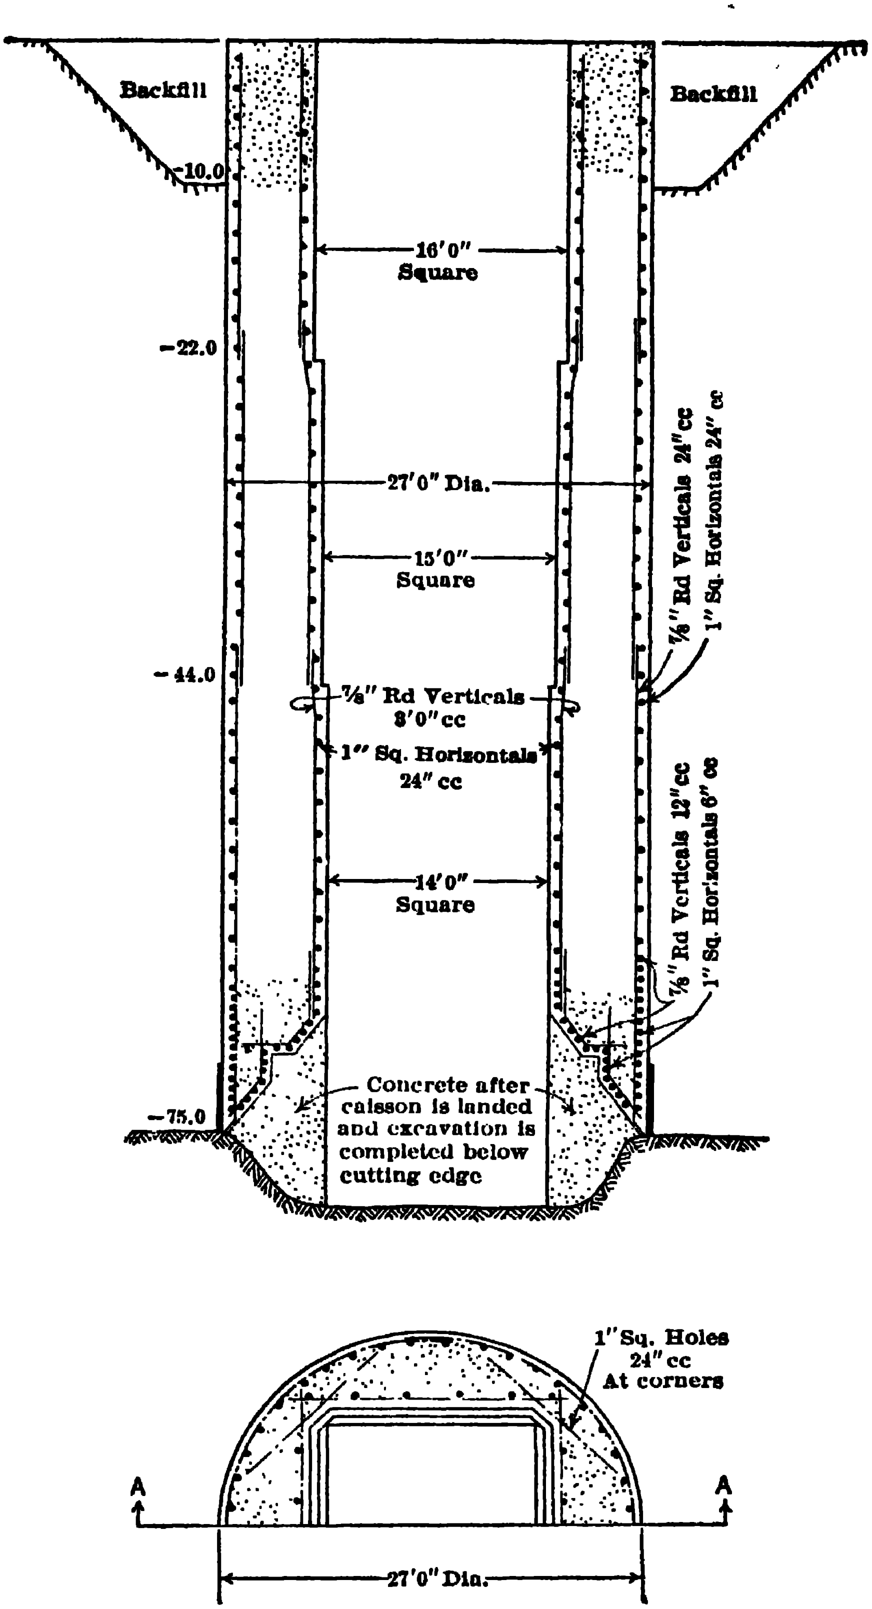

Fig 8. Drop-shaft

on that side. It is especially important to keep the shaft vertical during the early part of the sinking. It is sometimes desirable to sink a deep shaft in two sections, the lower section from the bottom of the upper section. An example of this is a shaft for the St. Albert Colliery, St. Albert, Canada (Fig 9).

If boulders are encountered, the ground under them may be cut away until they roll into the excavation, but care must be taken to avoid an inrush of ground and displacement of the shaft. Drilling and blasting by divers may be required. It is important to keep the weight of the shaft well in excess of the resistance due to friction, or to make use of the other expedients already mentioned, so that the cutting edge may always be buried in the ground below the bottom of the excavation. This is especially necessary in very soft ground.

Sealing to rock. When the cutting edge has reached rock or other firm stratum, a watertight connection must be made between the shaft bottom and the rock. Just above the rock level there is often a stratum of boulders, gravel and sand, through which the ground-water flows under heavy press. It may then be necessary to use the pneumatic method (Art 4). It is possible, however, to seal the whole bottom of the shaft with concrete and grout with cement around the shaft bottom, through holes drilled through the concrete. The concrete is then removed.

The sealing of the St. Albert shaft is an example. The upper section of shaft was sunk 107 ft through sand and clay, and 13 ft into a 25-ft stratum of clay, the presence of which made it easy to pump out the upper shaft, and start the lower, which was sunk through the clay stratum, and sand and gravel below it, to rock at 200 ft depth. As the rock was soft shale it was excavated by orange-peel bucket until the cutting edge reached a depth of 215 ft. A weighted wooden box of conical shape (Fig 10) was then lowered, and concrete (1-2-4 mixture) placed around and over the box until the whole shaft bottom was sealed. The concrete was placed by covered buckets, lowered through the water and emptied through their tripping bottoms. After allowing the concrete to set the shaft was pumped out and cement grout was forced into the surrounding ground through holes drilled through the concrete. When the grout had set the concrete plug and the wooden box were removed in sections (Fig 10). Only a small infiltration of water occurred, which was soon stopped by fine materials flowing in from the surrounding ground.

Cost. At present day prices and labor rates (Art 2) and including contractor's profit, the cost of a drop-shaft, 14 ft square in inside dimensions, sunk and sealed without unusual difficulty, would be $450 to $500 per vert ft. In Art 2 the cost of a shaft 14 ft square inside and 75 ft deep, sunk with steel sheet-piles, was given as $33 600. A shaft of same size, sunk as a drop-shaft, would cost about $37 200. In the first case the depth is almost the limit to which a shaft can be sunk by piling, while drop-shafts can go to much greater depths at a decreasing cost per linear ft, as depth increases. In presence of boulders, sinking by steel piling would involve difficulties that might prove insurmountable, whereas, with drop-shafts boulders are readily handled unless present in great numbers, and even then they can be removed by using the pneumatic method (Art 4). For very soft ground, however, steel piling has a very definite place.

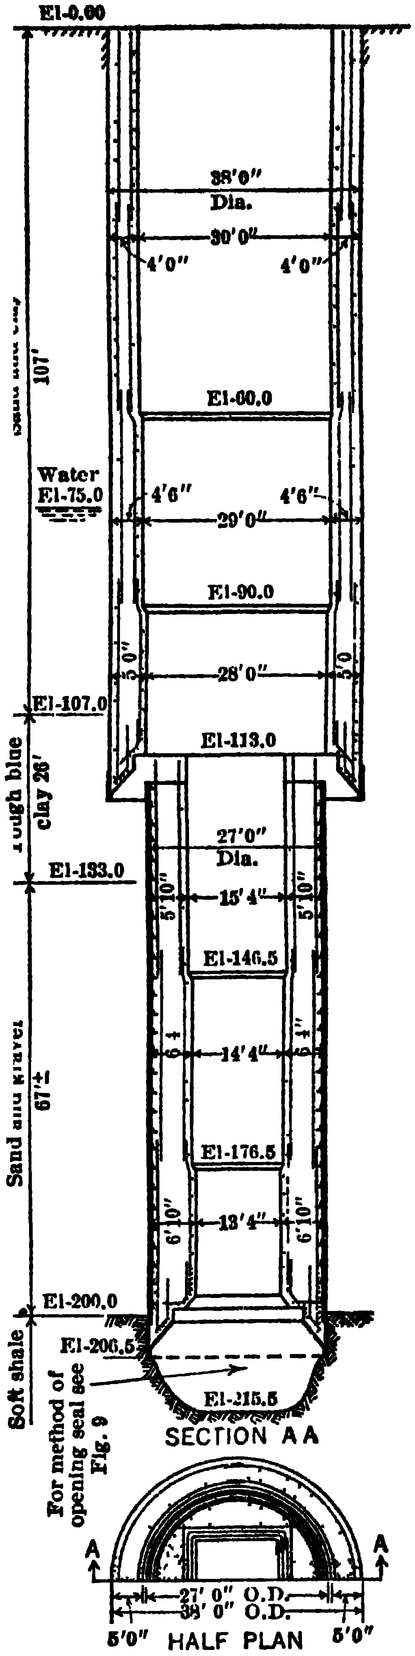

Fig 9. Drop-shaft in Two Sections St Albert Colliery, Canada

I. Shaft 2, Roundout siphon, Catskill aqueduct. The caisson for soft-ground portions of shaft was cylindrical, 26 ft outside diam, walls 2 ft 6 in thick. Shoe was built of 0.5 by 20-in steel plates, with 4 by 1-in filler at cutting edge, and was anchored to concrete by 80, 3/4 by 30-in rods, attached alternately to inner and outer plates. Concrete consisted of 1 cement, 2 sand, 5 stone. Inner and outer forms were of 2 by 6-in vertical wood lagging, supported by angle-iron rings, tied through walls with 5/8-in rods. Caisson was built in 5- and 10-ft lifts to full depth of 55 ft, lifts being bonded together by 1-in vertical reinforcing rods, 4 ft c-c.

Finished shaft was 10 ft 8 in by 22 ft in clear. Borings showed 60 ft soft ground, the upper 6 ft being sandy loam, and the rest a material resembling blue clay when dry, but was completely saturated in place, flowing "like cold molasses and very sticky." On bed rock, and surrounded by soft soil, were numerous hard boulders of all sizes. The shaft site was leveled, shoe assembled upon short planks laid on ground, and concrete forms started. 5 ft of concrete was placed and allowed to set for a week; 10 ft more was then placed and when sufficiently set, sinking was begun. Mud was loaded into shaft buckets, sometimes with shovels, sometimes with water buckets, by men standing on plank rafts. Concrete was added as caisson sank. At a depth of 45 ft a layer of very soft mud was encountered, which ran in under one side of shoe, throwing caisson 2 ft out of plumb. A trench was therefore dug through surface loam on high side of caisson, the material from it was piled against low side, and when sinking was resumed the caisson straightened up. About 6 ft from rock, the shoe was stopped by boulders for long enough time to allow mud to stick to caisson walls, so that after boulders were blasted out it was necessary to load caisson with 200 tons of clay, and also to agitate the mud with compressed air blown through 1.25-in pipes built into the wall. A layer of hardpan was found just over the rock, into which the cutting edge sank deep enough to seal the caisson automatically. Average progress, from building shoe to sealing of caisson was 1.2 ft per day, including concreting and delays. Cost per ft, before 1914: concrete and shoe, $61: labor excavating, $39; general expense, $32; total, $133. Before sinking was stopped by boulders, at depth of 50 ft, skin friction was less than 380 lb per sq ft; afterward, at same depth, over 500 lb.

II. Colliery shaft for D, L & W RR Co, near Wilkes-Barre, Pa (Fig 11). Caisson was of concrete, rectangular section, with rounded corners, and divided into 3 compartments by cross walls. End compartments were arranged to permit further subdivision by timber buntons. Outside dimensions, 28 by 59 1/2 ft; total height 90 ft. Thickness of walls at bottom: sides 7 ft; ends, 5 ft 4 in; outer surfaces vertical, inner surfaces stepped, in lifts of 9 ft 8 in; thickness at top, 2 ft 8 in; main walls reinforced vertically and horizontally with 1- and 1.25-in rods. At 7 ft above shoe, caisson was closed by an air-tight deck, for sealing caisson to rock under air pressure (12).

Ground was leveled, shoe assembled, and 20 ft of concrete placed. Sinking was carried on day and night, each shift consisting of a foreman and 16 men in shaft. After shoe reached rock, the soft ground was held back temporarily with timber blocks wedged into place under horizontal

portion of the shoe. As this stratum was not firm enough to make a permanent seal, the shoe was undercut and shaft excavated 4 to 5 ft larger all around than inside section of caisson at bottom. In blasting, great care was taken not to break the ledge under shoe and blocking. Sound rock was found 15 ft below cutting edge, and a wall was built up to underside of caisson. Drain pipes disposed of water breaking through blocking, and were grouted after wall was finished and concrete had set. During construction of this wall, water was led to the pipes by building a small brick dam upon the ledge. Total depth of soft ground, 70 ft; average progress, including building of caisson and construction of temporary seal, about 7 in per day. Skin friction, somewhat less than 700 lb per sq ft.

III. Colorado River siphon, Arizona (17). Shaft 30 ft outside diam. Walls 3.5 ft thick, except for 10 ft above cutting edge (Fig 11a). Shoe was assembled on bottom of a pit 10 ft deep, and concrete walls were carried up 10 ft before sinking began. Excavation by hand to depth of 73 ft, making 62 ft sunk and about same height of walls built in 71 days. Pumps were used for lower 45 ft. When inflow amounted to about 1 000 gal per min, inrushes of ground under shoe prevented further progress; the caisson was then flooded and dredged with a 1/2-cu yd

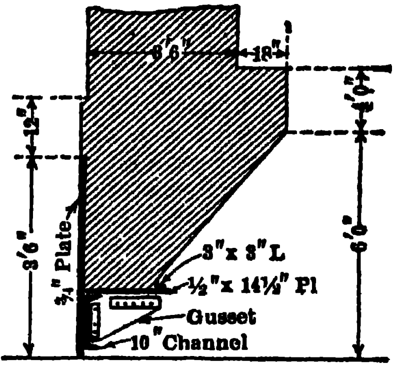

Fig 11a. Cutting Edge of Shoe, Colorado River Caisson (Rivets on outside countersunk)

clam-shell bucket. Ground was quite firm, and after caisson had sunk 5 ft farther it stuck, although all material that dredge could reach was dug out to depth of 10 ft below shoe. Advance of 11 ft was made by lowering water level inside caisson, and a further advance of 2 ft by exploding dynamite charges in pipes jetted down on outside to depth of 5 ft below shoe. 16 ft more were gained by blasting underneath shoe, with dynamite placed by divers. Caisson then stuck fast, being held by skin friction of over 400 lb per sq ft. The 34 ft done by dredging to this point took 50 days. Successful attempt to relieve skin friction by water jetting around the outside was now made; by which, and with use of dynamite, the caisson was sunk to final depth of 139 ft, a further penetration of 32 ft in 38 days. From completion of first 10 ft of wall above the shoe, 128 ft of caisson was built and sunk in 160 days. Max skin friction about 460 lb per sq ft even when caisson was flooded.

IV. Two shafts for Norwood-White Coal Co, near Des Moines, Iowa (1921), both 8 by 12 ft, sunk through 110 ft quicksand. Premoulded reinforced concrete sections 12 ft high, with simple cutting edge on bottom sec, were placed as excavation by clam-shell proceeded. Good joint secured by cutting edge settling in impervious material over rock. Main shaft was nearly water-tight and only 8 in out of plumb. Air shaft in poorer alinement and more leaky. Life of mine being estimated at 10 yr, expensive shafts not warranted (20).

4. PNEUMATIC METHOD

This is generally used in connection with the drop-shaft method where there is danger of an inflow of soft ground; when there are many boulders below water-level; or when making the seal between shaft lining and rock proves difficult. The procedure is exactly the same as described in Art 3, except that provision is made in the shaft for an air-tight deck, to be put in if the pneumatic method becomes advisable. The space below this deck is filled with compressed air, to drive out the water from the interstices of the ground, so that men can work in the shaft bottom.

Special equipment. The deck is of timber or reinforced concrete, designed to withstand the maximum air pressure that may be required, or to sustain the weight placed upon it for sinking. Edges of the deck project into a notch in the shaft walls. It is usually necessary to pump down the water before installing the deck, which is preferably placed 7 or 8 ft above the cutting edge. It may be advisable to provide an upper notch in the shaft walls, in which the deck can be set if the lower notch is under water.

Access to the working chamber below the deck is through a cylindrical steel shaft, bolted to the deck and extending vertically to a point above ground water-level. This shaft is usually 36 to 60 in diam and $^3/_8$ in or more in thickness, as may be required to withstand the air pressure. It is made in sections 10 to 15 ft long, bolted together with rubber gaskets at the joints. The shaft is equipped with ladder rungs.

To prevent escape of compressed air through the shaft an air-lock is mounted on the top. This is essentially a chamber with two doors and means whereby compressed air can be admitted to or discharged from it. When the lower door is closed and the upper door open, men or a bucket can enter the lock. The upper door is then closed and compressed air is admitted until the pressure within the lock equals that in the working chamber. On opening the lower door, the men go down the ladder to the working chamber, or the bucket is lowered. To leave the working chamber, the operation is reversed. Several types of air-lock have been devised, but at present those generally used are the Mattsen lock and the Moran lock (Fig 12, 13).

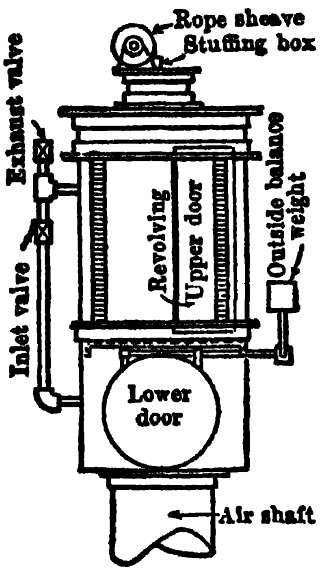

Fig 12. Mattsen Lock

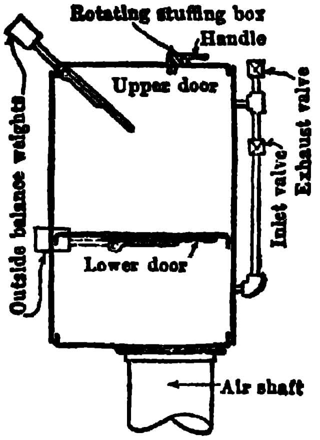

Fig 13. Moran Lock

The upper door of the Mattsen lock is in the side, opening and closing by rotating about the axis of the lock. The rope by which the bucket is hoisted runs through a stuffing-box in the top. The bucket can not, therefore, be hoisted through the top, but must be dumped through the side door; or the hoisting rope may be detached and another hooked to the bucket. The upper door of the Moran lock is in the top, and is in two sections which close around the hoisting rope; or, in another form, there is a single door closing around a slot provided with a stuffing-box, which is vertically above the center of the lower door. When a bucket is lowered into the lock it is swung over until the hoisting rope enters the stuffing-box, and the door is closed. The air in the lock having been equalised, the lower door is opened and the bucket lowered into the working chamber. Usually, only one shaft and air-lock are required; men, buckets and materials passing through the same lock. Air-locks should be placed above the level of the ground-water, so that in case of a sudden loss of air pressure and the flooding of the working chamber, the workmen can escape into the lock.

Excavated materials are shoveled into buckets and hoisted from the working chamber by a derrick and double-drum hoist at the surface. Buckets are 24 to 33 in diam and 33 to 46 in high, depending on the shaft diam and size of the lock. To facilitate dumping, they have a steel bail at the top and a ring on the bottom.

When the excavated material is granular, or is soft clay, and the air pressure is sufficient, the spoil can be discharged from the working chamber to the surface by a blow-pipe. This is a 4-in pipe running vertically from a point above the surface, through the deck and into a water-filled pit in the bottom of the working chamber. A quick-acting valve is placed in the pipe just below the deck. The excavated material is piled around the bottom of the pipe, the valve is opened for a short interval, and the air pressure forces the spoil up and out of the upper end of the pipe. The stream of spoil issuing from the blowpipe is deflected by an elbow, the back of which is of chilled cast-iron to resist wear and is renewable.

Compressed air is supplied to the working chamber by a low-pressure compressor, with a standby in case of breakdown. The piping, 3 to 4-in diam, should be in duplicate. For drilling, a high-pressure compressor may also be necessary. Smaller pipes are provided for electric light wires and a signal whistle. The principal features of a drop-shaft equipped for the pneumatic method are shown in Fig 14.

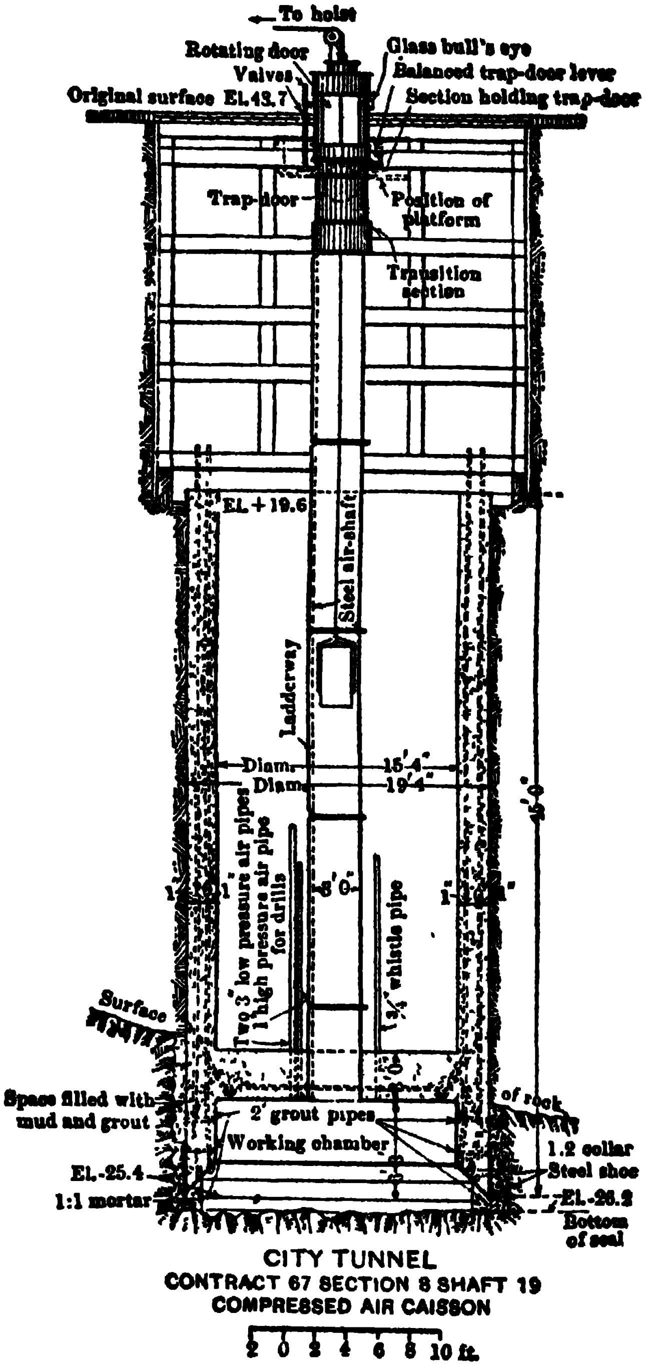

Fig 14. Drop-shaft equipped for Pneumatic Method

Weighting. To cause the shaft to sink, by overcoming the uplift of the compressed air plus the external friction, the walls must usually be heavier than those of an ordinary drop-shaft, or weight is added on top of the shaft, or on the deck. But, the escape of the compressed air under the cutting edge and up the outside of the shaft may materially reduce the exterior friction. In ground other than soft clay or quicksand, the shaft may sometimes be started by suddenly reducing air pressure in the working chamber (the men having left it).

Air supply. The air pressure may be greater or less than corresponds to the depth below ground-water level. A thick bed of clay may cut off water and so reduce the pressure; or the water may lie below such a stratum, artesian in character and under heavy pressure. Greater depths than would otherwise be attainable can be reached in gravel, boulders or loose rock, by maintaining a lower pressure than is required and blowing out through blowpipes the water entering the working chamber. Or the water level may be lowered by pumping through holes in the shaft walls above the deck. The supply of air for ventilation (30 cu ft per man per min) is usually less than is necessary to replace air escaping under the cutting edge.

Physiological effect. Men can usually work in compressed air, up to a pressure of 18 lb per sq in (equivalent to 41.6 ft below ground-water level), with little inconvenience. At higher pressures, the working time in each 24 hr must be reduced, and time spent in passing from the compressed air to the normal air must be increased. The maximum pressure in which men can work is about 50 lb (equivalent to 115.5 ft below water level). All men who are to work in compressed air should be examined and qualified by a physician (see Caisson Disease, Sec 15).

Table 1. Requirements of New York Law for Caisson Work

Pressure, lb per sq in above, normal	Shifts and rest intervals			Decompression	
	Total hr worked per 24 hr	Max length of shift; 2 per 24 hr	Min time in open air, hr	Pressure, lb per sq in	Min rate, lb per min

48–50	1	1/2	6	....	......

Sealing to rock by the pneumatic method is similar to that for ordinary drop-shafts, except that the men in the working chamber have direct access to the work, which therefore can be done in a more positive manner. The problem is to stop the inflow of water, while still preventing the escape of compressed air below the cutting edge into the surrounding ground. This may be done by plastering with moist clay, or by a strip of waterproofed canvas, but grouting, with cement or chemicals is often necessary.

Fig 15 shows the procedure in sealing a number of shafts sunk in connection with the NY City tunnel, of the Catskill aqueduct. The ledge rock was leveled, the shaft walls supported on posts, and excavation carried 3 ft into the rock, one ft larger in diam than the shaft shoe. The rock walls were lined with a 1 to 2 mortar wall, with a 3/4-in clearance outside the shoe. Grout pipes imbedded in this lining were sunk into the rock. A thick layer of oakum was placed under the cutting edge of the shoe, and the posts supporting the drop-shaft were shot out, thus allowing the shoe to drop on the oakum. Grout was then injected into the rock through the pipes imbedded in the shaft walls.

Wages of compressed-air workers. At the present time (1937), union wages of compressed-air workers in N Y City and vicinty are $12 per day for pressures up to 18 lb per square inch above normal. For each increase in pressure (approximately as in Table 1) the rate is increased by 50 cts to a maximum of $15. For placing concrete in the working chamber, 50 cts are added to the rate paid at the working pressure. Gang foremen receive $1 additional. Double time is paid for work on Saturdays, Sundays and holidays. In other parts of the U S, particularly in the South and Middle West, rates are considerably lower.

Costs of shafts sunk by the pneumatic method vary greatly with their diam, character of ground and depth sunk under compressed air. To the ordinary cost of the drop-shaft method must be added cost of assembling, installing, repairing and dismantling the sinking equipment (air compressors, air coolers and receivers, boilers or electrical connections and the special equipment already described); fuel or electric power; maintenance of compressed-air supply; experienced supervision; dressing and bathing facilities for the compressed-air workers; and the greatly increased cost of excavation done under compressed air. A shaft 14 ft square inside and 125 ft or more in depth, sunk in part and sealed by this method, may cost, including contractor's profit, $550 to $600 per vertical ft, or more, depending upon character of the ground.

Advantages. Notwithstanding its higher cost, the pneumatic method, within the limit of depth for which it can be used, is the most reliable. The men have direct access to the work: boulders can be blasted and the excavation made without danger of influx of the surrounding ground, or displacement of the shaft. Even if a drop-shaft becomes locked in the ground by boulders and refuses to sink farther, a new shoe can be assembled below the first one and jacked down, using the weight of the shaft walls as a reaction. Walls can be built on the new shoe as it moves downward. For these reasons all drop-

shafts should be provided with notches in the walls, at one or more levels, so that, if necessary, a deck can be put in and the pneumatic method used.

I. Shaft 19, N Y aqueduct (Fig 14). For structural reasons not related to sinking, both vertical and horizontal reinforcement of concrete was made unusually heavy. The wall thickness of 2 ft, for a required inside diam of 15 ft 4 in, was at least 1 ft less than ordinarily required for a caisson of same depth. The deck was a 3-ft slab of reinforced concrete, cast integral with caisson walls, and was cut out after seal was made. Except for the concrete deck, the design was typical: a 36-in circular opening was provided in deck and a vertical line of 36-in flanged steel pipe (air shaft) was led from opening to top of caisson, where air lock was attached. Opening was formed by casting bottom length of air shaft into the deck; (where deck is of wood or iron, the lower flange of air shaft is bolted to it). Air shaft was long enough to keep lock always above ground-water level, so that, in case of accident to lock or to air-compressing plant, the caisson men would not be trapped by rising water. Air shaft had ladder rungs so arranged as not to interfere with operation of bucket.

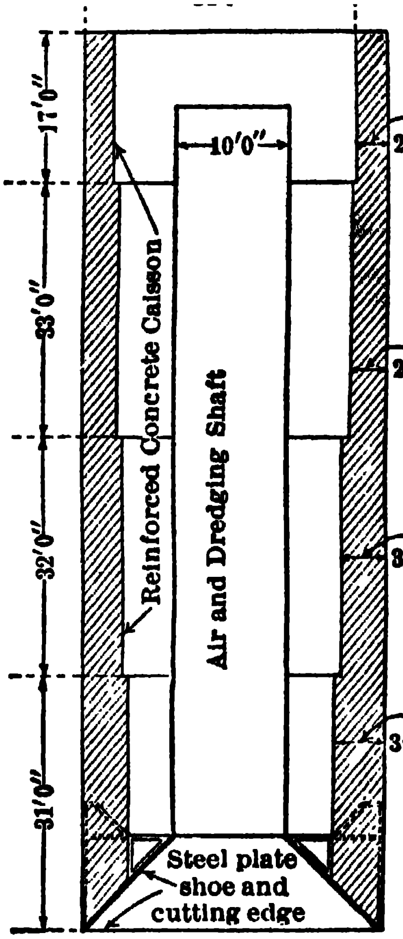

Fig 16. Caisson for Kidder Shaft, Cleveland-Cliffs Iron Co

Besides the air shaft, one or two 3-in inlet air pipes, fitted at bottom with check valves, a 0.75-in whistle (signal) pipe, a high-pressure air pipe, a conduit for electric wires, and sometimes a 4- or 6-in discharge or "blow" pipe, are led through deck. In deeper caissons, 2 air shafts were provided, fitted respectively with a material lock and a man lock.

II. Kidder shaft, Cleveland-Cliffs Iron Co, Mich. Caisson was 24 ft outside diam (Fig 16). Air shaft, 10 ft diam, was used first as a dredging shaft for a clam-shell bucket, which excavated to a depth of 87 ft. As it then became necessary to use compressed air, a deck and air lock were bolted to the top. Ledge rock was reached at 104 ft. Shoe was sealed to rock at 113 ft. Average progress, 0.72 ft per day elapsed time.

III. Two colliery shafts, near Terre Haute, Ind, 16 and 20 ft inside diam, were sunk in 1923 by pneumatic caissons, through 140 ft of sand and gravel, 111 ft of which were water-bearing. Caissons and working chamber roofs were of concrete. Air press reached 51 lb per sq in. One caisson landed on a coal stratum and then penetrated fireclay before reaching rock. Lubricating pipes were used. Shafts were near Wabash River and water conditions were probably affected by this proximity. Some difficulty in controlling the sinking of the caissons.

Table 2. Details of Sinking 5 Reinforced Concrete Caissons, Catskill Aqueduct

	Shaft 19	Shaft 20	Shaft 22	Shaft 23	Shaft 24
Outside diameter, ft	19 1/3	19 1/3	19 1/3	24	24
Inside diameter, ft	15 1/3	15 1/3	15 1/3	18	18
Total height, ft	45	105.3	100	123	105.6
Number of locks	1	2	2	2	2
Concrete proportions, cement: sand: stone	1 1/3 : 2 : 4	1 1/3 : 2 : 4	1 1/3 : 2 : 4 to 1 : 2 : 4	1 1/3 : 2 : 4 to 1 : 2 : 4	1 1/3 : 2 : 4 to 1 : 2 : 4
Depth sunk under compressed air:					
In sand, ft	11	77	50.3	105	59.5
In rock, ft	14.2	33.7	13.7	14	10
Average progress:

Sinking under pressure in sand, ft per hr	0.0275	0.0346	0.0393	0.0591	0.028
Sinking under pressure in rock, ft per hr	0.0035	0.0075	0.0056	0.004	0.0025
Hours constructing seal	64	35	51	51 1/2	51
Average progress, ft per day elapsed time, from placing shoe to completion, to total depth	0.82	1.18	1.25	1.20	1.22
Maximum air pressure, lb per sq in	17	39	28	46	29.5
Weight of caisson, tons	460	1 050	978	2 323	1 780
Weight of caisson, with max load of sand and pig-iron, tons	700	2 100	2 470	4 612	4 046
Frictional resistance, lb per sq ft of outer surface, at various depths of shoe	300 to 400	630	630 at 81 751 at 95	1 411 at 45 1 202 at 86 872 at 116	1 685 at 49 1 101 at 79 945 at 93.5
Contract price per ft for sinking only (concrete and reinforcing steel paid separately)	$466	$471	$456	$735	$614

Note.—All these caissons were weighted with excavated sand piled on top of deck around air shafts. In each case, a pit was excavated and timbered square to depth of about 20 ft. The shoe was set on bottom, and caisson built to its full height before sinking was started. Contract price allowed a fair profit to contractor.

5. FORCED DROP-SHAFTS AND HONIGMANN METHOD (30–35)

Until it becomes necessary to reach the more deeply buried orebodies, American practice can furnish no such examples of deep shaft sinking in soft soils, by freezing, cementation and forced drop-shafts, as are common in Europe. There, exhaustion of the easily accessible deposits has compelled high development of the art, intensive study of methods and large expenditure of money. Hence, for detailed information, it is necessary to consult the large volume of European technical literature on this subject.

General description. To penetrate depths of quicksand and other unstable, water-bearing material, beyond the limit of open or pneumatic caissons, a method has been developed in Germany of jacking down a telescopic series of iron drums, inside of and reacting against a previously installed concrete curbing. The latter is strong and heavy, and built into it, near the top, is an internal cast-iron flange, the REACTION RING. This, anchored by vertical rods extending to the shoe, resists thrust of the jacks, which are attached to and bear against under side of ring. The caisson is sunk by dredging in the open to a depth of 50 or 60 ft; then a concrete floor (SEAL) is placed in the bottom (under water if necessary), and shaft is unwatered. A cast-steel shoe, with an outside diam slightly less than inside diam of curbing, is set on the concrete floor, and a cylindrical drum, of flanged and bolted cast-iron segments (similar to shaft tubbing, Sec 7) is built up from shoe to under side of the jacks. The concrete seal is then broken, thus admitting water to natural level, and the drum is jacked down, the material being excavated under water by grab bucket, " mammoth " pump, or sack borer (described below). Finally, the jacks are removed and more segments of lining added as required. With hydraulic jacks, a drum 20 ft outside diam can usually be forced down 250 to 300 ft before it sticks. If rock lies still deeper, the bottom is again sealed, the shaft is unwatered, a second drum of smaller diam is built inside the first, the jacks are shifted inward to bear upon it, and sinking is resumed. Frequently a second drum has been necessary; less often, a third (3).

Details of construction of curbs, drums and sinking plant are shown in Fig 17 and 18. A head-frame handles the machinery, which includes: trepans, similar to those used in the Kind-Chaudron boring method for rock (Sec 7), for breaking up the concrete floor and any boulders or partly cemented ground that may be met; the curbing, with reaction ring and hydraulic jacks; and sinking drums. The outer drum (Fig 17) is the patented Pattberg compound, the cast-iron shell of which is lined with 22 in of strong brick or concrete, for additional weight and stiffness; the second is a simple iron-segment drum. The compound drum is made necessary by the great earth press at depths of 300 or 400 ft, a number of shafts having been lost by collapse of unsupported iron drums, notwithstanding use of segments 3.5 in thick. The segments are about 5 ft high, flanged and bolted on both horiz and vert joints, and 8 to 10 of them make up a ring. The shoe must be very strong and heavy, and anchor and reaction rings and all bolts must be designed to carry safely the full thrust of the jacks. For considerable depths, the grab bucket used in ordinary caissons has been superseded by the mammoth pump in firmer, and the sack-borer in softer, soils.

Mammoth pump (Fig 17) is essentially an air-lift pump (Sec 15). Inside the hollow stem of the trepan is a small pipe carrying compressed air to a point near bottom of the cutting tool and releasing it into the stem. The air lightens the column of water in the stem, and discharges it at the surface, carrying with it the material pulverized by the borer.

Sack-borer (Fig 18) is a large auger-like tool, with its stem in center of shaft. The stem is composed of a series of lengths of heavy flanged pipe, terminated at upper end by a splined section, on which is mounted a large horizontal gear-wheel. A wire rope, from hoisting engine drum to swivel link at top of stem, suspends the sack-borer. The stem is rotated through the gear-wheel by another engine, and is lowered gradually by hoisting rope. New sections of borer stem are added as shaft is deepened. Cross arms are attached to the stem at intervals, having rollers at their ends which bear against sides of shaft and keep stem in line. Material cut by the rotating borer is swept into two heavy, open-mouthed canvas sacks, fastened to backs of cutters. From time to time the borer is raised and emptied. In an improved form, the sacks are mounted on a frame sliding on guides attached to cross arms on stem, and are hoisted by an independent engine. The sack-borer is best adapted to clay and sand.

I. Shaft 5, Rheinpreussen colliery, Homburg am Rhein, Germany, was started in 1901 with a brick caisson 29.2 ft inside diam, walls about 3.5 ft thick. This reached a depth of 65 ft. Concrete plug, 9 ft thick, was then placed on the bottom, under water, the shaft was pumped out, the anchor ring, rods and reaction ring (designed for a pressure of 3 000 tons) were erected, and an inner truly vertical, brick lining was built, reducing inside diam to 25.68 ft. A compound sinking drum with outer and inner diam of 25.52 and 21.32 ft respectively was then constructed, and sinking was begun with a percussion borer and mammoth pump. The concrete was bored through in 4 days, and thereafter the average progress was about 5 ft per day. The compound drum stuck at 245 ft, and shaft was filled for 60 ft with sand and gravel (instead of concrete). Shaft was next pumped out and an iron drum, 3.5 in thick and 19.35 ft inside diam, was built up to the jacks. This drum stuck at 315 ft; the shaft was again partly filled and pumped out, and another drum, 17.38 ft inside diam was forced to a depth of 343 ft, where the shoe entered clay firm enough to permit shaft to be pumped out. A fourth drum, 15.3 ft inside diam, was finally forced to the coal measures, at a depth of 508 ft. The sinking took 3 years, the average progress being about 6 in per day (3).

II. Sterkrade shaft, near Holten, Germany, was started with a brick caisson 24.6 ft inside diam, which was sunk to a depth of 59 ft. The excavation was continued by hand to 131 ft, where an iron sinking drum, 22 ft inside diam, was constructed. This drum was forced to 264 ft; a second drum, 19.3 ft diam, to 433 ft; and a third, 16.75 ft diam, to 448 ft. Here the water was found to be successfully shut out, and sinking was continued by hand (3). For cost, see Table 3.

Average cost per ft of sinking-drum method in Germany, at various depths, is given by Henry Louis (1) as follows: 82 to 164 ft $260; 164 to 328 ft $593; 328 to 492 ft $817; 492 to 656 ft $1 040.

Sassenberg process of hydraulic flushing reduces skin friction and adhesion in some soils. Shoe and 4 lining rings above it are about 1.5 in larger outside diam than the rest of the lining, and in the shoulder thus formed are water passages, connected through pipes to a high-press pump. By operating this pump during sinking, the drum is partially surrounded by a film of water.

The forced-drop-shaft has been used in sinking a number of shafts. At present, however, it has been replaced by the Honigmann method, or by freezing, or cementation.

Honigmann method (35). The essential difference between this and a forced drop-shaft is that the lining is installed after the excavation is completed, instead of closely following the cutting tool. The advantage of this is that the cast-iron tubbing can be assembled and bolted together above the surface, before it begins to sink. Access for calking the outside of the joints can therefore be had, and the cost of assembling and placing the lining is reduced.

Honigmann observed that the walls of a boring in sand fell in, even when the hole is filled with water to a level above that of the ground-water, but if the walls were coated with clay they remained

Cost per ft		807

standing. The theory is that the increased head of water in the boring, over that in the ground, causes a pressure against each grain of sand in the walls. As the water flows between and around the grains, the pressure is equalized, with no force to resist the force of gravity which caused the sand to fall. But, if the walls of the hole are coated with clay, no water can enter between and behind the sand grains in the walls, and there is therefore a pressure against the inside face of each grain to keep it in place. This idea he applied to large borings like shafts.

The boring tool of the Honigmann method (Fig 17) is an inverted cone, with the apex at the center of the excavation, provided with steel knives which cut the ground as the tool is rotated. The hollow stem is extended through the tool to the bottom of the conical pit thus made. Compressed air is carried down through a small pipe in the stem and discharged just above the bottom. The stem thus becomes a mammoth pump (Fig 17), which discharges at the surface the material loosened by the borer. The shaft is filled with an emulsion of clay to a level considerably above that of the ground-water, to provide support for the excavation walls. At the surface the spoil deposits from the discharged water by sedimentation, the water being returned to the shaft with an additional admixture of clay if necessary. To coat the sides of the shaft properly, the percentage of clay in the water varies with the character of the ground. In clayey soil, 15% is considered sufficient; in sand, 20% and in gravel, 35%.

The shaft excavation is never made to its full diam in the first cut. It is begun with a diameter of 6.5 to 8 ft and completed to the bottom. The diam is then increased by one or more successive cuts, with larger tools mounted on the stem. Between the tools, the stem carries a cylindrical guide fitting closely to the walls of the first cut, which must be true and plumb; otherwise, the installation of the sinking lining would be difficult.

The first ring of the tubbing or lining, which has a cutting edge on the bottom, is assembled over the mouth of the shaft. It is laid out in a true circle, leveled with its axis coinciding with the shaft axis, and hung by threaded rods to the tower over the shaft. This ring is bolted up with lead gaskets in the vertical joints. The second ring is assembled and similarly bolted to the first. The gaskets are then calked from the outside and a false bottom of concrete is placed in the bottom of the assembled rings. By means of the threaded rods the two rings are lowered in the shaft and additional rings are added and calked. Because of the false bottom, the assembled rings will eventually float in the water, and, to continue sinking, water must be run into the cylinder. When the lower edge of the tubbing reaches a point about 3 ft above the shaft bottom, the space under the false bottom and around the outside of the lower rings is filled by a tremie with cement grout between the lining and shaft-walls. The lining is then lowered into the grout, and when it has set, the grouting behind the lining is continued to the top of the shaft. The false bottom is then cut out by jackhammers, after borings through it have tested the watertightness of the grouting.

This method is simple and ingenious in all its details. It requires little material and equipment and few men, and is much less costly than the freezing method hereinafter described. It is best suited to soft ground, but strata of cemented sand and gravel, sandstone or limestone can be passed if not too thick. A great advantage is the security afforded the workmen, in not being exposed to accident during sinking and lining the shaft. The method can not be used, however, if a subterranean water course or absorbent stratum is encountered, which might carry away the water in the shaft. This situation developed while a shaft, 17 ft net diam, was being sunk for the Dutch Govt; after reaching a great depth, the work had to be abandoned. Another disadvantage is that the excavation may get out of line, if inclined hard strata are encountered. Trouble may also arise because of the swelling of the walls of the excavation and sticking of the lining during its descent. To obviate this the bottom of the lining is furnished with a conical piece which is removed after the false bottom is cut out.

The Honigmann method has been used successfully for a shaft 19.7 ft net diam, excavated to a diam of 24 ft and sunk to a depth of 1 385 ft. The Dutch company (La Société Mijnbouw) holding the rights states the cost and rate of progress as follows (39):

Depths, meters	Cost per meter	Monthly progress
to 100	15 000–25 000 francs	15–20 meters
100–200	25 000–37 000 "	10–12 "
200–350	37 000–52 000 "	9–11 "
350–500	52 000–75 000 "	8–10 "

The above costs apply to 1933, or early 1934, when the franc was worth 6 1/4 to 6 1/2 cents, U S currency. Furthermore, these costs are much lower than would be possible in the U S.

6. FREEZING METHOD (3, 6, 7, 8, 14, 18, 22, 24)

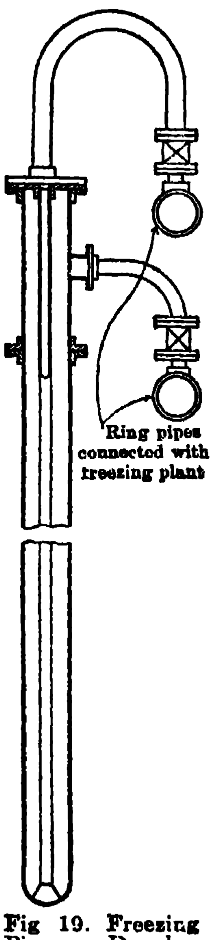

Fig 19. Freezing Pipes, Dawdon Colliery, England

General principles. This method was invented by F. H. Poetsch in 1883 and introduced into this country by Charles Soöysmith. Its essential feature is the solidifying, by freezing, of water-bearing ground in which the shaft is sunk. The freezing is sometimes continued into water-bearing rock. The method has been much used in recent years in England and on the Continent, for shafts 200 to more than 2 000 ft deep. Vertical holes, 2 to 4 ft apart, are first bored on the circumference of a circle outside the periphery of the proposed shaft. Into each hole are lowered pairs of concentric pipes, through which brine, cooled to low temperature, is circulated. The brine passes down through the inner pipes and up through the space between the two, the outer pipe being closed at the bottom. This method has been used even when the ground-water is saline and in circulation. It is, therefore, so widely applicable in all kinds of soft ground and fissured rock, and its details have been so well worked out, that for very deep shafts, it has largely replaced all other methods.

Freezing pipes. The holes for these are bored by the usual methods and, in soft ground, are cased (Sec 9). They must be vertical, or nearly so; otherwise the distances between them, at the bottom, may be too great to permit the formation of a complete ice wall. In very deep shafts, due to the difficulty of keeping the borings vertical and properly spaced, the freezing is sometimes done in stages, each 200 to 300 ft deep. Each section of shaft is then excavated and lined before freezing the succeeding section. In this case, the holes for the freezing pipes are driven outward, at a slight vertical angle, from the bottom of the preceding section. In the most recent practice, however, the holes are bored continuously from the surface to the bottom of the proposed shaft; their direction being checked at frequent intervals and, in case of deviation, is corrected, or in case of great deviation, additional borings are made. The usual form of freezing pipes is shown in Fig 19. The outside pipe, 4 to 6 in diam, closed at the bottom, is lowered into the casing and tested hydraulically. The casing is then withdrawn so that the ground may close around the freezing pipe. The inner pipe, one in or more in diam, is lowered into the outer pipe. Both pipes are connected at the top to header pipes, to and from which the brine is pumped from the central freezing plant.

Additional borings should be made, one at center of the proposed shaft and others inside and outside of the circle of the freezing pipes. These are used to take the ground temperatures at different levels, for checking the formation and maintenance of the ice wall. As saline solutions freeze at lower temperatures than pure water a leak in the piping may cause a weak spot, or a hole, in the ice wall, making necessary a longer period of freezing.

Ice wall, in its several phases of formation, is shown by Fig 20. It must be thick enough to withstand the pressure to which it will be subjected, and the freezing pipes are located accordingly. Frozen sand is stronger than clear ice. Abby's experiments show that frozen saturated sand crushes at about 2 500 lb per sq in at a temperature of −25° C, and at about 1 700 lb at −12° C. It should therefore carry safely 300 lb per sq in and assuming full hydrostatic pressure on the outside of the ice cylinder, the thickness of the wall, for a shaft 300 ft deep and 20 ft diam should be about 7.5 ft.

Freezing plant. Ammonia, compressed and expanded, is generally used as the refrigerating medium. Carbonic acid is occasionally used because lower temperatures are obtainable. The brine, chilled by expansion of the ammonia and circulated through the freezing pipes, is commonly $CaCl_2$, but $MgCl_2$ is recommended, as it has less tendency to precipitate at low temperatures and clog the piping. The capacity of the freezing plant depends upon the diam and depth of shaft, thickness of the required ice wall, and the time allotted to the freezing of the ground.

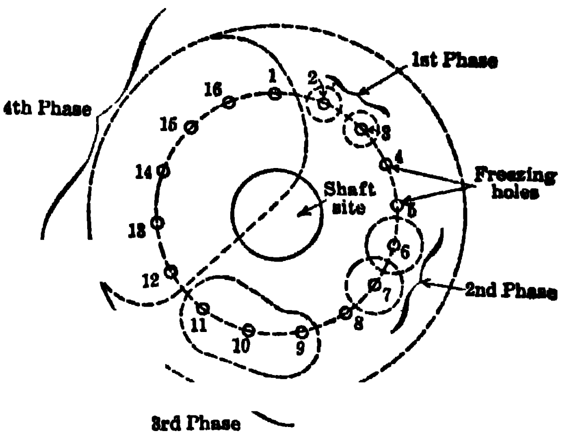

Fig 20. Formation of Ice Wall

Sinking, after the ground is frozen, is done by drilling and blasting with light charges, but, to avoid cracking the ice wall, pneumatic hammers are often preferable.

Lining. Shafts of 200–300 ft, or even more, may be lined with concrete, but care must be exercised because of the effect of the frozen ground upon the concrete. Shafts of great depth are usually lined with cast-iron rings (tubbing), bolted with lead gaskets and backed with concrete.

Thawing. After completing sinking and lining, the ground is thawed by filling the shaft with water, or by gradually raising the temperature of the circulating brine and continuing circulation for a long period, or by the aeration of the shaft. During this time, in deep shafts, the lining requires continual tightening and calking.

Average speed of sinking, considering the process as a whole, depends largely upon the boring, and is quite variable. If holes prove to be nearly plumb, both boring and freezing are expedited; but, if some of the holes deflect badly near the bottom, new holes must be bored, and the irregular spacing of the pipes makes necessary a longer freezing period.

Table 4. Speed of Sinking by Freezing

Shaft	Location	Depth sunk by freezing, ft	Time, months			Average progress, ft per month
			Boring	Freezing only	Sinking and lining	
Anhalt government salt mine, No 6	Germany	310	17	5.5	7	10.5
Marie mine......................	"	180	6.5	5.5	4.5	10.9
Consolidated Sophie lignite mine...	"	262	6	2.5	6	18.1
Castlereagh shaft....	England	259	10.5	6	12	9.1
Theresa shaft............	"	113	10	13	6	3.9

I. **Shaft 6, Anhalt government salt mine,** Leopoldshall, Stassfurt, Germany. Twenty-six 5-in holes were bored in a circle, 26.25 ft diam and cased to depth of 325 ft. The boring was difficult, and, as shown in Table 4, consumed 17 months. Freezing was continued for 3 months before sinking was begun. After only 30 ft had been sunk, a small leak broke through in shaft bottom, and flooded shaft. Sinking was stopped and freezing continued for 2.5 months more, after which a progress of over 60 ft per month was maintained to a depth of 202 ft. The shaft was lined with iron tubbing (Sec 7), the space behind being filled with concrete mixed with water containing calcined soda. Sinking and lining were prosecuted alternately until the tubbing was sealed to rock at 325 ft. Aside from difficulty of boring the holes, this sinking was entirely successful (3).

II. **Theresa and Castlereagh shafts,** Dawdon, County Durham, England, were first sunk (with pumping) through very wet rock to depths of 350 and 204 ft respectively. It was then decided to continue them by freezing through underlying sand to the coal measures at a depth of 463 ft. Thirty-eight holes were bored around each shaft, including two extras at each, on 30-ft circles, 7 well drills being used. The holes were 8 and 10 in diam, lined with 6.25-in casings. The freezing plant comprised two 135-h p steam engines, driving 4 ammonia compressors. As shown by Table 4, the freezing of Theresa shaft was especially slow, 13 months elapsing before sinking could be begun. Both shafts were successfully sealed to rock in 2.5 years (19).

III. **Chapin shaft, Iron Mountain, Mich** (7) was sunk in 1888–9, through 95 ft sand, gravel and boulders, with water level 10 ft below surface. Twenty-six 10-in casing pipes were put down in a 20-ft circle; inside of these were 8-in freezing pipes, inclosing 1.5-in circulating tubes. Casings were then withdrawn. Ice machine was a Linde (ammonia type) of 50 tons daily refrigerating capacity (1 ton equals cooling effect of 1 ton melting ice). Freezing fluid was saturated solution of commercial $CaCl_2$; velocity of flow in the 1.5-in pipes, 2 ft per sec. In about 21 days after starting ice machine, the frozen ring was complete and excavation was begun. Rock was reached in 135 days (including a 30-day stoppage, when shaft was allowed to fill with water). There was some trouble and delay from leakages through ice wall, the elapsed time being about 200 days.

IV. In Campine district, North Belgium, so great an advance has been made in developing the freezing process for shafts 1 500 to 2 000 ft deep to the recently discovered coal measures, that previous applications of the process do not maintain their former importance as examples to be studied. Sinking in stages by freezing has in some of these shafts alternated with cementation. Some of the most notable work is the sinking of 2 shafts for the Helchteren and Zolder project, where 2 034 ft of ground were frozen by a single current of refrigerating fluid in 7 months' time. Sinking and lining took 21.5 months; cost, aside from fuel and tubbing, $1 177 per ft (22).

H. Muller gives (1917) estimates of cost, under two different assumptions, for a shaft sunk 300 ft by freezing in stages, at $1 100 and $1 600 per ft, respectively (29).

V. Two shafts, sunk by freezing for the Houthaelen Coal Mines (42) in the Campine district were completed in 1932 and 1934. Cementation was first tried and abandoned. Shaft I was sunk to 2 106.3 ft; shaft II, about 230 ft from shaft I, to 2 139.1 ft. Both passed through 1 968.4 ft of water-bearing ground to a much fissured stratum of sandstone about 33 ft thick, overlying the coal. The soft ground above the sandstone was as follows:

Tertiary deposits		Secondary deposits	
sand	426.5 ft	tufa	203.4 ft
clay	232.9 "	chalk	147.6 "
sand	183.7 "	marl	380.6 "
clay and marl	298.6 "	sand	78.7 "
sand	16.4 "		810.3 ft
	1 158.1 ft		

In each case a preliminary pit was sunk, 42.7 ft diam and 15.6 ft deep.

The borings for the freezing pipes, begun Sep 5, 1927, for shaft I and Nov 20, 1927, for shaft II, were spaced about 3.5 ft c–c, on the circumference of a circle 36.1 ft diam. The borings were 2 066.9 ft deep for shaft I and 2 093.2 ft for shaft II, continuous from surface to full depth. The plumbness of the borings was checked by the Denis-Foraky teleclinograph and in case of deviation the direction was corrected (Sec 9). The theoretical number of freezing pipes for each shaft was 32, but 5 additional borings were required for shaft I and 4 for shaft II. The borings were cased to 1 148 ft, below which no casing was installed. The freezing pipes were lowered into the borings and their headers, in the bottom of the preliminary pits, were connected with the freezing plant.

Net diam of each shaft was 16.4 ft. The cast-iron tubbing lining was 19.4 ft outside diam; behind it was placed 1.3 ft of concrete, so that the diam of the excavation was 22 ft. At center of each shaft an additional boring was made, in which were placed concentric pipes for drawing off water at 4 levels, viz: at bottom of the preliminary pit, at bottom of the clay (656 ft below surface), at top of the tufa (1 158 ft depth), and in the marl at 1 739 ft. These pipes were to draw off excess water after the closing of the ice-wall. The amount of the water was 24 525 gal in shaft I and 41 889 gal in shaft II. For test purposes additional borings were made from the bottom of the preliminary pits. These were on the circumference of circles, around the center of each shaft, with diameters of 21.3, 32.8, 36.1 and 41 ft. The total length of casing for borings was 132 961 ft; of outer freezing pipes, 152 334 ft; and of inside freezing pipes, 147 711 ft.

The freezing plant was in six units (total, 2 891 h p), each unit of a capacity equivalent to 100 tons of ice per day, melted from and at 32° F. The elec power for the sinking operations was 1 285 h p, supplied from an outside source. A standby Diesel unit of 800 h p was installed. Ammonia was used at a pressure of 15.4–26. 4 lb, reduced to 1.1–2.2 lb at the condensers. Chloride of calcium, at 27°–15° Baumé, with point of freezing at about −16.6° F, was used as the circulating brine.

The ground was frozen to 2 050.5 ft for shaft I and 2 091.5 ft for shaft II. Freezing for shaft I began June 13, 1930 and to Dec 6, 1930, when excavation was begun, 19 842 500 000 btu had been used for refrigeration; equivalent to 68 898 tons of ice melted from and at 32° F. At a depth of 2 106.3 ft (Dec 15, 1932), 45 637 750 000 btu had been used, equivalent to 158 464 tons of ice melted from and to 32° F. For shaft II freezing began Jan 29, 1931, and when excavation was begun (July 6, 1931) 17 858 250 000 btu had been used, equivalent to 62 008 tons of ice melted. At depth of 2 139-ft (Jan 9, 1934) 67 464 500 000 btu had been used, equivalent to 234 252 tons of ice melted. The flow of brine through each freezing pipe was 282.4 cu ft per hr, at velocity of 3.67 ft per sec in the descent and 0.98 ft per sec in the riser pipe.

The performance of the freezing plant and the formation and maintenance of the ice-wall was, at all times, under strict surveillance. Temperatures of the ammonia throughout its circuit were taken every 3 hr; also the temperatures at the start and return of the brine, and the pressure and discharge of the pumps. A weekly check of the discharge from each freezing pipe was made.

Meters installed at the central station measured the general discharge of the brine and electric indicators warned of any considerable loss. The closing and progress of formation of the ice-wall was checked: (*a*) by temperatures taken at every 328 ft down to the 1 640-ft level, at the center boring of the shaft and in each of the other 4 series of borings made for this purpose; (*b*) by amount of water pumped from each of the 4 levels in the center boring.

Excavation and lining of shaft I begun Dec 6, 1930; completed Dec 15, 1932; aver progress per working day, 3.33 ft. Shaft II, begun July 6, 1931, reached 1 177.8 ft June 3, 1932, when a rupture of the ice-wall occurred, due to breakage of one of the freezing pipes. After repairs, excavation was resumed Jan 12, 1933 and completed Aug 1, 1934. Average progress per working day, 3.6 ft. Nearly all excavation was done by jackhammer; only in sandy tufa and chalk were the ordinary mining methods used. At the bottom of the preliminary pit the non-frozen core was about 20 ft diam; at 328 ft, this core was only 3–7 ft diam and thence to 1 148 ft the ground was frozen to the center, or nearly so. At top of the tufa was found a non-frozen core containing water under pressure. Below, the ground was completely frozen.

These shafts were lined with cast-iron tubbing, the possible pressures upon which were computed as the hydrostatic pressure multiplied by the following coefficients: 1.8 for sand; 1.5 for mixed sand, clay and marl; 1.25 for marl; 1.0 for tufa and chalk. The ultimate compressive strength of cast-iron was taken at 85 000 lb per sq in, for thicknesses of $2^{3}/_{8}$ in or more, and 71 000 lb per sq in for thicknesses of $3^{15}/_{16}$ in, or more. Safety factor of 6.3 was used in soft ground and 5.3 in firm ground, the thickness being determined by the cylinder formula. These computations gave thicknesses of $1^{3}/_{16}$ to $6^{11}/_{16}$ in. The rings were about 5 ft high; bolted with lead gaskets. In upper part of shafts the excavation was made to some depth before starting lining, which was then built up from the bottom. Below this, lining kept pace with excavation. The lining segments were provided with holes for grouting.

On completing excavation and lining, and before thawing was begun, all bolts in the lining were tightened, lead joints were calked and cement grout injected at a pressure equal to half the pressure which each ring might be called upon to support. Thawing was done by progressively warming the brine in the freezing circuit, and by aeration of the shaft interior. Other shafts sunk by this method in the Campine district have been thawed by inundating the shafts, with the idea of keeping the tubbing in balance and avoiding a sudden thaw, but this method stops all work below and prevents observation of the behavior of the lining. As tubbing adjusts itself for some time after it is placed, joints which open must be cared for. After thawing was ended, another calking and tightening of bolts was necessary. Before this, leakage through joints was about 600 gal per hr per 328 ft of depth, but after recalking and tightening the joints, leakage was only about 6.5 gal per hr per 328 ft; practically watertight. Thawing of shaft I was begun Nov 22, 1933 and completed Oct 6, 1934, $7^{2}/_{3}$ years after beginning work. The time for thawing shaft II was not reported. The freezing pipes were removed down to the 1 148-ft level. The holes which were occupied by them were filled with cement grout.

7. CEMENTATION AND GROUTING METHODS (25–28, 43)

The idea of filling fissures and voids, in the ground, with cement is old. By injecting cement in a boring in the Lens mines, M. Reumaux succeeded in 1882 in closing a large flow of water. From 1900 the method has been much used for shaft sinking. In 1904–7, La Compagnie des Mines de Béthune sank 4 shafts by cementation, and later several others at Lens and Liévin were successfully completed. Thereafter, the method spread over France and other countries (39). It is most successful in fissured rock; in quicksand, it is entirely unsuccessful, because the bore-holes can not be kept open except by casing, or by clay coating (Honigmann method, Art 5), both of which prevent cementation. Also in spongy ground such as tufa the cement coats the surface but does not penetrate the pores. Fissured chalk and limestones lend themselves best to this method. In the first applications, 6 to 8 borings, 5.5–6 in diam, were made to full depth around the site of proposed shaft. A mammoth (air-lift) pump was lowered gradually into each bore hole, so that the induced flow of ground-water would wash out the mud from fissures and voids. Then water under pressure was pumped into the holes, to force any remaining mud back into the ground, and cement grout was injected under pressure. In the Saclier method the grout is injected into all holes simultaneously; in the later Portier method injection is made into each boring singly, one at each end of a shaft diameter, then at each end of a diameter perpendicular to the first, and finally at ends of other diameters. Pressure is maintained until the grout has set, otherwise it might be washed out by the flow of ground water.

François method employs 20–24 borings, 1.5–2 in diam, in two concentric circles around the site of the shaft. They are not immediately bored to full depth, but deepened after each injection of cement. The pressure on the grout is 1 500 to 3 000 lb per sq in or even 4 500 lb. The grout is injected into each hole separately. After injection, boring is resumed when the grout has taken its initial set, but is not yet hard. In certain clayey ground chemicals are first injected, to coat the ground particles and facilitate flow of the grout. The theory of the François method is that more bore holes of the larger number used are likely to reach fissured ground, and small diameter holes cost less than larger ones.

Also, injection of grout in a part of the bore hole, instead of its whole length at one time, is more likely to fill the smaller fissures, and great pressures still further increase the chances of success. The chemicals used before grouting are silicate of sodium and sulphate of aluminum, injected separately; the combination of the two forming silicate of aluminum, a white colloidal precipitate. This, under pressure is dehydrated, leaving a solid filling in the capillary fissures which the grout could not enter and covering the clayey walls of larger fissures, thus facilitating entrance of the grout.

Only the Portier and François methods are now used. Both are cheaper than freezing, or the Honigmann method, but are applicable only to cementable ground. Shafts sunk by cementation are lined with reinforced concrete, or with cast-iron tubbing.

Injection of other materials has also been used to shut off water, but only in shallow shafts.

Joosten method uses sodium silicate, injected under pressure and followed by an injection of calcium chloride. These form an insoluble calcium silicate, which sets so quickly that the casing pipes must be pulled as the calcium chloride is injected, to prevent their being immovably set in place. The chemicals penetrate to a distance of about 3 ft around the end of the casing pipes, which are spaced accordingly. This method is especially useful to consolidate the ground around the bottom of a shaft, at its junction with the rock, but has recently been used successfully for shaft sinking itself.

Asphalt grouting has been used considerably in the U S, and is better than cement grouting for fissured rock where there is a large flow of water. The asphalt is pumped into the ground as a hot fluid, which solidifies in the water. Its injection is facilitated by steam, or by a method patented by G. W. Christians, consisting of an electrical resistance wire in each casing which keeps the asphalt hot. The asphalt is injected at a pressure of 50 lb, or more, and can be forced for a long distance into open fissures.

Clay grouting (43). In case of large cavities, as frequently found in limestone, thoroughly mixed clay and water, pumped in under a pressure of 100 lb per sq in, or more, has been successfully used. At the Madden Dam, Panama Canal Zone, as much as 70 000 cu yd of clay grout were used to fill cavities around the rim of the reservoir, at a cost, exclusive of drilling, of $5.35 per cu yd. Clay grouting is not efficient in seams containing running water, as it is easily eroded.

Choice of method for sinking in soft, water-bearing formations is often a matter of great difficulty, and the reconnaissance borings, upon the results of which the decision rests, should be in sufficient number and so carefully made that a thorough knowledge of the ground is obtained. The cementation method is probably the cheapest when the ground can be cemented, but it can not be used in quicksand or clay. Honigmann method is almost as cheap, in some cases cheaper, when the ground is soft, and diam and depth of shaft are not too great. The freezing method has the widest application, but is too costly for ordinary depths where another method could be used. It can however compete with the Honigmann method in harder ground for shafts of large diam and great depth.

BORING

1. WASH-BORING RIGS (DRIVEPIPES)

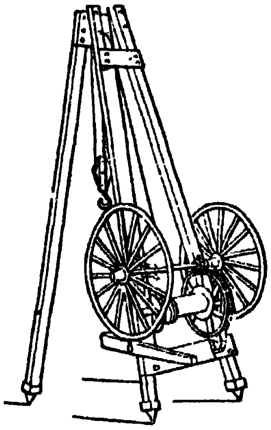

Fig 1. Derrick for Wash Boring

These rigs are for sampling soft strata overlying solid rock, to ascertain depth of bedrock below surface, and to sink standpipe for diamond drills. Rarely used for depths exceeding 100 ft. For testing superficial deposits much time is spent in moving from point to point; hence a light, portable outfit is necessary, as follows: 1 derrick, with 20-ft legs of 4 by 4-in timber, complete with windlass and sheave for 1.25-in rope (Fig 1). Truck wheels should be heavy, about 40-in diam, one tight and one loose on axle. 50 ft of 1 $^1/_8$-in hoisting rope. Flush-joint casing, 2.5-in, 5-ft lengths, for the probable maximum depth of hole; also a few lengths, each 1, 2, 3 and 4 ft. (Sleeve couplings can be used, but are troublesome in sinking and pulling.) 1 casing driveshoe; 1 casing drivehead; 1 casing tee. Flush-joint, 1 $^1/_8$-in drill rods, in 10-ft lengths, with couplings, totaling 10 ft longer than casing. Add two 5-ft lengths. (0.75-in gas pipe can be used in light sandy material.) 1 hoisting water swivel and coupling; 1 hoisting swivel; 3 cross chopping bits; 1 chisel bit; 1 bushing, water swivel to casing; 1 shoe for taking dry samples; 1 worm auger; 1 hand forcepump, 4-in cyl by 4.5-in stroke; 15 ft, 1.5-in suction hose, with coupling and strainer; 50 ft, 0.75-in 4-ply rubber pressure hose, with couplings for pump and water swivel; 1 axe; 2 5-ft crowbars; 15 ft of $^3/_8$-in chain, with hook and ring; 1 coldchisel; 2 hose couplings; 1 150-lb drive-block; 2 three-cornered 6-in files; 2 10-in flat files; 1 machinist's hammer; 1 oiler; 1 pick; 1 galvanized pail; 1 saw; 1 screwdriver; 1 shovel; 1 tape line; 2 36-in pipe tongs; 1 tool box; 2 hose unions; 3 Stillson wrenches, 10, 14 and 24-in; 2 monkey wrenches, 6 and 15-in; sample boxes and 4-oz wide mouth bottles; 1 firing battery; dynamite, electric detonators and 400 ft insulated copper wire; 1 pair sister hooks for 1.25-in rope; 1 shovel; 1 pair combined nippers and pliers; 1 brace with bits 0.25 to 1 in; 4 pairs Brown's patent pipe tongs, 2 No 3 and 2 No 4; 1 pair pipe clamps for 2.5-in casing; 2 10-ton jack screws; extra valves, liners and packing for pump; 4 balls candle-wick; 1 hank sash cord; 1 1-gal oil can and lubricating oil; 1 wagon. This outfit, for 50-ft holes, costs $350 to $400, and will last several years.

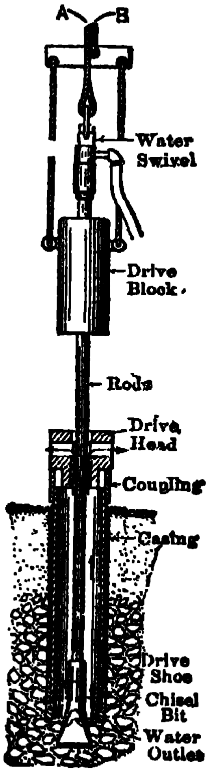

Fig 2. Chopping Bit in Combination with Drive Pipe

Operation (1). A pipe of the required diam is sunk, the core is broken up by a jet of water, or, if necessary, by a chisel bit, and the disintegrated material is brought to surface by the current of water. For penetrating SOFT GROUND, a smaller pipe carrying water under pressure is worked ahead inside the drivepipe as fast as the loosened stuff is carried to surface. In such material the drivepipe sinks of its own weight, or can be made to do so by rotating it by cross-bars (brace head), weighted by old carwheels, if necessary. In HARDER MATERIAL, a chisel bit is attached to lower end of wash pipe, and churned up and down to cut a hole below the drivepipe. Cuttings are washed to surface by a stream of water issuing from holes in the sides of bit. In this case the rig shown in Fig 2 is used, ropes *A* and *B* passing through a double block in the derrick. In GRAVELS the fine material is washed out, leaving coarser pebbles in the hole. If small enough, these are bailed out with a sand pump. If too large, they are broken with a cross chopping bit before pumping. BOULDERS are drilled through ahead of the casing, then broken with dynamite. The charge, made up for electric firing, is lowered to the proper depth by the leading wires. Before shooting, the casing is raised several feet to prevent injury. After shooting, casing can usually be driven through the broken rock. For testing overburden 2.5-in drivepipe and 0.5 or 0.75-in water pipe for drill rods are common sizes.

For deep holes or holes in bad ground, several strings of pipe may have to be sunk, before reaching bedrock. Oblique holes can be sunk by wash boring, but cost increases rapidly with degree of deviation from the vertical. In soft soils, and when samples are not required, pipe can be flushed down rapidly by attaching a water swivel and drivehead to the pipe itself; then driving and twisting the pipe ahead, while pumping down water. The water washes the core from under the shoe and rises outside of the pipe. Crew for a wash-boring rig consists of a foreman, 3 or 4 laborers, and a team.

Pulling casing. Drivepipe is pulled from test holes after they have served their purpose. If possible, this is done by attaching windlass rope to the pipe by a swivel head; then pulling while the pipe is twisted with tongs. If necessary, clamps are put on the pipe and it is raised by jacks or levers; a bight of chain around the pipe will sometimes take place of a clamp. By proper arrangement of clamps, the drivehead may be caused to give an upward blow on the pipe. Pulling pipe is often more difficult than placing it, especially in clay.

Speed. In soft soils, 12–18 ft per hr may be made to depths of 50 ft. In stiff clays, 5–6 ft per hr is good work. In holes over 100 ft deep, in sand, 12–15 ft per day is aver progress.

Cost of wash boring depends on the speed of advance, size of crew, wages paid, distance apart of holes, character of country, water supply, and climate.

In exploring a route for the N Y State Barge Canal, 666 holes were sunk by wash boring in alluvial soil, clay, sand, gravel, and hardpan. Aver depth of holes drilled in any month, 14 to 47 ft. Lowest monthly aver cost per ft was $0.18, in Sept, 1906, when 49 holes averaging 40.5 ft deep were sunk in easy soil. Highest monthly cost, $2.70 per ft, in July, 1905, when 3 holes averaging 47 ft were sunk in clay, sand, and hardpan. Aver for 666 holes, totaling 18 130 ft, was $0.35 per ft. Crew: 1 foreman, 3 laborers, a double team and driver. Charge for labor and team ranged from 87 to 98% of total cost (1). In making the Bahio dam borings for the Panama Canal, aver cost of 115-ft holes, in material ranging from quicksand to coarse gravel, was $0.83 per ft, including $0.14 for freight and traveling expense, and $0.15 for plant.

2. AUGER AND HAND CHURN DRILLING (2)

Augers are used for wells and for prospecting in soft ground. Fig 3 shows typical outfit for wells in middle west and south, consisting of derrick, windlass, auger, rods, and handles for rotating the rods. Rotating may be done by a horse, and in some more elaborate rigs horse power drives both rods and hoist. Fig 4 shows typical augers for well work, varying in diam from 6 to 24 in. Form *A* is used for clays, *B* when considerable sand is present, *C* in sand, and *D* in clayey ground containing boulders.

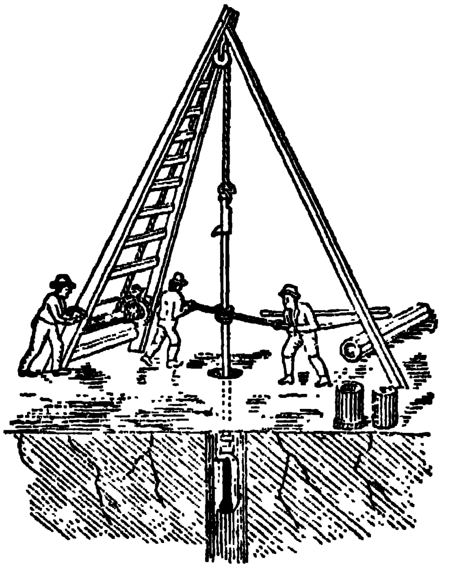

Fig 3. Well Borer Operated by 3 Men

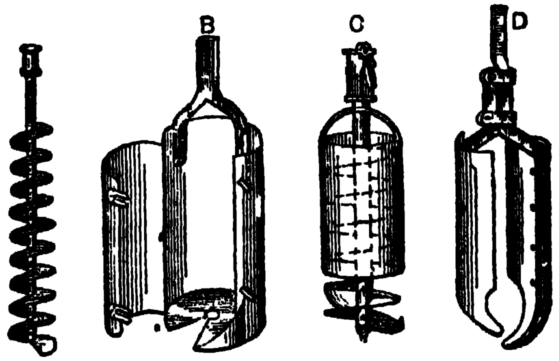

Fig 4. Four Types of Earth Augers

Holes to 700 ft deep have been bored with this type of rig. On Long Island, wells 250 ft deep are bored with the auger rig more cheaply than with power machines. Small augers, 1.5 in upward, with post-hole diggers and chisel drills as accessories, have been largely used for prospecting and geological work.

C. Catlett lists following outfit as used by him in prospecting soft, superficial iron-ore deposits: (*a*) 2-in auger bit of steel or Swedish iron with steel point, twisted into a spiral, thickness of blade not less than 0.25 in, length 13 in, pitch of spiral 4.25 in. This was welded to one end of an 18-in length of 1-in iron pipe which was threaded at other end. (*b*) 2-in chisel bit, made of 1 ft of 1³/₈-in octagon steel, welded, like the auger, to an 18-in length of 1-in pipe threaded for connection. (*c*) 10 ft of 1.25-in iron rod, threaded both ends for connection with 1-in pipe. (*d*) Lengths of 1-in pipe with couplings. (*e*) Iron handle, length 2 ft, with central eye and set screw. (*f*) Sand pump or sludger, 1 in diam, 2 ft long, with a leather flap valve. (*g*) 2 pipe tongs. (*h*) Oil can, 25-ft tape, flat file, spring balance, water bucket. The auger was turned by 2 men, standing on opposite sides of hole. Enough water was added to soften the material. Hard ground was penetrated with the chisel bit. Two men operated to depth of 25 ft; 3 men, 25 to 35 ft, a rough frame 15 to 20 ft high being built for the third man. Table 1 records the work done by one of these outfits in favorable circumstances. A similar outfit was used in prospecting residual iron deposits at Moa and Mayarí, Cuba. B. Halberstadt lists a similar outfit for coal prospecting, costing about $25.

Table 1. Prospecting with 2-in Auger and Chisel Bits

Hole	Material	Depth, ft	No men	Time, hr	Hole	Material	Depth, ft	No men	Time, hr
1	Sand, gravel, clay, ore.	16	2	10	6	Sand, ore, clay, sandstone	19	2	8.5
2	Surface ore, clay	40	2 3	11 4	7	Sand, sandstone, clay, flint	52	2 3	15 4
3	Clay, sandstone, flint	18	2	5	8	Sand, sandstone, clay, ore, flint	63	2 3	5 25
4	Mostly clay	29	2	5					
5	Clay and ore	26	2	6					

At Toronto, Can, in similar work, the cost of 30 to 70-ft holes with labor at $2 per shift was 29 to 55¢ per ft, respectively in clay and made ground. Supplies and blacksmith repairs comprised 15% of total cost per ft.

E. Low states (2) that boring 450 6-in holes, averaging 13.26 ft deep, with pod auger, in earth, clay, sand, and gravel, 3 men to a crew, the aver progress was 40 ft per day; length of moves 200 ft; cost about 18¢ per ft.

R. V. Thompson, Ophir Hill Consol Mining Co, Utah, used a 2-man sand auger for sampling piles of mill tailing varying from coarse dry sand to wet clayey slime with 35% moisture; all −200 mesh. Holes averaged 50 ft. Core-barrel, just above cutter, was a section of 6.5-in pipe, 9.5 in long, with a wood fiber cover wired in place. Two cutter blades, 6 5/16-in diam by 1/8-in thick, were brased on a 0.75-in pipe. A short tripod and chain blocks were used to pull auger when core-barrel was full. Aver speed, 10 ft per day; aver cost, 85¢ per ft. Casing was used in sampling a dry sand with no clay binder.

Post-hole diggers are used alone or in connection with earth augers.

New Market Zinc Co, Tenn, used an ordinary post-hole digger for prospecting a deposit of zinc carbonate and silicate, in tough, residual dolomite clay, 10 to 75 ft thick. The strap by which the handle was attached to the cutting blade was reinforced. Upper end of handle was threaded and attached to a 10 or 12-ft piece of 1-in gas pipe, making a 15-ft handle. From a ring at upper end of gas pipe a rope passed over the pulley in an ordinary 3-leg derrick, by means of which the digger was churned. In ordinary soil half-a-dozen drops filled the tool, which will extract 3 or 4-in lumps of ore. Boulders were broken by dynamite and churned up. Two men made 20–40 ft per day.

Hand churn drill is used for shallow holes, where conditions do not warrant machine drills. Hexagonal 7/8-in steel 8 ft long is common, with chisel point, which for extra hardness is coated with Stoodite by an acetylene torch, and then ground; thus avoiding frequent sharpening by blacksmith. In soft rock, holes 5.5–6 ft deep are drilled in 30–35 min by 1 man, at labor cost of 18–20¢ per hole; in harder rock, 3 or 4 times these figures. For drilling in overburden of coal-strip mines, a string of hollow rods may be used, with a chisel bit. A ball valve is placed between rods and bit. As the hole is kept full of water, lifting and dropping the rods produces a pumping effect, causing the cuttings to enter the rods through holes in the side of the bit and then rise to discharge at surface. Crews of 2 or 3 men can drill to 70 ft with fair effic (4).

3. SPRING-POLE DRILLING RIG (3)

Spring-pole rig is a primitive form of churn drill, useful where fuel and water are scarce, transportation difficult, labor cheap, and where few holes are to be drilled. For such work, due to low first cost, maintenance, and operating cost, it rivals the power churn drill in cost per ft of hole. Fig 5 shows usual outfit: spring-pole, 20–30 ft long, with ratio of lengths on the two sides of fulcrum of 1 to 3 or 5. Anchorage may be a pile of rocks, or a wooden frame. Fig 6 is a special form. Drilling is done by a chisel bit on a string of iron rods, suspended by rope and swivel from the spring-pole. The rods are churned up and down with aid of the pole by 1 or 2 men, and turned in a direction that will tend to tighten the screw joints. Water is poured into hole to keep cuttings in suspension, and pumped out, as necessary, with a sand pump. Holes 75–200 ft deep can be drilled.

Equipment: round spring-pole, 6 in small end by 10 in butt; derrick and windlass with platform for foot wrench; 50 ft, 1-in Manila rope, to attach rods to spring-pole; 50 ft, 1-in rope for lifting rods with windlass; 250 ft, 0.5-in rope for sand pump; splicing iron, 10 in long; iron-bound oak pipe-driver, 4 ft long, 12 by 18 in; 3-in earth auger; 5 pieces 2-in drivepipe, 1, 2, 3, 4 and 5 ft long; 33 pieces 2-in drivepipe, 6 ft long; drivehead and driveshoe; pipe lift; chain wrench for pipe 5 in outside diam; alligator wrench for pipe 5 in outside diam; 2 screw-jacks for loosening casing; 2 clamps for holding and raising pipe with jacks; 1 rod 1 ft 8 in, 1 rod 3 ft 8 in and 1 rod 5 ft 8 in between shoulders; 16 rods 11 ft 8 in between shoulders (all rods 1.25 or 1.5-in round iron, with 1.25-in square section near joints). 6 3-in drills, of 2-in octagon steel; 2 swivels, for windlass and spring-pole ropes; brace head; reamer; foot wrench; hand or disconnecting wrench; sand pump for light drillings and 1 for coarse or pasty drillings; grab for drills and rods; grab for pump; 2 water barrels; black oil for rod and pipe joints; blacksmith's and pipe fitting and threading tools; carpenter's tools. Fig 7 shows several of the tools used. Cost of a rig for 250 ft will not exceed $400 (3).

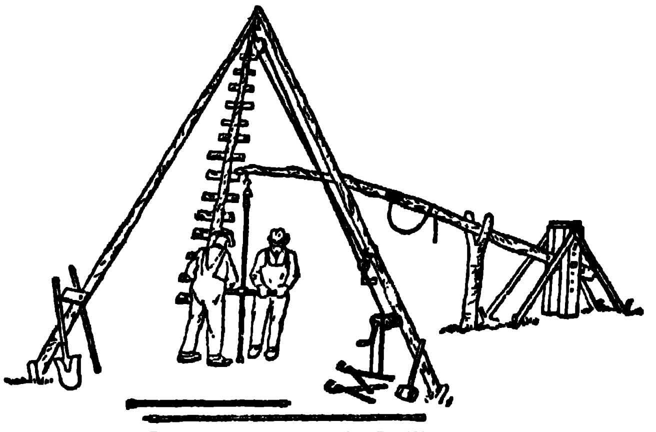

Fig 5. Spring-pole Drill

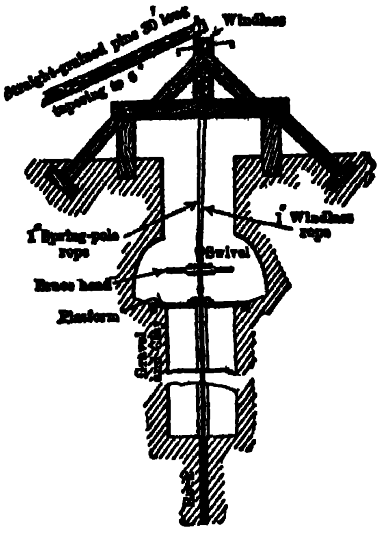

Fig 6. Spring-pole Rig Operated in Pit

Speed of drilling. In shales and soft sandstones, 1.5 and 2-in holes, 8–10 ft per shift for first 100 ft, and 4–8 ft for second hundred, are fair averages. In the same rocks 3-in holes will advance 7–8 ft per shift for first 100 ft and 4–5 ft for second hundred.

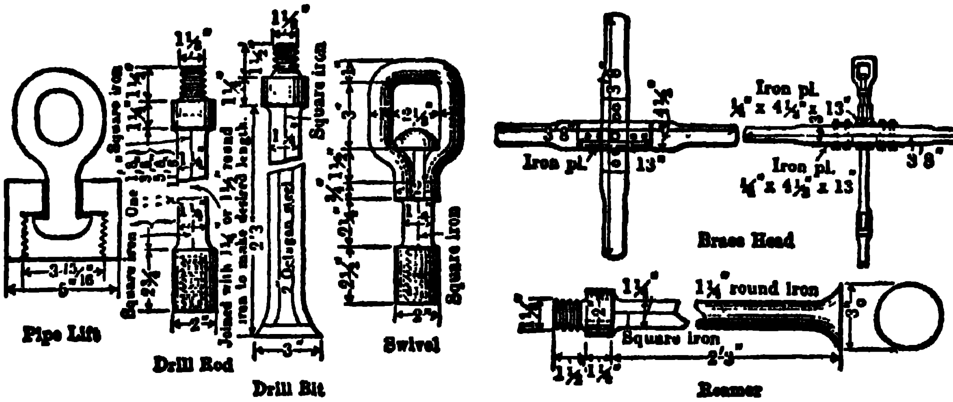

Fig 7. Parts of Spring-pole Drill

4. EMPIRE DRILL

This drill is well adapted to testing placer deposits where depth is not over 100–125 ft, and, due to its light wt, is useful in remote regions where transport is difficult and labor cheap. It is generally worked by hand. A power drive can be used, but decreases accuracy of sampling for Au, Pt or Sn. Costs: $1 per ft for shallow, easy drilling, to say $3.50 for deeper holes. Outfit (Fig 8) consists of a string of seamless high-carbon, flush-joint pipe, with a toothed bit. Near upper end of pipe, above the surface, is a circular steel platform, on which stand 4 men. By a sweep, platform and pipe are rotated by man or horse power. In loose ground, the pipe sinks due to turning and wt of platform and men; or, a 200-lb driving ram is operated by the men while the pipe is rotated. Core is brought to surface by a drilling "pump," on a string of rods within the pipe; 8 or 10 strokes being required to fill the pump with the sample, which is then withdrawn for examination, and drilling is resumed. In running ground, the pipe is driven to a firm stratum, before pumping out the core. Generally, 3–4 in of core are left in bottom of pipe as a plug to prevent entrance of unwanted material. For depths over 30 ft, a spring counterbalance minimizes wt of the rods. Equipment for a 50-ft, 4-in hole, including pipe, weighs about 2 200 lb; cost, approx $1 000 at N Y; for a 6-in hole, wt is 3 200 lb; cost, $1 500. All can be sectionalized into 1-man packs of 75 lb. One 30-ft hole per day can be made in aver placer ground (see below), by 6 to 8 men. Additional equipment: 180-lb sample rocker, $65; 120-lb steel dump box, $55; 150-lb water heater and tank, $75; assay outfit, 75 lb, $75.

Examples. Cost and speed. Prospecting on Island of Banka in tough clay, holes 11 to 32 ft deep, with raw crew, 4 men on platform and 6 on ground, averaged 1.33 to 2.06 ft of 3.5-in hole per hr. Actual boring occupied only 8 to 30% of total time. Record of work done in Colombia, in a jungle where steam drill could not be used: Day 1: Moved across river and made 14 ft in top soil and 11 ft in gravel. Day 2: Finished hole 1, 2.5 ft to bedrock, 27.5 ft total depth. Pulled casing and moved 100 ft before noon. Sunk 17 ft to bedrock in 4 hr. Pulled casing and moved to hole 3 and made 9 ft in overburden. Day 3: Finished hole 3, 24 ft total depth. Pulled casing and started hole 4 by 2 p m. Drilled 12 ft overburden and 10 ft sand and gravel by 5 p m. Day 4: Finished hole 4, total depth 28 ft to bedrock. Pulled casing, moved 300 ft to hole 5 and started by noon. Made 22 ft by 5 p m, passing through buried tree. Day 5: Finished hole 5 to 28 ft. Pulled casing and began hole 6. Made 14 ft in overburden and 9 ft in gravel. Day 6: Finished hole 6, to depth of 32 ft. Moved across and 1 mile up river and at 2:45 p m started hole 7. Made 6 ft in overburden and 9 ft in gravel. Day 7: Finished hole 7, total depth 29 ft. Moved 50 ft, sunk hole 8, 22 ft to rock. Started hole 9 after 50-ft move and made 6 ft in top soil. Summary: 7 days; 213.5 ft drilled; 30.5 ft per day. J. Chisholm reports aver advance of 30 ft per 9-hr day; 5 to 30-ft holes; 6-in drill; 9 to 10 ft of loam underlaid by gravel (6). In aver tin alluvials in Banka, native crews of 8 men make 4 to 8 holes, 18 to 30 ft deep, in 8 hr, when distance moved between the holes does not exceed 60 ft. One blacksmith can do repairs and sharpening for 8 outfits (7). Following are figures on work with two 4-in Empire drills in Siberia, when the thermometer read from 0° to −45° F (7). Total depth, 6 696 ft; time, 193.5 days. Percent total time in field, 81, as follows: drilling, 63.7; putting on pipe, 2.9; pulling pipe, 5.0; clearing surface, 1.8; moving from hole to hole, 2.8 (aver time, 17 min); moving from line to line of holes, distance 6 083 ft (aver time per move, 2 hr 5 min), 3.1; lost time while drilling, 1.8. Percent total time lost, 18.9, as follows: moving camp (twice), 1.8; storms, 8.8; holidays, 5.2; resting screws, 3.1. Crew of 7 men on each drill. Aver time per day, 8 hr 20 min. Aver advance per hr of total time per drill, 2.1 ft. E. F. Wilson prospected some 250 acres at Quebradas, Guatemala, drilling 83 holes, aggregating 3 147 ft, in hard ground with many large boulders. Total actual drilling time, 1 060 hr; aver, 2.97 ft per hr; cost for labor, 97¢ per ft.

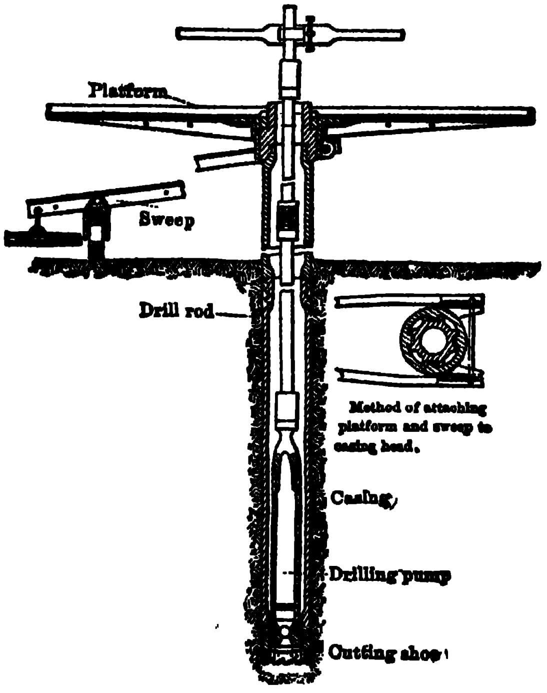

Fig 8. Empire Drill in Operation

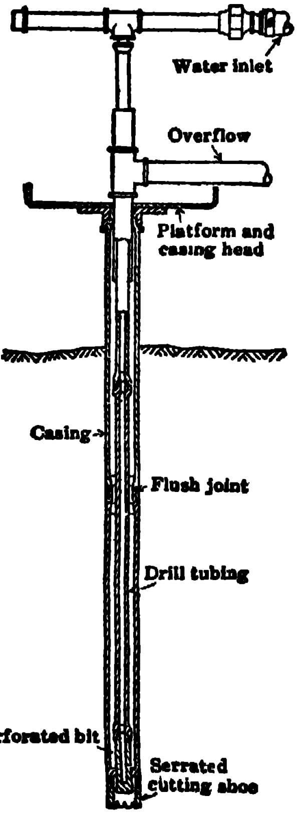

Fig 9. Empire Hydraulic Jetting Drill

Empire hydraulic testing drill comprises a gasolene-driven force pump, casing, cutting shoe, drill tubing, jetting bit and platform (Fig 9). Casing, 2 5/8-in, with flush joints. Drill tubing, 1 1/8-in, with its bit is connected to the pump. Perforations in the bit let water escape just above edge of bit. It is sometimes possible to wash down some distance without casing. When casing is needed, men stand on platform and churn the string of tools, the material being washed out of hole. Casing can be driven by striking on a drive head with a wooden maul. On reaching bedrock, the casing is pulled by chain tongs and light jack, or by a heavy casing jack. A light core-drilling rig can be used for coring to small depths in bedrock. Drill is driven by a water motor, operated by the pump. Wt of complete outfit for depth of 50 ft, 800 lb; cost, approx $1 030.

Empire drill (Ward type), with light derrick, is also used for prospecting to depths of about 100 ft. For driving the pipe or for drilling, a bar or 2-in pipe is put through a loop on the spudding arm, which is worked by 2 men for raising and dropping the drill stem. The pipe is 4 $^5/_8$ in outside diam, and $^3/_{16}$ in thick. Complete outfit for 50-ft poles weighs about 2 600 lb; approx cost, $800. Speed of drilling depends on accuracy of test desired, as well as kind of ground; a 50-ft hole in aver placer gravel takes 2 days; a 30-ft hole is often made in a day.

5. MISCELLANEOUS RIGS FOR SHALLOW BORING

Mackintosh outfit is used in soft material, to reach bedrock or ground-water level; not suitable for hard rock or very stony soil. Depth of holes, rarely over 50 ft; has been used for locating placer gravels below overburden, and sampling subsurface water.

A series of 4-ft by 0.5-in rods are coupled by 1-in nipples, and have a nickel-steel, 1 $^1/_{16}$-in driving point. One man operates the tool by a lifting and driving device of two 15-in hinged steel arms. When the arms are folded, they will pass over the rods; but, when brought into alinement, the jaws grip the rods. By bearing down and turning on the arms, the rods are forced down. On reversing the position of arms, and pulling and twisting, the rods are withdrawn. The outfit can also be used for horiz or upward boring underground, requiring only 4 ft width of operating space. In tough ground on surface an anvil ring is attached to the top rod. Striking on it is an annular hammer, which is dropped and raised (as in Fig 2).

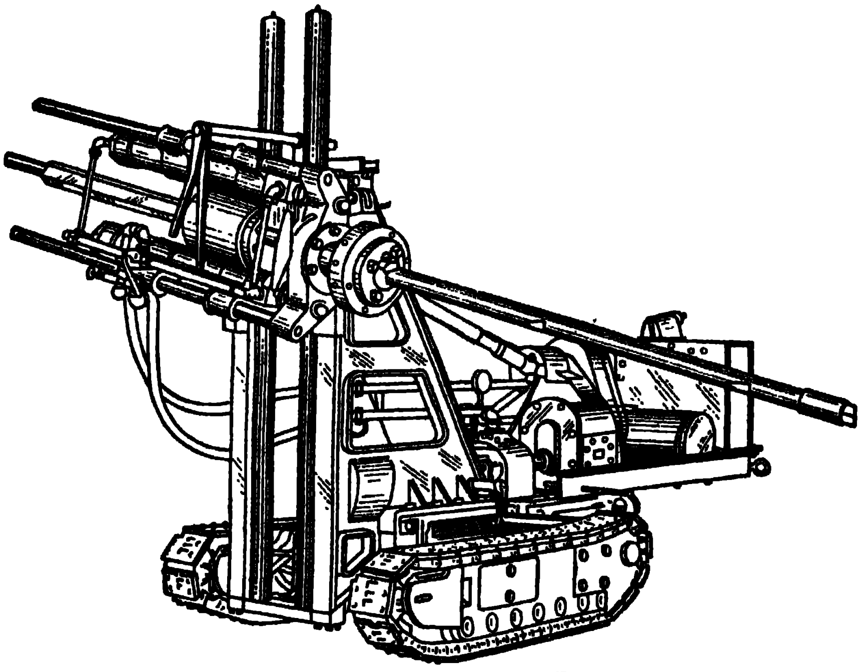

Fig 10. Stripborer Drill

The borer can make 20 holes 20–30 ft deep in a day. Outfit for 50 ft: 12 rods, $^1/_2$ in by 4 ft, with nipples; 1 driving point, 9 in long by 1.25 in diam, and another, 18 in long by 1.25 in; driving head; core tube, 24 in by $^3/_8$ in; lifting and driving head; total wt, 50 lb. Extras: additional rods, auger tool, pulley block, 30 ft of $^5/_8$-in wire rope and swivel hook for lifting rods.

Core samples are taken by replacing the driving point by a core-barrel, 24 in long and $^3/_8$-in bore, the rods being hammered and rotated to cut the core. Two ports in top of core-barrel allow escape of solids picked up as core enters the tube. To take SAMPLES OF WATER, a driving point with 1 aperture is used, sliding in a sleeve also having an aperture. When lowered, the sleeve is kept in its top position by friction on the sides of the hole. On reaching water, the rods are raised a few inches in the sleeve, to bring the 2 apertures together. Water enters and is retained by giving the rods a half turn.

Stripborer drill is self contained, caterpillar or skid mounted, for horiz holes 2–6-in diam, to 100-ft depth, in easily drilled material, without use of water (Fig 10). Operated by 30-hp Diesel engine or elec motor. Rods are in 10-ft lengths. The 3-wing, toothed bit is faced with tungsten-carbide. The twin-cylinder oil feed has a travel of 30 in, and can exert a 5-ton press. Two vert hydraulic cylinders adjust position of the drilling head. Total wt, 10 000–10 500 lb; cost, $9 400. At one coal mine, 1886 6-in holes were drilled in shale to aver depth of 48.4 ft, at 46.5 ft per hr.

Concore core-drill is a small, light machine, for 1.5–16-in holes, chiefly used for cutting test specimens, as from dams and walls. Holes can be drilled in any direction, as the base-plate is bolted against the face of the material to be drilled. Usual diam of core is 4 in, in lengths of 12–15 in; length of feed, 2–5 ft. The toothed bit, of mild steel, is faced with tungsten carbide. Wt of drill, with 4-hp gasolene or 3-hp elec motor, 240 lb; with 4-hp air-motor, 190 lb. Rate of drilling 4, 6 or 8-in cores is 30–45 min per ft.

McKinlay entry borer. Two of these, installed in New Orient coal mine, Nov, 1927, have been developed efficiently (5). Cutter bars *E* and *F* (Fig 11), each 7 ft 2 in long, have 6 rows of teeth, with an axial bit at center. The bars, 5 ft apart, make overlapping circular grooves *AB* and *CD*, by means of teeth 1 and 6; teeth 2, 3, 4 and 5 cut concentric grooves around the bit. Coal between the grooves is broken out by bevel rollers. Back of the cutter bars are toothed chains, supplementing the cutters' work by removing the coal from *B* to *C* and *A* to *D*. The coal is carried by buckets on the cutter-bar shafts to a conveyer, driven by a 15-hp motor, and dumping into a car. A pump, driven by a 5-hp motor, exerts a press against the face of 3 000 lb per sq in, giving a normal advance of 5 in per min; generally, the pressure control is set to kick out at 2 400 lb, for an advance of about 3.5 in per min. The cutters and chains are driven by a 100-hp, 460-rpm motor, through bevel and worm gears. Power is brought to within 300 ft of the borer by a 1 000 000 circular mil cable, with a trailing cable to the machine; current is 200 ampere, at 240 volts.

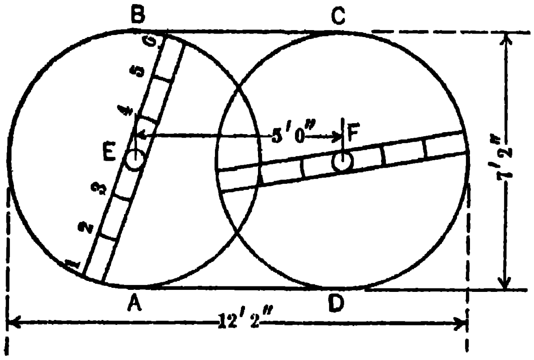

Fig 11. Diagram of McKinlay Entry Borer

Curves of 80-ft radius, and grades from −11% to +17% are easily negotiated. The smooth surface left and the arched support on the ribs, no explosive being used in driving the entries, minimise cost of timbering. From Apl, 1934 to Jan, 1938, aver advance was 45 ft per 7-hr shift. Typical time study (minutes): boring and loading coal, 175; changing cars, 78.5; track work, 17.1; waiting for locos, 27; setting jacks, 17.8; setting bits, 46.2; repairs, 32.4; misc, 26; total, 420 min.

P. A. P. alluvial prospecting drill is a light 4-in drill, with 3.5-hp gasolene engine mounted with gearing and drum, on a base of small channels and I-beams; operated by 2 men. The tubular derrick has 4 legs, 2 of which are hinged to base plate. The outfit can be mounted on 2 wheels for moving. With engine running, drilling is done by tightening a turn or two of the rope on the drum to lift the drill, then loosening the rope to allow it to drop. To change from drilling to pumping, the rope is reversed, the drill being attached to one end, the pump to the other. Equipment for drilling 50-ft holes: drill with engine, gears, drum and derrick; 125 ft of 1-in rope; bit; jarring clamps; 50 ft 4-in casing; drive head; cutting shoe; pipe clamps; sand pump; pipe wrenches; Barrett jacks; net wt, about 2 450 lb.

Buda-Hubron drill is for shallow boring, for soil testing, etc. An attachment for drilling small holes in soft rock can be furnished. Standard rig makes holes to 30-in diam and 24 ft deep; 42-in holes can be drilled to 10 ft; 50-ft depths are possible. The helix cutter resembles a post-hole digger, but has lips and teeth for boring in frozen ground and shale. Engine rotates a square shaft carrying cutter, the weight of which forces it down until 15–18 in of dirt is built up on the cutter. Rotation is then stopped, lifting clutch engaged and 2 roller chains bring dirt to surface, where the drill is automatically stopped and locked; then, a moment's rotation throws dirt off by centrifugal force. In hard soils, press is brought on the drill spindle by a feed lever, pumped up and down by hand, as in working a jack. The helices are in sizes from 13 to 42 in. In aver soil, 2 men can drill about 1 ft per min; in shale, 18-in holes, 20 ft deep, in 40 min. In soft soils, a twin cyl, 12-hp gasolene engine is used, cost with special base for mounting on a 1.5-ton truck, $1 935. For harder soils a 25-hp, 4-cyl engine is used. Cost of truck-mounted outfit, $2 346; wt, 2 700 lb. With caterpillar treads, winch and derrick, cost is $5 250.

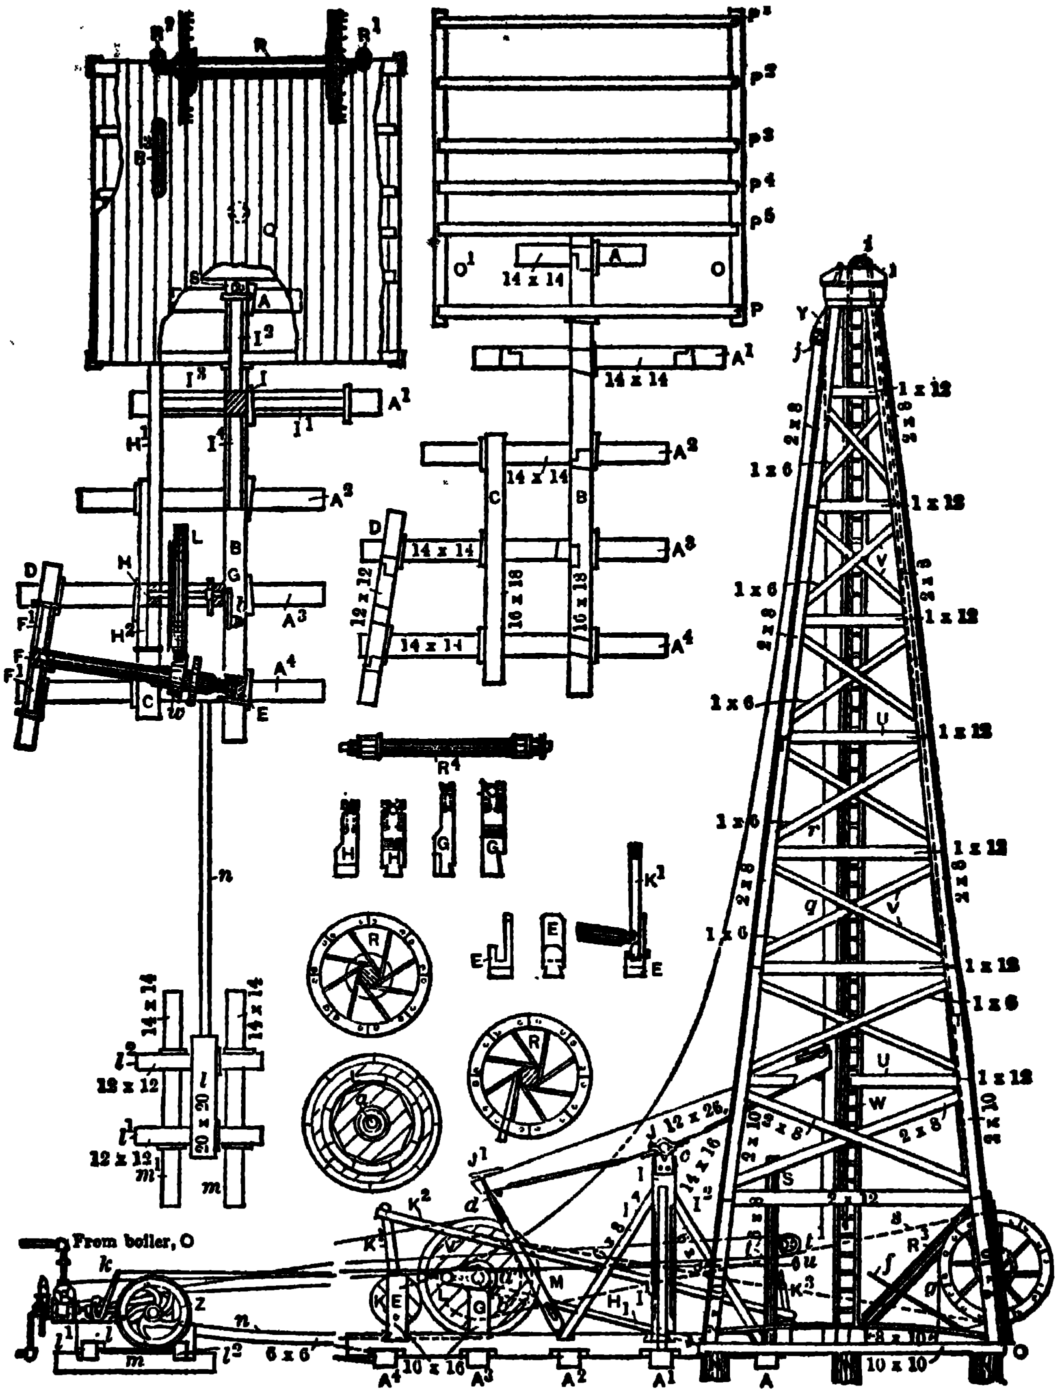

Fig 12. Standard Oil-well Rig

6. CABLE-TOOL DRILLING FOR OIL

This old method, for oil, gas, sulphur or water, is also called churn drilling. In 1859, the first oil well in the U S was drilled near Titusville, Pa, using a steam rig; depth, only 69.5 ft. The rotary method of drilling (Art 7) is now exclusively used for deep wells, say over 6 000 ft, but statistics show that about 45% of the oilwells in the U S are still drilled by cable tools.

There are 2 general classes: the standard rig, with stationary derrick (Fig 12), and the portable rig; both consist essentially of a band-wheel, bull-wheel, walking-beam, samson post, pitman, crank and wrist pin, sand reel for bailer, and may also include a calf-wheel (Fig 19).

Standard rig developed in Pennsylvania, is commonly used in the eastern fields for oil and gas wells.

Names of parts of typical rig shown in (Fig 12): *A*, nose sill; A_1, A_2, A_3, A_4, mudsills; *B*, main sill; *C*, sub or counter-sill; *D*, sandreel tail-sill; *E*, knuckle post; *F*, tail post; F_1, tail-post braces; *G*, *H*, front and rear jack posts; H_1, H_2, jack-post braces; *I*, samson post; I_1, I_2, I_3, I_4, samson-post braces; *J*, walking beam; J_1, walking beam cap; *K*, sandreel; K_1, K_2, K_3, sandreel lever, reach, and handle; *L*, bandwheel; *M*, pitman; *N*, derrick foundation posts; *O*, O_1, derrick mudsills; *P*, P_1, P_2, P_3, P_4, P_5, derrick floor sills; *R*, bullwheel; R_1, R_2, R_3, bullwheel posts and brace; *S*, headache post; *T*, *U*, *V*, derrick legs, girts and braces; *W*, derrick ladder; *X*, crown block; *Y*, sandline pulley block; *a*, flanges; *b*, shaft, crank and wristpin; *c*, saddle and side irons; *d*, stirrup; *f*, brake lever; *g*, brake band; *i*, crown pulley; *j*, sandline pulley; *k*, reverse lever; *l*, engine block; l_1, l_2, engine pony-sills; *m*, m_1, mudsills; *n*, engine-block brace; *o*, boiler; *q*, sandline; *r*, cable; *s*, bull rope; *t*, t_1, telegraph cord and wheel; *u*, reverse cord; *v*, bandwheel tug pulley; *w*, sandreel friction pulley.

Rig irons consist of: bandwheel shaft, with crank and flanges complete; jack-posts boxes, saddle and side irons for supporting the walking beam; stirrup for connecting pitman to walking beam; sandline and derrick pulleys; gudgeons for bullwheel and sandreel. Size of the outfit is denominated by the diam of bandwheel shaft; standard sizes are 3.5, 4, 4.5 and 5-in.

Table 2. Details of String of Tools, Oil-well Rig

Tool	Length, ft	Diameter, in	Weight, lb	
Bit	3.5 to 6	4 to 20.5 ^{a}	170 to 3 750	*a* is length of cutting edge, or gage, of bit.
Auger stem	16 to 48	2.75 to 6	20 to 98 per ft	
Jars	about 5.5	3.5 to 8	100 to 800	
Sinker bar	6 to 16	2.75 to 6	20 to 98 per ft	
Rope socket	2 5 to 4	2.75 to 6	40 to 350	

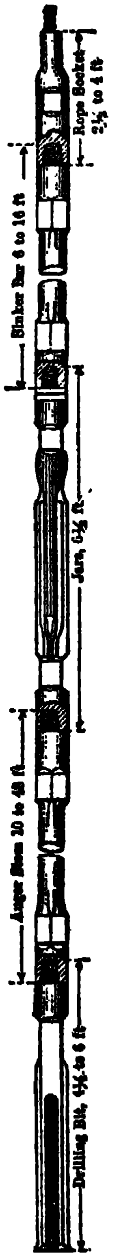

Fig 13. String of Tools for Standard Oil-well Rig

String of tools (Fig 13) is attached to walking beam, and the feed regulated by means of the temperscrew (Fig 14). The jars, a pair of links for loosening bit on upstroke, have a 4 to 12-in stroke; special fishing jars, 36 to 48-in.

Derrick is high enough to allow string of tools to swing clear of hole. Standard height, from top of sills to under side of crown block, is now 72–84 ft. Base generally 20 ft square. See also Art 7.

Load on drilling cable, under ordinary conditions, is that of the string of tools, or a string of casing. Possible max load on the derrick is twice the ultimate strength of drilling cable. This load must be distributed evenly by the crown block to the derrick legs. Fig 14 gives sizes for the important timbers in an 84-ft, spike-joint derrick. Other designs by the oil-well supply houses are built of bolted wooden members, gas pipe or structural steel. These derricks can be set up and dismantled with little, if any, destruction of material, and in less time than the spiked wooden derrick.

Hoisting and transmission machinery. Bandwheel shaft, which distributes the power, is actuated by belt from the engine pulley to the bandwheel. From it the bullwheel is driven by a crossed rope running in grooved pulleys, the sandreel is driven by friction from the bandwheel, and the walking beam is actuated through crank, wristpin and pitman. Bullwheel carries drilling cable and casing line. It is thrown out by throwing off its crossed driving rope. When not connected with the engine it is controlled by a band brake. Sandreel is used to run the bailer in and out of the hole. When the sandreel lever is pulled forward, the friction pulley engages the bandwheel and bailer is hoisted. Speed of lowering is controlled by throwing the friction pulley against a friction post (not shown).

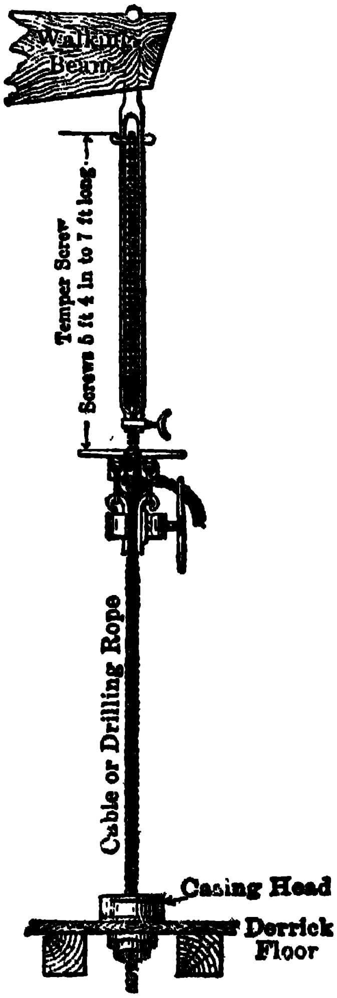

Fig 14. Method of Suspending Drilling Rope

Cants, arms, handles, and shafts for bullwheel, bandwheel and sandreel can be purchased from well-supply houses. Engine throttle is controlled by the telegraph cord running from the telegraph wheel on the headache post. Reversing lever is controlled by a rod running to the headache post.

Ropes. Hawser-laid Manila cable, or wire rope, is used for drilling. Wire rope, though causing more wear on casing, is best in holes filled with water, where the buoyancy and stretch of hemp rope may interfere seriously with action of the string of tools. The usual WIRE ROPE is 6-strand and 19-wire extra strong cast-steel hoisting rope. For sand-lines, 6-strand 7-wire cast-steel rope is the rule. For data on ropes see Sec 12.

Power. For steam the engine is single-cyl, 12 by 12-in, with a 40-hp boiler; for deep drilling, a 14 by 14-in engine and 75-hp boiler. Boiler press, 100–150 lb; hp, 80–150, at 100–300 rpm of engine. With elec power, the motors are 25–65 hp; 2 motors being coupled to a common countershaft for deep drilling. When Diesel or gasolene engines are used, they are usually 50–75 hp, up to 150 hp for deep drilling. More attention is being paid to fuel economy than formerly.

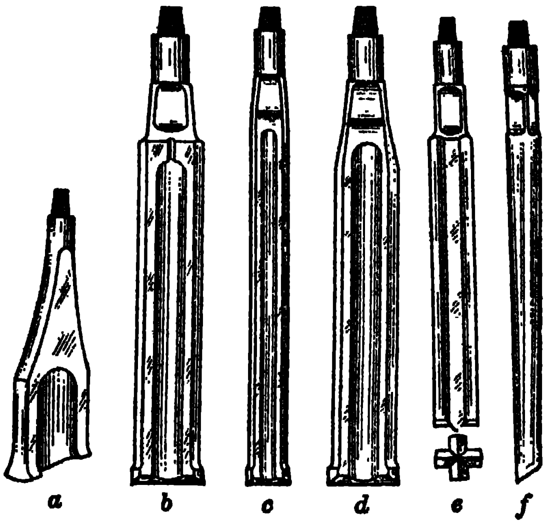

Fig 15. Churn Drill Bits (Star Drilling Mach Co)

Bits (Fig 15): spudding bit (*a*), for sand, gravel or clay, is thinner than the rock bit, as its action is merely to stir and mix the material with water; "Mother Hubbard" bit (*b*), for hard rock, completely fills the hole, and keeps it straight; *c* is the regular bit for water-well drilling; *d* is California pattern of Mother Hubbard bit; star bit (*e*) is for hard, creviced rock, its 4 wings tending to keep the hole straight; placer bit (*f*) is made thin to stir up rather than crush the gravel, as in placer drilling (Art 14).

Spudding, employed for the first 150 to 200 ft of hole, consists in churning the tools up and down on a short length of cable. Two methods of actuating the cable are employed: (*a*) one or two turns are taken around the bullwheel shaft, the operator grasping free end of cable. By alternately tightening and loosening the cable on the revolving shaft, the tools are raised and dropped; (*b*) end of drilling cable is attached to the bullwheel and a "jerkline" passed from bandwheel crank to a SPUDDING SHOE (Fig 16) placed on the drilling cable, a few feet above bullwheel. The weight of the tools is held by bullwheel band brake and churning motion is obtained by the jerk on drilling cable.

A special form of BIT (Fig 15*a*) is used for spudding through surface soil. While spudding, water is poured into the hole to make a mud which will hold cuttings in suspension. When sludge becomes so thick that fall of the bit is impeded, tools are withdrawn, and hole cleaned out with BAILER (Fig 17). String of tools for this work usually omits sinker bar and jars. If surface soil will stand without support until bedrock is reached, the hole is drilled "open." When rock is reached, the tools are withdrawn and conductor pipe is lowered into hole and seated firmly in rock to prevent entry of surface soil. If soil caves, drive pipe must be driven ahead of bit.

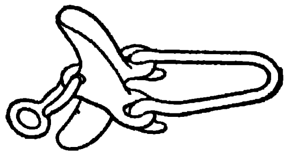

Fig 16. Spudding Shoe

Driving pipe. A shallow hole is dug and in it is placed the first length of drivepipe with shoe and drivehead. The pipe is plumbed and earth filled in around it. Driving is done by a block running in guides in the derrick or by drive clamps bolted to a square on the stem. Weight is raised and dropped by either of the methods described under Spudding. When the pipe has been driven to refusal, the core is churned up and hole bailed. Lengths are added to the pipe as necessary (Art 8).

Drilling. After the hole has been spudded to such depth that there is about 100 ft of cable in the hole, the walking beam is brought into play. The drilling cable is wound onto the bullwheel, pitman connected with one of the inner holes on crankshaft, temperscrew hung on forward end of walking beam, the tools rested on bottom of hole, and the cable let out until there is about 4 in slack in the jars. The cable is wound with marline at the point where the temperscrew clamps grip it, temperscrew is clamped on, and the bullwheel slacked off, thus transferring the weight to the walking beam. About 25 ft of cable is run off the bullwheel and thrown on the floor to prevent lashing. On starting engine, the tools are picked up with a shock as the links of the jars come together, thus preventing the bit from sticking in the hole. Downward stroke of the string of tools is quicker than the movement of the end of the walking beam, because of the spring in the cable, action of the tools being that of a weight suspended by an elastic cord. As hole deepens, the bit is fed down by temperscrew (Fig 14). For the first 200 ft or so the cable is twisted to keep the hole round. Beyond this depth, the twist in the cable itself is sufficient to bring the bit to a new seat at each stroke. When temperscrew has run out, it will usually be advisable to pump out the cuttings. Slack of the drilling cable is taken up on bullwheel, temperscrew clamps loosened, temperscrew run back, pitman thrown off the wristpin, and rear end of walking beam lowered. Tools are hoisted, swung to one side, and the bailer run in. After hole is pumped out, the tools are again lowered, attached to walking beam, and drilling is resumed.

Reamers (Fig 18) are primarily for enlarging a hole already drilled (below casing that is to be lowered farther), or for dressing a rifled hole. Under-reamers (*A*, Swan, *B*, Ideal) have 2 cutting wings, which are forced outward by springs. On pushing the reamer past lower end of casing, and churning it up and down, the hole is enlarged. *C* is a solid eccentric under-reamer; *D*, a round reamer for straightening or dressing a hole; *E*, hollow reamer for removing cuttings from around the top of an object in the hole that is to be fished out.

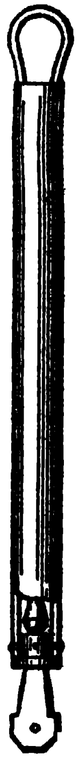

Fig 17. Dart Bailer

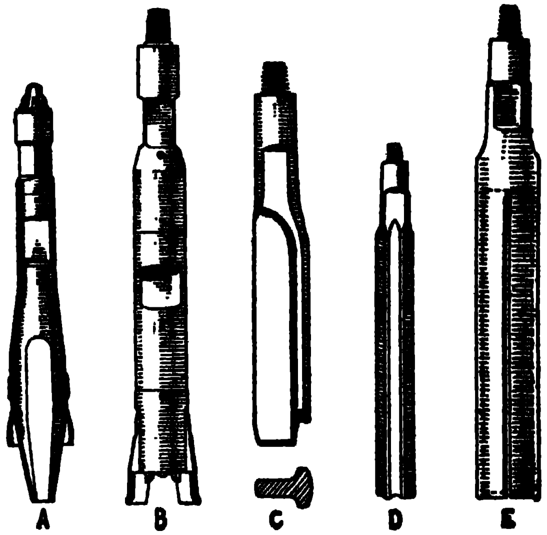

Fig 18. Reamers

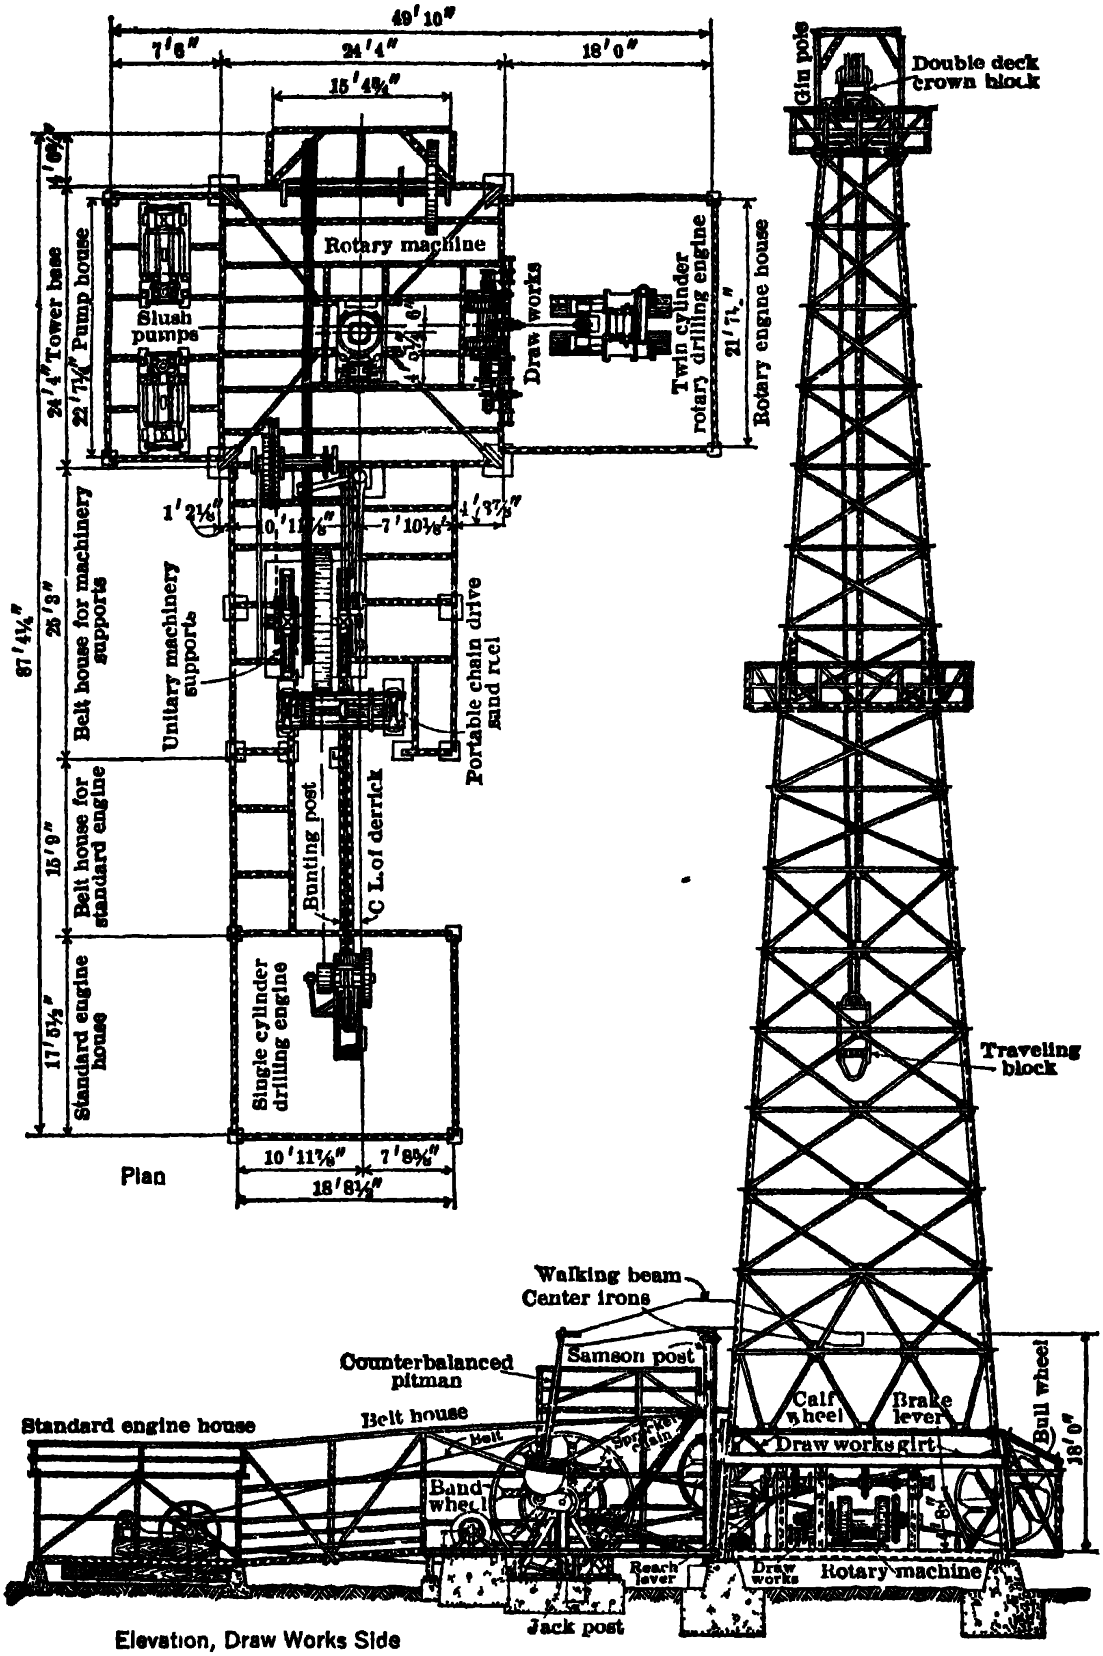
Fishing tools are for recovering lost or broken tools from the hole. The commonest accidents in drilling are: (*a*) sticking of the tools, due to wedging of the bit or caving of the walls; (*b*) breakage of some member of the string of tools; (*c*) unscrewing of a joint in the string of tools, resulting in loss of the lower portion; (*d*) breakage of drilling cable; (*e*) breakage of the sandline; (*f*) sticking of the bailer; (*g*) "freezing" or sticking of the casing; (*h*) loss of a part of the string of casing; (*i*) loss of some small article by dropping into the hole.

Catalogs of Oil Well Supply Co (Pittsburgh) and other makers contain cuts and descriptions of the tools for dealing with different accidents, and expert drillers sometimes devise special appliances. Fishing tools are too numerous to be detailed here; following are a few brief notes. Stuck drilling tools. If continued jarring with the drilling jars fails to loosen tools, a spear may be run into the hole on a separate line, and churned around the string. Failing this, the rope is cut off close to rope socket by a rope knife; after which an attempt is made by a slip- or horn-socket, attached to long fishing jars, to grip the tools. Broken rope may be picked up by a serrated rope spear. If part of string of tools becomes unscrewed in the hole, it can often be recovered by lowering a sinker bar on a string of tubing and screwing it onto the lost tools; or the horn-socket may be used. If a broken string is battered or forced into the walls of the hole, a spud is used to drill around the lost part, which may then be gripped by a horn-socket. Many other cases arise.

If fishing fails to recover the lost article it may often be broken up by drilling, or blown into the side of the hole with dynamite; or the hole may be diverted at some point above. This latter operation is accomplished by obstructing the hole at the desired point with some material more resistant than the rock being drilled (flint, steel or even old cordage will serve) and then drilling with a string of tools of smaller diam than the standard size for the hole, the bit being sharpened to a chisel edge. A hole is rarely abandoned because of an accident.

Combination rig (Fig 19) is designed for both cable-tool and rotary drilling. Formerly, it was considered best to drill to oil sands with rotary tools, and then bring in the well with cable tools, since rotary tools might pass through oil sands where the formation



Plan

Elevation, Draw Works Side

Fig 19 Combination Rig (Cable-tool and Rotary) (Emsco Derrick and Equipment Co)

pressure was low, without their being recognised. Improvements in rotary drilling technique (Art 7) have practically eliminated this objection.

Table 3. Specifications for Cable-tool Rigs

	A	*B*	*C*
Depth of well, ft	to 4 000	5 000	6 000
Derrick 80 ft high, 20 ft square at base, 5.5 ft at top, with base plates, ladder, gin-pole, headers, bullwheel girt and all bolts; safe working load, lb	244 000	244 000	333 000
Steel base, 20 by 20 ft, with all sills and headers	1	1	1
Crown safety platform	1	1	1
Bandwheel, diam, ft, by width of face, in	11 by 12	12 by 14	12 by 14
Double-tug pulley, 7-ft diam	1	1	
Triple-tug pulley, 7-ft diam with braces	... .	....	1
Bullwheel (*a*); diam, ft, by width of face, in	8 by 12	8 by 14	8 by 14
Bullwheel shaft, tubular, with dogs; diam, in	12	18	18
Set of wire-line clamps, steel-lined; number	2	18	18
Crown block and sheaves; number of shaves	2	6	6
Steel bullwheel posts, with bearings and knee bracing	2	2	2
Set of A. P. I. rig irons; size, in	4.5	5	6
With 12-in (*A*) or 14-in (*B*, *C*) brake irons, comprising			
Crank and shaft; size, in and ft	4 1/2 by 5 1/2	5 by 8	6 by 8
Walking beam saddle with stirrups and plates, size, in	4.5	5	6
2 side-irons and bolts; size, in	4.5	5	6
Brake band (*b*); thickness and width, in	1/4 by 12	1/4 by 14	3/8 by 14
6-ft brake lever; size, in	2 1/4 by 12	2 1/4 by 14	2 1/2 by 14
Brake staple; size, in	1 1/4 by 12	1 1/4×14×16	1 1/2×14×16
2 brake-band clamps; size, in	12	14	14
Front and back jack-post bearings, with bridle irons, in	4.5	5	6
Wrist pin; size, in	2 75	2.75	3.5
Steel pitman with stirrups	1	1	1
Sandreel (*c*), with swing lever and tail post	1	1	1
Steel walking beam, 26 ft long, with temperscrew and pitman stirrup bearings	1	1	1
Foundation timbers, set	1	1	1
Steel jack-posts, 5 ft high	2	2	2
Steel samson post, 15. 5 ft high	1	1	1
Steel calf wheel for 80-ft derrick, 7.5-ft diam by 12-in face, with 24-in tubular shaft and 90-in sprocket tug rim, steel spool flange and reserve spool	1	1	1
Calf-wheel posts, with bearings	2	2	2
Calf-wheel irons, with 12-in brake irons, set	1	1	1
Approx weight, lb	60 000	78 500	85 000
Approx price	$3 750	$5 950	$6 775

(*a*) for *C*, with double brakes, one 12-in and one 14-in brake wheel. (*b*) Length: for *A*, *B*, 29 ft; for *C*, 26 ft. (*c*) For *A*, 12-in diam, 42-in straight face; for *B*, chair-driven, 36-in, with crank shaft parts; for *C*, Model 70-A, chain driven. Above specifications do not include lumber, engine belt, forge and derrick houses and walk, tools, cable, cordage or motive power.

Portable cable-tool rigs are suitable for 1 000 ft or less, to 4 500 ft or even deeper. They are of steel throughout, and may be truck-mounted, and move under power of a steam engine and boiler, or a gasolene engine. Some are moved on wagons, and then assembled with mast or derrick. The lighter portable rig is the "spudder," similar to churn drill (Art 3).

Truck-mounted rigs for depths to 1 000 ft may have broad tread wheels, caterpillar treads, or a combination of the two. Engine, of 35–40 hp, uses either gasolene or natural gas, and may propel the machine. A folding mast is customary, and can be quickly erected; usual height, 40 ft from sheave to mouth of hole. Larger portable rigs can drill 2 500 ft, or clean out wells as deep as 4 500 ft. They will handle a load of 40 000 lb of casing, or an equal load in pulling out a string of stuck casing or tools. Power is commonly from a 4-cyl engine, of 90 hp, at 1 000 rpm, with a planetary reversing gear. Other regular equipment has a 56-ft mast, 7.5-ft bandwheel, 4.5-ft bullwheel, friction driven sandreel and chain-driven calfwheel; higher and heavier masts are obtainable. Complete rig of this type weighs about 42 000 lb, without tools. Another portable rig, for which the individual parts are assembled where required, can drill to 3 000–4 500 ft. Masts are 60–65 ft high, of 50 000 lb capac, and can handle 2 lengths of casing at one time, with a 100-hp engine. Total wt, 25 400–35 500 lb. Tractor rigs are often used

with a standard derrick, and are important in drilling exploration holes, to secure samples of strata within relatively shallow depths.

Examples. Fort Worth Spudder, Model C, drills to 1 500 ft. Drum holds 2 500 ft of $^5/_8$-in cable. Mast, 38 ft; bandwheel, 60 in; hp, 20–30; wt of machine, less power plant and tools, 13 600 lb; cost $1 550. Main sills on back end can be extended for mounting engine; or, engine may be placed 40–60 ft away, with belt drive, to avoid danger of igniting well oil. Model Jumbo J, for 5 000 ft, has a 52-ft mast; drum for 9 100 ft of 1-in cable; engine, 100–150 hp. Weight, without engine or tools, 39 800 lb; cost, $5 700. Local conditions determine details of outfit. Thus, the Jumbo J complete with tools, for east Texas field costs $8 000–$9 000, but in Montana about $15 000. Fig 20 shows No 3 National belt-driven rig for 4 000 ft, with 65-ft steel mast that will handle 50 000 lb of casing, or 100 000 lb with aid of shear poles. Lighter rigs are made for 2 500–3 500 ft, with 65-ft mast, 3-sheave shear poles, hoisting blocks, 300 ft of $^5/_8$-in cable, 65-hp Ajax engine, boiler, and gas burners; wt, 70 000 lb; cost, $9 500. A smaller outfit with Diesel engine, weighs complete 8 000 lb; cost, $6 500. Accessories: 100 ft 12-in belt; belt clamps; 4.25, 5 and 5.5-in by 34-ft drill stems; two sockets; 5.5-in drilling jars, 4-in stroke; 5 sets of bits, 6$^5/_8$, 8.25, 10, 12.5 and 15.5-in by 7 ft; set of bit gages; 5 bailers, 14-in by 16 ft, 10.75-in by 20 ft, 9-in by 25 ft, 7-in by 30-ft and 5.5-in by 30 ft; 2-in bailer dump; 4 500 ft $^7/_8$-in cable; two 4 500-ft sand lines, $^5/_8$ and $^9/_{16}$-in; 2.75-in by 6-ft temperscrew; set 14-in cable clamps; 60 ft of $^3/_8$-in wire line for raising temperscrew; No 2 tool jack; BJ tool brace; 1.5-ton derrick crane, with trolley; 2-ton ball-bearing chain-hoist; swivel wrench; bit pulley, with $^5/_8$-in by 8-ft endless chain; six 5-in Hay Fork pulleys; 500 ft 1-in casing line; set (2 each) extra heavy center-latch elevators for bits, with 72-in links; two sets 15.5-in casing tongs with bushings; 8-ft casing pole; 37 by 20-in casing block; 37 by 20-in triple-sheave block; No 3 derrick forge; No 3 slack tub; 400-lb anvil; set 450-lb tool wrenches with liners; rear casing wagon; 3 KW steam-turbine rig lighters; tool box; No 743 pipe vise; No 1 and 00 stocks and dies, complete; hand tools, pipe cutter, fittings and about 200 ft each of 2-in and 1-in black pipe. Approx total wt, 20 000 lb; cost, $10 300. Costs as of 1938.

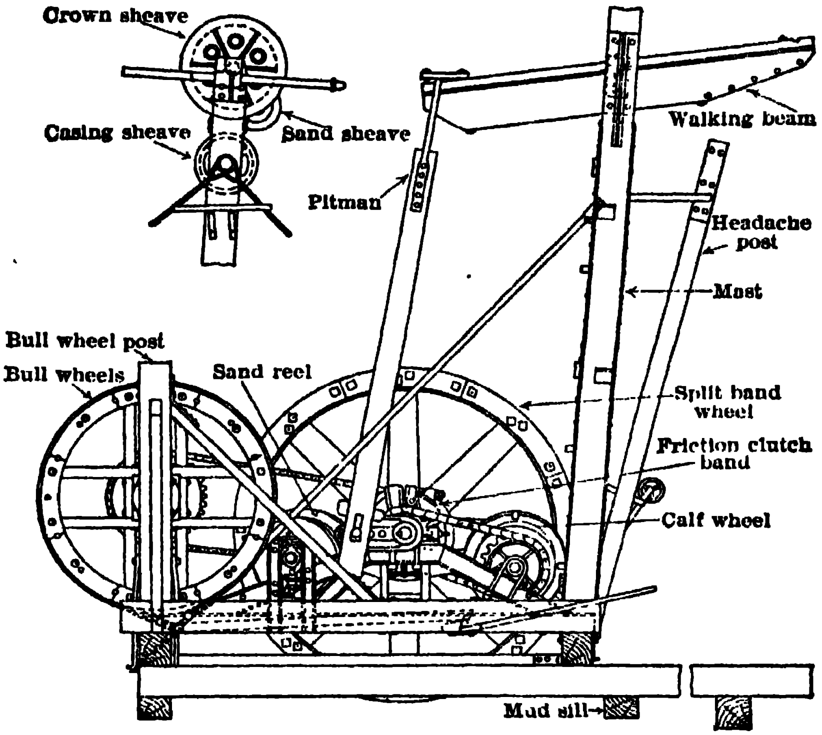


Fig 20. No 3 National Portable Drilling Rig

7. ROTARY DRILLING FOR OIL (see also Sec 44)

This important method had its inception in 1882, when the Baker brothers, drilling contractors, of Yankton, Dak, tried a crude bit on a rotating string of pipe, pumping water down the pipe to raise the cuttings in the annular space between pipe and walls of hole. About 1895, they interested 3 Texas water-well drillers, Johnston, Aikin, and Rittersbacker, formed the American Well and Prospecting Co, and built the first rotary outfit in Spindletop oil field, Texas, in 1901. The method has since been highly developed.

In rotary drilling, the bit, of various designs (Fig 24) depending upon the material drilled, is screwed to a string of heavy drill pipe (20–30 ft lengths), at upper end of which is a rod of square section, 30–60 ft long ("grief stem" or "Kelly"). This passes through a square hole in a horiz "rotary table," driven by engine or motor (Fig 21). During rotation, the Kelly and attached drill pipe, suspended by a swivel from a hook and multiple hoisting block, are free to move up and down. The cable is reeved under the hoisting block and over sheaves in the crown block at top of derrick down to the hoisting drum, which, driven through chains and sprockets with clutches, has 3 or 4 speeds. This apparatus is called the "drawworks." A "slush pump" forces muddy water through the swivel, down the drill pipe, thence through holes in the bit, and back outside the pipe to surface, bringing with it the cuttings. The discharge goes to the mud pit, where it is screened and settled for reuse.

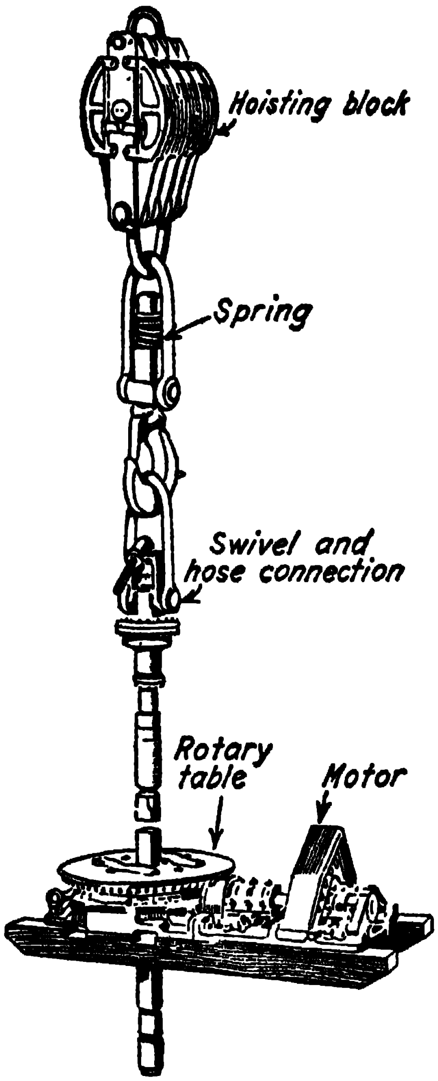

Fig 21. Rotary Drive (Union Tool Co)

Since about 1933, the technique has greatly improved. Drilling to 15 000 ft requires heavy, rugged equipment. Effects of temp of 200°–300° F must be controlled, and faster drilling done to economize costs. Important factors leading to better results are: concentrating wt close to bit by using more and heavier drill collars; hence, fewer failures at the neutral point, where tension changes to compression; increasing speed of rotation from 125 to 300 or even 400 rpm; use of wt indicators to show the load carried on bits; improved bits; shaker screens for cleaning mud fluid; applying methods of colloid chemistry to control and keep mud in best condition; higher steam press and use of superheated steam to lessen line losses; unitizing the individual drives of drawworks and rotary tables, with resultant better control; improved drill-pipe and tool-joint connections to minimize breakage; general use of survey instruments to check divergence of wells; better equipment for deflecting holes where required; use of equipment for shallow holes that can be quickly assembled or moved; skidding casing racks, pumping and drilling equipment, even derricks, to next location.

Driving equipment. Where fuel is cheap and good water available, steam plant is preferred, as drillers understand it better and engine can readily take overloads. Individual engine drives are favored for the rotary table and drawworks. In Okla City field (8), depth about 6 000 ft, 2 125-hp to 4 100-hp boilers are used; steam press, 250–350 lb. Water for steam rigs, 1 800–3 000 bbl per day, plus 400 bbl for slush pumps. For deep drilling in Calif (13 000–15 000 ft), plants range from 6 125-hp boilers at 250 lb press to 5 135-hp at 350 lb, steam superheated to 650° F. Sometimes a central boiler plant serves several wells. In Louisiana, for 10 000-ft wells, usual plant is 3 125-hp boilers, at 350 lb press, and 14 by 14-in twin engine. An effic steam plant, near Bird Island, Gulf of Mexico, comprises: 2 125-hp, 350-hp boilers, with feedwater heater and superheater, mounted on a barge; 136-ft derrick and substructure on piling; twin vert 12 by 12-in engine for drawworks; twin vert 7.75 by 7-in engine for rotary table; 14 by 7.25 by 18-in duplex pump; 7.25 by 18-in power pump, driven by twin vert 7.75 by 7-in engine with V-belt. Drilling below 7 100 ft, possibly to 12 000 ft, insulated steam lines and condenser reduced back press on engines and returned heated, clean water to boilers; approx 47 bbl of fuel oil and 300 bbl of water consumed daily for all purposes, the rig taking 200 bbl (18). If natural water is hard, a lime, soda-ash or alum chemical treatment is used. In Okla City field (9), such a plant treated 260 000 bbl water per day, at aver cost of 1 to 3¢ per bbl.

Diesel power is common where gas is corrosive because of sulphur content, and water too hard for boilers. As gas engines are limited-torque machines, a friction clutch is required to pick up load. The heavy loads in deep drilling impose severe strains on clutch and transmission parts. But, gas engines are economical; under aver conditions, 2 350-hp Diesels consume 7.5–10 bbl fuel oil, and 3–5 gal lubricating oil per day. With enclosed cooling system, water lost through evaporation averages 50 bbl per day. In KMA field, Tex, trend is toward two 225–250 hp Diesels for depths to 4 000 ft; fuel and lubricating oil cost 39¢ per ft on 11 000-ft wells, to 26¢ on 6 400-ft wildcat wells. In proved fields, costs are 19¢ per ft on 6 700-ft wells to 14¢ for 4 000-ft, where drilling conditions are average and fuel-oil is $1.70 per bbl. Total water for Diesel rig is about $^1/_{20}$ of that for steam. In an Eastern field, drilling to 6 000 or 8 000 ft, 2 200-hp 6-cyl gas engines used 40 000–50 000 cu ft of gas per day, and 100 bbl water. A steam rig in same region used 15–20 ton coal per day.

Electric power is flexible, easy to control and has high effic. First cost of a Diesel-electric rig is relatively high; operating and maintenance costs, low. Twin-motor drive is used on deep wells. Motors must be explosion proof, if well is gassy. Diesel-elec plant, with dc motors and Ward–Leonard control, is a very flexible unit. For medium duty, 2 260-hp Diesels drive 2 125-kw, 1 200-rpm dc generators, with two 150-hp, 200-volt, 900-rpm shunt motors, or one 150–300-hp, 220–400 volt, 450–900 rpm motor. Wash-down and fresh-water pumps use 2 5-hp 115-volt motors. Separate generators drive drilling and pump motors. For hoisting, 400-volt generators are in series. A drilling motor develops half full load at 220 volts and 450 rpm; hoisting motor, full load at 400 volts and 900 rpm. Two drilling motors are sometimes used.

Table 4. First Cost and Annual Charges of Prime Movers (10)

Type	First cost	Per-cent	Annual fixed and operating charges	Per-cent
Steam	$18 700	100	$37 800	100
Alternating current	31 160	166	24 500	65
Variable voltage, ac or dc	32 650	175	27 500	73
Gasolene engine, direct drive	41 090	220	40 500	107
Variable voltage (gasolene) dc	39 580	211	37 000	98
Diesel engines, direct drive	42 500	227	26 600	70
Variable voltage dc, Diesel drive	45 540	244	24 800	66

In Okla City field, to 1932, some 25 wells were drilled by elec power. Equipment ranged from two 65-hp motors to one 250-hp motor for drilling; slush pump motors, 150–250 hp. An aver for 21 wells, aver depth 6 484 ft, was 54.35 kw-hr per ft drilled. Delays in 7 wells caused abnormal consumption of current (8).

Special drilling outfits include: Oilwell-Hild or Ideal Halliburton differential drive, and Hydril rotary outfit; first two give close control over wt on bit; the last has a vert engine (geared to the rotary table), which lifts and lowers the drill stem by hydraulic jacks, and thus exerts a downward press on drill pipe, if drilling must be done under press, as when "heaving" formations are encountered (8). Hydraulic feeds are also obtainable. In general, use of weight indicators, improved bits, long lengths of heavy drill collars, and frequent surveys, have tended to faster drilling and closer control over the deflection of holes.

Derricks. Before standardization of equipment was begun by American Petroleum Inst, each manufacturer used his own specifications. As most makers have adopted API standards, much equipment is now interchangeable. There are 9 regular sizes of steel derricks (Table 5) and 8 of wood.

Table 5. American Petroleum Institute's Steel Derricks

No	Height, ft	Base, ft	Water table opening, ft	Capacity, lb	Weight, lb	Approx price, 1938
8	66	20	$4\,^1/_3$	159 000	9 730	$ 800
9	73	20	$4\,^1/_3$	159 000	10 560	825
10	80	20	$5\,^1/_2$	244 000	13 350	1 000
11A	87	20	$5\,^1/_2$	244 000	14 080	1 050
11	87	24	$5\,^1/_2$	333 000	16 560	1 200
12	94	24	$5\,^1/_2$	333 000	16 530	1 300
16	122	24	$5\,^1/_2$	537 000	30 120	2 300
18	136	26	$5\,^1/_2$	645 000	37 980	2 660
18A	136	30	$5\,^1/_2$	800 000	47 090	3 400

Sizes of wood derricks are same as in Table 5, except that No 10 has a 22-ft base. Columns 5, 6 and 7 give approx data for aver designs. Heights are measured vert from floor joists to bottom of water-table beams in top of derrick. API capac of steel derricks, stamped on name plates, is 4 times the static load capac of a single leg, based on safety factor of 2 at the yield point, or factor of 3.5–4 on ult strength of steel, omitting wt of derrick and vibration of live loads. It is good practice to assume the max crown-block load plus wt of derrick to be equal to the API safe working load. To this add wt of substructure and machinery supported by foundation piers, and distribute the total to determine max load on piers. Assume 1 1/8-in plow-steel cable, of 94 000 lb ult strength; if reeved 10 times through crown and traveling blocks, effective load on crown block is 94 000 × 10 − [(10 × 3.4%) × 940 000] = 620 400 lb; 3.4% being the loss per reeve. Due to eccentric loading of crown block and angular pull of drawworks and dead-end lines, a horiz component of the load is applied to top of derrick, reducing its capac. API specifications state: approx 20% reduction, if dead-end line is anchored to corner of derrick opposite drawworks side; approx 7% reduction if dead-end line is anchored to calf-wheel opposite drawworks; if the dead-end line is anchored to derrick on same side of drawworks, the derrick capac is reduced about 40%. Derricks are designed for wind load of 70 miles per hr. Derricks like Emsco or Ideco are built in 6–12 subsizes for each standard API height; main leg angles ranging from 5 by 5 by 3/8-in to 8 by 8 by 5/8-in. Special reinforcing members may be used, at added cost of $600–$850; that is, a No 18 derrick may be had in capacities of 243 000–1 132 300 lb. After completing the well, the reinforcement may be transferred to another derrick, the stripped derrick handling the pumping equipment. In general, a well should flow for at least 2.5 years to warrant replacing original derrick by a light one when pumping begins. Since wells are now being drilled to 10 000 or even 15 000 ft, derricks of 136, 175 and 185 ft are coming into use; one company proposes 250 ft. A new design in the Wasco field, is 178 by 26 ft, but instead of the usual uniform taper it is tapered slightly at first, to 18 ft square at 125 ft (the "fourble" board), giving more space for stacking drill pipe in stands of 4 lengths or "fourbles," within the derrick.

Tall Calif wood derricks have legs of five 2 by 12 and one 2 by 10-in plank, to form continuous laminated angles. Inside girts, 1.5 by 12 in, 16 ft apart; outer girts, two 2 by 12 in, spaced 8 ft, with 2 by 8 bracing. A combination wood derrick, 122 by 24 ft, requires approx: 40 500 bd ft Oregon fir and 11 540 bd ft redwood; wt, with wood parts of operating mechanism, about 146 750 lb; corrugated iron siding, roofing and nails, 2 960 lb. Wood derricks are now little used, except for shallow wells to keep cost low; local ordinances may prohibit them within 500 ft of a building. A small redwood derrick in one field cost, with casing racks and mud ditch, about $1 900.

Erecting derricks is done at fixed charge by skilled crews specializing in such work, or by oil company's men. Extras include: cellar, at top of hole, 6 to 20 ft deep and walled with concrete; derrick foundations; woodwork and corrugated iron for roof and wind break around bottom of derrick. Derricks may be set on a steel substructure, 7–8 ft high, that carries rotary table, drawworks and engine; or on concrete pillars, or steel extension legs may be used. A 122 by 24-ft derrick, API capac 465 000 lb, with concrete cellar and all woodwork, costs about $4 500. Approx cost of 136 by 26-ft derrick, API capac 935 000 lb: steel, $9 500; erection, $1 000; woodwork, $1 500; concrete, 100 cu yd, $1 800; total, $13 800. Concrete may amount to 70, 80, or 100 cu yd, at $12–$19 per yd. For a 150-ft derrick, Macco Construction Co gives aver labor cost of $1 500, equally divided between steel, concrete, and woodwork. To this add: say 70 cu yd concrete, 18 000 bd ft of lumber at $35 per M, and about $150 for corrugated iron. In Wyoming, erecting foreman is paid $14 per day; rest of crew, $11.50; labor on concrete, 80¢ per hr; 9 skilled men can erect an aver derrick in one day, all foundations being in place, and gin pole and hoist ready. An oil company gives following generalized costs:

94-ft	derrick,	steel	cost,	$1 600,	cost	erected,	$3 000
122-ft	"	"	"	2 300,	"	"	4 000
136-ft	"	"	"	2 800,	"	"	5 000
178-ft	"	"	"	6 000,	"	"	10 000

To reduce cost one company is trying out a portable derrick of 3 28-ft sections; total height, 84 ft; capac 323 000 lb; derrick will hold 2-joint stands of pipe (about 30 ft per joint), or say 6 000 ft of 3-in pipe, or 4 000 ft of 4-in. It is for drilling only; can be erected in 5.5 hr and dismantled in less time. Salvaging a 136-ft steel derrick costs about $250 for dismantling; loss in bolts, etc, $100–$150; total loss, $400. Local laws may require breaking out concrete and restoring ground to original condition. Salvage of woodwork, about 60%, large timbers can be reused, also form lumber and casing racks.

Skidding derricks from one location to another is increasing (11). Four skid plates, 10 by 10 ft on top and 7 by 7 ft at bottom, are connected to derrick legs by ball-and-socket joints. Another type is a heavy timber sled runner of two 8 by 10-in timbers, with tapered steel-shod shoes on each end, so that the derrick can be moved in either direction. One caterpillar tractor may do the hauling; 2 are better; 3 may be required. Dry ground resists skidding. Time to prepare derrick for moving is 14 to 16 hr; actual moving time, 40 min to 3 hr, at 1 mile an hr under good conditions; a 175-ft wood derrick was moved 3/4 mile for $1 000; distances of 3 miles have been reached.

Mud fluid (Sec 44). Functions are: to raise cuttings from the well; to cool and lubricate bit and drill pipe; to hold solids in suspension when drilling is stopped; to seal off minor oil, gas and water-bearing strata, by building up an impervious coating on walls of hole; to exert through its wt a press exceeding that of surrounding strata, thus preventing blow-outs of gas or oil (see Table 6).

Successful drilling to 12 000–15 000 ft, where the temp may be 260°–300° F, demands definite control over the mud fluid by applying principles of colloid chemistry. As clay contains only about 5% colloidal matter, more must be added to make suitable drilling mud. Good muds having marked fluidity when in motion are plastic when at rest, due to colloidal "gel-forming" (12, 13, 14). "Aquagel" (largely Bentonite) is a gel-forming substance; used alone with water, it gives a mud of 64 lb per cu ft, or 2–5% of it (by wt) is added to ordinary mud. "Gel strength" cannot be measured directly, but by noting the viscosity at outflow, and again after the mud has stood for 5 min; the difference indicates the "gelling" rate. This is important in very deep holes, where changing bits may take 8–10 hr. If gel strength is too low, cuttings will settle and cause bit or drill pipe to stick in the hole; if too high, it is difficult to start circulation on resuming drilling. Wt for wt, viscosity of colloids is 10 times that of solids; hence, percent of solids must be kept as low as consistent with necessary wt of fluid. Also, the higher the percentage of solids, the longer it takes to form the impervious coating on the hole walls. To remove solids at outflow, vibrating screens are best; mesh, 20 to even 60 in presence of much fine sand; 30 mesh is common for deep holes, where outflow may not exceed 200 gal per min; 20 mesh has been used for 750-gal flow.

To determine viscosity, the Marsh viscosimeter is standard; a funnel 6-in diam at top and 12 in long, with a $^3/_{16}$-in tube at bottom. It is filled with 1 500 cc of mud, and 1 000 cc is run into a measuring flask, the time required being noted with a stop watch. In laboratories, the Stormer viscosimeter is widely used. Wt of muds is found by the Braun Mud-rate hydrometer.

Formation pressures. Normal press is the hydrostatic head equal to depth of hole; but, due to geologic changes, press may vary from normal. In Calif, formation press rarely exceeds the hydrostatic; Table 6 shows the relation in Gulf Coast fields. When press is hydrostatic or less, a mud of 9.5 lb per gal (sp gr 1.4) is satisfactory if it contains proper amount of colloids (Fig 22). Viscosity should be between 25 and 30 seconds by test, to prevent entrainment of gas in the mud that might cause a blow-out. Assume 0.5 cu ft sand per ft of hole, containing 0.2 cu ft gas at 1 500 lb press; drilling speed 0.5 ft per min, releasing 0.1 cu ft gas at hole press or 10 cu ft at surface; 200 gal (27 cu ft) mud or 1 900 lb circulated per min at 9.5 lb per gal or 71.1 lb per cu ft. At surface the mud-gas mixture occupies 27 plus 10 or 37 cu ft, weighing 1 900.5 lb, or 51.36 lb per cu ft. As the aver wt of mud in the hole is $^1/_2$(51.36 + 71.1) or 61.2 lb per cu ft, the mud would be blown out. At a 15 000-ft well in the Wasco field, the mud was degassed in a steel cylinder, fitted with baffles, where it was subjected to a vacuum of 12–14 in, increasing its wt 10 lb per cu ft. Vol of gas from wells varies greatly in different fields; from 10 to 40 cu ft per bbl of oil, to as high as 100 000 cu ft. In some wells the mud is so badly "gas cut" that it must frequently be replaced by new mud.

Table 6. Formation Pressures in Some Gulf Coast Oil Fields (16)

When gas press is high, the mud may be weighted with a heavy material, as Baroid (mainly barytes), or Calox (Fe_2O_3), both of about 4.2 sp gr. As wt material adds little to viscosity, using too much causes some to settle out. The mud should be thinned, so that the clay just stays in suspension. Tested by diluting a sample in a beaker until free water shows on top after standing; then mix in the heavy material, until desired wt is reached (Fig 22). Gel strength may be increased by adding alkaline or soluble salts; decreased by sodium tannate or sodium gallate (15). Viscosity of an aver mud increases when temp exceeds about 185° F. As max dispersion of colloids occurs when the mud is slightly alkaline, the effect of chemical treatment should always be determined (17). Fig 23 shows a device for testing behavior of a mud; filter paper is placed over the screen *F* and cylinder *C* filled with 600 cc of mud; *C*, with its top closed by cap *A*, is set on support *K*. Air, or nitrogen, in the cylinder should be sufficient to maintain press at 100 lb for 3 hr; amount of water present being noted at intervals. Finally, pour out mud and remove filter cake; remove the soft layer by a gentle stream of water, measure thickness of cake and note its compactness; thickness and water loss are influenced by sand and salt content, gel-strength, viscosity, wt and percentage of solids; hence the test shows the over-all behavior of the mud and whether colloidal content is sufficient; a thick cake and high water loss are undesirable. Use of molten sulphur instead of mud is being investigated, for penetrating loose formations and consolidating them. On freezing, it makes an impervious supporting wall, nearly as strong as concrete.

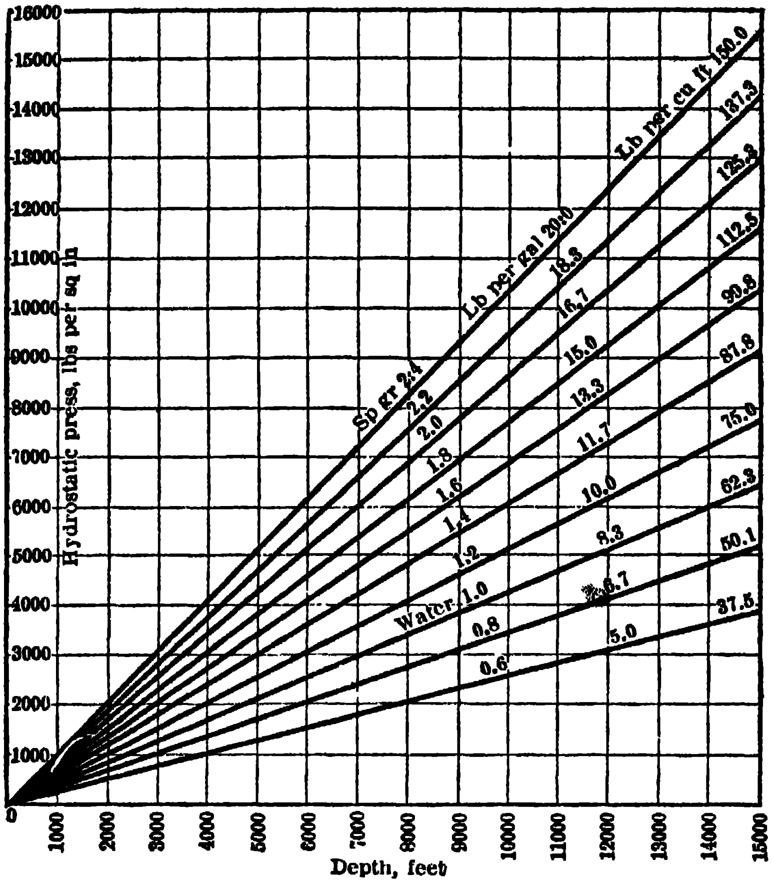

Fig 22. Pressures of Mud Fluids

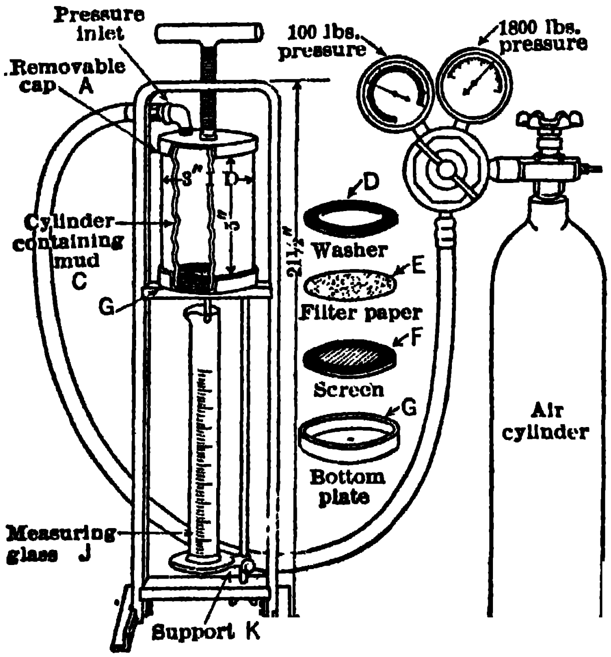

Fig 23. Baroid 100-lb Tester

Rotary bits and speed of drilling. Heat-treated alloy steels are used for bit heads; blades are drop forged from chrome-nickel steel and hard surfaced with Stellite or tungsten carbide; roller teeth wear longer, and cones have ball-bearings to insure free operation. Bits are designed in groups for service in: hard formations (chert, dolomite, basalt and quartzite); medium hard formations (limestone, hard shale and anhydrite); softer material (shales, salt, gypsum and chalk). Roller bits are customary for hard rock; fishtail (drag bits) for softer strata.

In Fig 24, *A* is Reed roller bit for hard ground; *B*, Hughes bit for medium ground and *C* for medium ground; *D* is 4-blade scraper or drag bit; *E* the Reed replaceable fishtail bit; *F*, Hughes roller bit for softer material. Many special bits are used instead of fishtail bits for soft top formations (19). In deep holes, requiring 5–10 hr to run drill pipe out and back for changing bits, any increase in footage per bit has a marked effect on total drilling time. Roller bits can not be dressed, and are scrapped. Fishtail bits can be sharpened, or new blades put on. Assume cost of $10 per hr to operate a rig. Fishtail bit costs $150, drills 32 ft in 8 hr, and 3 hr are required for round trip from bottom of well; then, $5 for dressing plus $110 for 11-hr operation makes $115 total. Actual drilling rate may be 4 ft per hr, but including round trip only 2.91 ft per hr, at $3.595 per ft. If roller bit drills 200 ft in 50 hr, with 3 hr for round trip; then $150 for bit, plus $530 for 53-hr operation, make $680 total. At drilling rate of 4 ft per hr, over-all aver is 3.77 ft, at $3.40 per ft. This comparison shows 29.55% increase in speed and 5.4% decrease in cost (20). Roller bits are generally rented from makers, not sold outright; rental, from $62, for 3.75 to 4.25-in size, to $700 for 25 1/8 to 26-in size. Replaceable-blade fishtail bits cost $30 for 4.25 to 5.5-in head, to $150 for 15 to 25-in head. Blades cost $2.75 per in, that is, a 10-in blade, $27.50; 4-blade drag bits, with blades welded in, from $60 for 6 to 7-in bit, to $199 for 20 1/8 to 23-in. For bits with 2 or 3 blades, deduct $10–$30 for each blade less than 4. In Rio Bravo field, Calif, one company used roller bits in drilling to 11 200 or 11 600 ft; three 17.5-in bits to 2 500 ft; then 12.25-in bits to 10 000 ft and 11-in below, totaling 75 to 85 bits per hole.

In Appalachian area, hard coarse-grained sandstone was drilled at rate of 1 ft in 15 min. Thin-bedded sandstone, 3 400–7 443 ft deep, required 50 8.75-in bits; time, 3–48 min per ft. In a chert, six 8.75-in bits were used in first 20 ft; drilling rate, 25–200 min per ft (21). In drilling 1 468 ft, largely anhydrite, in La, 15 hard-faced 12.5-in bits were used; time, 339 hr; aver per bit, 98 ft; aver hr run, 22.6; aver speed, 4.3 ft per hr; cost, at $148 each, $2 220; aver bit cost per ft, $2 (22). In a Texas field, 9-in holes from surface to 1 400 or 1 800 ft required 3 or 4 fishtail bits; below, through sharp sands, broken limestones and shales to 3 650 ft, 8–13 roller bits were used. Weight on bits, about 1 000 lb per in of bit diam (23).

Proper rotative speed and close control over wt on bits are essential (24). In upper part of hole, under favorable conditions speed may reach 300–350 or even 400 rpm, but 150–250 rpm are commoner. At depth, speed falls off to 125–150 rpm. In Calif, drilling rate may reach 160 ft per hr near surface, but only 2–3 ft per hr in very deep holes. Recently, an 11 500-ft well was completed in 61 days, from spudding-in to oil in tanks. Wells of 2 000 ft require 12–16 days; 4 000–4 500 ft, 18–25 days; 5 000–6 000 ft, about 30 days; 7 000–7 500 ft, 35–40 days; 8 000 ft, 55–60 days; 10 000–11 500 ft, 75–90 days, sometimes even 120 days.

Since rig expense may be $375–$500, or even $1 000 per day, it does not pay to use dull bits. Wt is brought close to bits by using drill collars (extra heavy pipe) just above bit. Actual wt on bit is wt of drilling pipe less flotative effect of the mud fluid. As much as 350 ft of 147-lb drill collars have been used; 80–200 ft of 80-lb collars are com-

moner. Wt on bits is generally shown by wt indicators, like the Martin Decker. In principle, a slight offset is made in the dead-end line. As the press making this offset is balanced by a small quantity of fluid back of a flexible diaphragm, it is a measure of the load on the line. Pressures are recorded either in lb, or "points" which must be converted into lb. The fluid press causes a hollow shaft, with smaller shaft inside, to move the recording pointer and vernier hand on the dial; a continuous record is kept on the other dial. In the "Quintuplex" form, the instrument records: steam press in engine as a measure of the torque required in drilling, rpm of rotary table, mud press in pumps, wt of drill pipe and of mud.

Examples of rotary-drill outfits. It is estimated that in U S 29 014 wells were drilled in 1937, of which 20 091 were oil wells, 2 531 gas wells and 6 392 dry holes (25). Aver depth, 3 230 ft. About 55% were rotary drilled. Rotary outfits are costly compared to the cable-tool, but are best for depths over 6 000–8 000 ft. Recently a deep well was completed in hard formation, after cable-tools failed to make further progress. Drilling equipment is subjected to hard usage, and its life is short. One operator states 1 095 actual operating days, or approx 4.5 years of elapsed time, as the serviceable life of a rotary outfit (25). Roughly, a light outfit costs $50 000, medium outfit $70 000, and a heavy outfit $98 000 (26).

A steam-driven rotary, for 2 000–3 000 ft, is as follows: two 100-hp locomotive type boilers, complete, each 27 090 lb; two 6 by 4 by 6-in boiler feed pumps, for 250 lb steam, with water end for 500 lb, each 818 lb; one 11 by 11 semi-enclosed twin-cyl horis steam engine, 7 635 lb; two 12 by 6 by 16-in slush pumps, each 8 300 lb; one 17-in oilbath rotary table, complete, 5 985 lb; 1 set 4.5-in rotary slips, 152 lb; 1 chrome nickel-steel square Kelly, 4.25-in by 40-ft long, 2 060 lb; 1 unit type rotary hoist, 13 500 lb; 1 500 ft of 1-in 6 by 19 API or Lang-lay plow-steel casing-line, 2 600 lb; one 7-in Wigle casing hook, with safety latch, 1 196 lb; one 2.5-in by 45-ft Thermoid No 325 rotary hose, with couplings, 620 lb; 4.5-in double side-door elevator, 150 lb; set 2.25-in by 72-in weldless elevator links, 304 lb; set 4.5-in extra heavy BJ rotary tongs, 674 lb; center-pin crown block, 2 770 lb; 4-sheave roller-bearing traveling block, 3 775 lb; 6-in oilbath swivel, 2 350 lb; total wt, 116 047 lb; approx cost, fob Los Angeles, $24 000 in 1938. The above specification does not include derrick, drill pipe, bits, steam lines, and misc tools.

Steam rotary equipment for depths to 5 000 ft (L. G. E. Bignell): 15-in sheave crown block; 66-in 4-sheave traveling block; 150-ton hook; 100-ton swivel; 27.5-in rotary table; hoist; double drive of two 7.75-in by 7-in vert steam engines, on skid base, with pillow blocks, clutches and sprockets; 7.25-in by 14-in slush pump; superheat steam generator; feedwater unit, consisting of 5- and 10-in by 6-in by 12-in heater pump, 10-in by 4.5-in by 10-in boiler feed pump, oil separator, 5-kw generator and steam turbine, skids, piping and valves; total approx wt, 140 000 lb; approx cost, $36 000. Additional items include: derrick, 4.5-in drill pipe, steam lines, wire line, and misc rig tools.

" Slim-hole " exploratory drilling refers to holes of small diam, bored by portable outfits. The first of these were diamond drills (Art 17), long used in oil fields, and recently built heavy enough for depths of 4 000 ft. Such a drill, mounted on a truck, has a folding mast or tripod. The automobile engine supplies power, with a special engine for the slush pumps. A similar truck-mounted outfit for driving a rotary drill has been developed especially for slim-hole work. It has a 60-ft folding derrick, and hydraulic feed for the drill pipe. A 6.25-in hole can be bored to 4 000 ft. Wt is about 64 000 lb, not including drill pipe; price, $35 000. Machines for 7-in holes to 6 000 ft weigh 75 000–80 000 lb; cost up to $45 000. For elec or Diesel engine drive, cost is $4 000–$10 000 more. Another slim-hole portable unit is mounted on skids. Gas engines are used; derrick of standard type. Diesel units cost about $40 000 each, as against $51 000 for a steam rig. Diesel unit in Table 9 drilled 6.25-in holes in west Texas for about $3 a ft. It is predicted they will be so improved that a skilled crew can drill holes for $2.50 a ft, everything included. One company found that holes in same formations and to same depth could be completed in 200 hr less time by 5 9/16-in drill pipe and 9 7/8-in bits, instead of 3.5-in stem and 6.75-in bits (reasons not explained, Apl, 1938).

Table 9. Comparative " Slim-hole " Drilling Costs
(L. G. E. Bignell)

	Light steam rig, 9 7/8-in hole, per ft	Diesel unit, 6 3/4-in hole, per ft
Rig labor	1.30	$1.42
Transport	.28	.14
Bit cost	.36	.522
Fuel	.375	.088
Supervision	.092	.092
Supplies and repairs	.395	.325
Indirect costs (wire lines, deprec, misc charges)	.645	.83
Totals	$3.45	$3.43

Use of seismograph (Sec 10A) for oil prospecting has created demand for light, mobile, fast-drilling rig for shallow holes of small diam for blasting. Cores may be taken, if desired. As many as 240 shot-holes, averaging 100 ft, have been drilled by one machine in 30 days, 16 hr per day. One type is mounted on a steel frame for placing on a truck, barge, trailer or skids; powered by two 4-cyl gasolene engines, for pump and drilling. Pump,

Table 10. Report on 60 Oil Wells in Nowata County, Okla, in Aug, 1936 (8 Star "K" Spudding Machines)

24 Drillers, 31 days at $6	$4 464
24 Tool dressers, 31 days at $5	3 720
1 Tool pusher, monthly wages	400
1/2 General supt's salary	250
1 Sample man, $150, and 1 office man, $125	275
1 Man on engines	150
Labor total	$9 259
Labor insurance, $11 per $100	$1 018.49
Interest on investment of $40 000 at 6%	200.00
Deprec and up-keep, 5-year basis	666.66
Expense of 3 cars, for supt, tool pusher, and sampler	350.00
Insurance and taxes	200.00
Gasolene, 2 gal per machine, 11¢ per gal	1 298.44
Engine oil, 2 qts per engine per 24 hr, 75¢ per gal	93.00
Total expense	$13 085.59
Cost per ft of hole, $0.4825	

These 60 wells were 445 to 460 ft deep; total, 27 120 ft. Time includes moving, drilling, cleaning out, and setting casing. 1 000 ft of 0.75-in pipe line (not included in above cost) drilled 30 wells (13 650 ft of hole), averaging over 10 ft of hole per ft of pipe. Cost 1.5¢ per ft. Total cost, $0.5008 per ft.

4 by 5-in, or 4 by 6-in duplex. Derrick is of tubular design, 24 ft high; capac, 12 ton. Bore is 3.25-in, to pass 2 3/8-in pipe and tool joints. For drilling to 500 ft, with 2 3/8-in pipe, machine weighs 12 000 lb; cost, about $10 000. Accessories: drill pipe and collars, 4 wing drag-bits, rotary hose, suction hose, slips for setting casing and tools.

Comparison of cable-tool and rotary drilling. The CABLE-TOOL driller can stop the hole in the most productive formation, with little danger of mudding off a producing stratum. If bottom water is drilled into, the actual depth of well is known and shutting off water is thus easier. Costs of equipment and operation are lower than for rotary drilling, but drilling speed is less, and it is difficult to complete a well where oil or gas pressures are high; tools may be blown out. The well can be filled with water or mud, but drilling is then very slow. More strings of casing are required, with much underreaming. Cable-tools use less water, and wt of equipment transported is less. ROTARY METHOD, though drilling about 10% faster than cable-tools, is used almost exclusively in soft formations and for holes deeper than 4 500–5 000 ft. As mud fluid controls high formation press, holes can be kept open for greater depths, and fewer strings of casing are necessary. Improved methods of drilling and surveying make it possible to keep hole practically vert, or to deflect it in any desired direction. Better coring equipment enables operator to determine nature of strata, and avoids danger of drilling through productive sands. Rotary bits can drill hard rock in which cable-tool bits make little progress.

8. CASING BOREHOLES AND OIL WELLS (27)

Casing is used: to prevent walls of hole from caving; to shut off water from running into oil formations; to close off oil or gas-bearing strata, in order to drill deeper, or prevent migration of oil and gas to surface or into porous strata above the producing horizon. In hard rock there is a little danger of caving, but holes in shales, sands and clays must be cased. If water is struck, it is shut off by a "water string" of casing, "landed" in some suitable stratum below the water and above the oil horizon, and the space outside is sealed with cement. If caving or water-bearing strata prevent carrying a single string of casing to bottom, several telescoping casings are used, from the surface down. Through the final "oil-string" the oil flows to surface. To admit oil or gas, the oil string is perforated, or a length of screened casing set at the producing stratum. A "liner" is a casing extending from bottom of hole up to and past the lower end of nearest water-string, or the last cemented casing. It saves running a full oil-string to the bottom; the latter is preferable, but more expensive. For rotary drilling fewer casing strings are required than for cable-tool, because the mud fluid plasters and shuts off water-bearing or weak strata. When the position and thickness of the formations are known in advance, the casing program can be pre-determined. If possible, the oil-string should be not less than 5.75 or 6 5/8-in diam, to insure sufficient space for the pump (Sec 44).

Kinds of casing pipe. Conductor or surface pipe is the lining through surface soil. It may be about 25 ft of riveted No 8 gage, or ordinary stove pipe. Seamless slip-joint casing (Table 11) has one end of each length belled out, to receive 5.5 to 6.75 in of straight casing to make the joint.

Inserted-joint threaded casing is used for light press; for drive-pipe (Table 12), the threads are cut so the ends meet in middle of coupling, to take the driving blow. Flush-

Table 11. Seamless Slip-joint Casing (weights and dimensions are nominal)

* Tentative API standards. On special order, casing has holes for tack-welding drilled in the bell. Permissible variation in wt is 10% above and 5% below; minimum tensile strength, 80 000 lb per sq in; in random lengths of 35-40 ft, unless otherwise ordered.

joint pipe serves for driving in sand or gravel. Casing is for lining to any depth, when hard driving is not required. A casing string of 250-500 ft is often set and cemented to form the surface string; advisable in deep wells to prevent blow-outs. Anchors ("blow-out preventers") are placed at top of casing, to hold the well under control if necessary. To lessen the number of casing sizes on the market, API Pipe Specifications list standard sizes (Table 13). Plain-end casing costs about 15% less than threaded; welded joints eliminate possible leakage, and effic is higher; as welded joints need less clearance, inner strings may be larger. By welding 2 40-ft joints outside, and then joining them at the hole, cost is reduced 5-12% below that of coupled casing (28).

Examples of casing programs. (*a*) for depth of 3 150 ft: set 15.5-in to 600 ft; 12.5-in to 1 200 ft; 10-in to 1 800 ft; 8.25-in to 2 400 ft; 6 5/8-in to 3 000 ft; 5 3/16-in to 3 150 ft. (*b*) depth, 8 500 ft: 50 ft of 24-in, 600 ft of 16-in, 7 540 ft of 9 5/8-in, 8 000 ft of 7-in, 500 ft of 5.75-in. (*c*) depth, 13 333 ft: 60 ft of 26-in, 310 ft of 18 5/8-in, 3 250 ft of 13 3/8-in, 6 640 ft of 7-in, 13 333 ft of 5-in liner. (*d*) depth, 10 960 ft: 99 ft of 20-in, 1 494 ft of 13 3/8-in, 10 950 ft of 5-in.

* Fob Calif R R terminals; min carload, 60 000 lb.

Results in the 15 004-ft Continental Oil Co's well indicate that, in drilling to great depths, even slight deviation would cause failure of the pipe from friction against the walls; "protection" casing eliminates friction. Special alloy steel pipe (yield point, 100 000–120 000 lb per sq in) is stronger than API Grade D, and would therefore extend drilling limit.

Tubing, 1.5–4 in diam, is hung in well at completion for the flowing oil (Sec 44). It prolongs the flowing life of a well by creating back press from friction; frequently reduces the gas-oil ratio; and is ready when pumping begins. By control valves (flow " beams ") at the surface, oil is flowed through tubing, or through both tubing and space between it and casing. Fig 25 shows how one well can be made to produce from 3 different zones; lower terminal zone, through tubing; upper terminal, through space between tubing and 5-in flow string; "ranger" zone is cemented off, but would produce through space between 5-in and $8\,^5/_8$-in strings on sealing this space below the ranger and perforating the $8\,^5/_8$-in line at that zone. Mechanical perforators can be used, or the recent "gun-perforator" (29). The latter is a steel cylinder, containing 10-12 short 45-caliber gun barrels; it is lowered inside the casing, and shots fired by elec control; by reloading, 180 holes have been made at 3 200 ft depth in 7 hr, and 1 431 holes at aver depth of 8 000 ft in 73 hr; holes can be placed 6 in apart in a spiral.

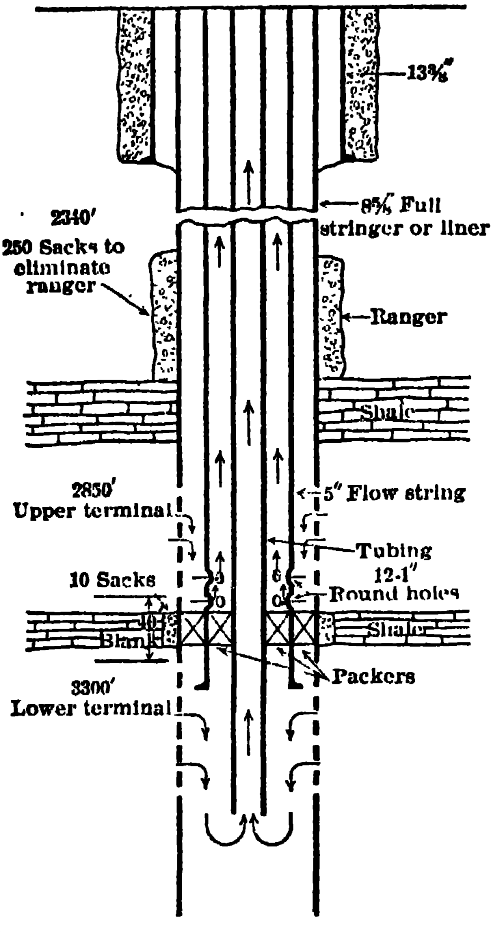

Fig 25. Multiple Zone Production (*Oil Weekly*)

Handling casing. Each string has a steel shoe (Fig 26), of slightly larger diam than the casing. Shoe may be serrated, for cutting through small obstructions, but this is not desirable where casing is to seat tightly on solid formation, for shutting off water. To drive casing, clamps are bolted on the squared end of drill stem, and by operating the drilling tools as in spudding (Art 6), the clamps strike the casing drive-head (Fig 27). Hard driving may deform or telescope casing; it is safer to drive by a rod or casing spear, set inside near the bottom, and striking this with the jars.

For lifting casing a clamp and elevator are used. Fig 29 shows a heavy clamp, with slips for gripping flush-joint casing. Two steel links pass through the elevator eyes and hang from the hook under the traveling block. On lowering into the hole, casing is held, while elevator is being released, by slips dropped into the pipe ring (Fig 28), resting on top of conductor pipe. When wt of a long casing string becomes great, the pull on the derrick can be lessened by "floating" the casing. A plug, screwed on lower end, buoys the string in the mud fluid. Fig 30 shows a plug that serves to guide the casing, and aids in floating it by a ball valve excluding outside fluid, and through which cement can later be pumped down for cementing casing in place.

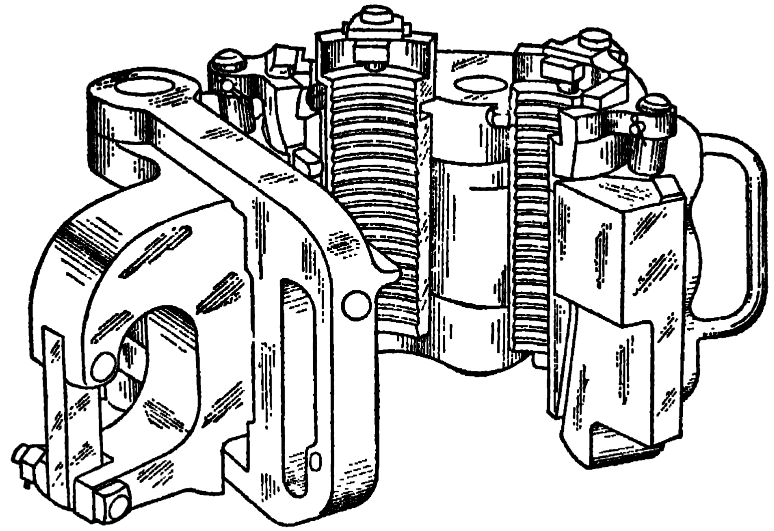

Fig 29. Ideal Door Grip Tubing Elevator

Casing troubles include collapsing, telescoping, freezing, parting and splitting (30). If casing pipe is dented or partly collapsed, swages are driven by the jars down and back past the injured place. This may so weaken the pipe that an inner string of casing is necessary. If casing parts, it may be recovered, by a bulldog spear, trip spear, bell socket, or an overshot; for details of these and other casing fishing tools see makers' catalogs.

If casing is so damaged that it cannot be recovered, it may be drilled past (sidetracked), if ground is soft and caving; sidetracking in hard ground is difficult. Drilling on the damaged casing, with the regular string of tools, is continued until it is sufficiently displaced to insert a new string, which must usually make a slight bend to get by. "Frozen" casing, or if collar-bound by loose material, can generally be freed by raising and lowering it 15–20 ft a few times; or, bailing out may cause enough hydrostatic pressure outside the casing to clear away obstructing material. If hole is too small, casing should be pulled above the tight place and the hole reamed. Heavy pulling on frozen casing may wreck the derrick; jarring may be more effective. A strong pull can be exerted by screw or hydraulic jacks on the surface, while the casing is vibrated by a spear and fishing jars. A casing cutter or splitter can be used to cut off casing at a desired point, or to split frozen casing for pulling it more easily. In rotary drilling, rotary jars give the same effect as jarring with cable-tools.

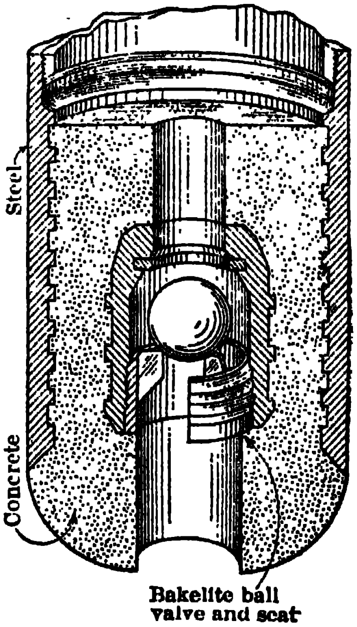

Fig 30. Baker Cement Float Shoe

Strength of casing. Resistance of lap-welded pipe is given by Stewart's formulas (National Tube Co): $P = 50\,210\,000\,(t \div d)^3$, and $P = 86\,670\,(t \div d) - 1\,386$, where P = collapsing press, lb per sq in; d = outer diam, in; t = thickness, in. First formula is for values of P less than 580 lb, or $t \div d$ less than 0.023; second formula, for greater values. Allowable hydrostatic press on casing $P = 2St/d$, where P is in lb per sq in, t is thickness of pipe wall, in; d is outside diam, in; and S, allowable fiber stress (14 000–16 000 lb per sq in for lap-welded steel, Grade A seamless; 18 000–20 000 lb for Grades B and C; 24 000–26 000 for Grade D; 12 500–14 000 lb for iron). Bursting press is computed by same formula, replacing S by tensile

strength: 48 000 lb per sq in for Grade A, 70 000 for Grade B, 75 000 for Grade C, 95 000 for Grade D, 42 000 for WI.

9. MEASURING DEPTH OF WELL (31)

For deep wells the only practical method is to measure the drill pipe used; each length separately, or in stands of 3 or 4 lengths, as stacked in the derrick. Accuracy requires corrections: (*a*) for the slight bending of pipe lengths as they stand off the vertical; (*b*) for expansion due to increase in temp (bottom temp of the Continental 15 004-ft well was 300° F). Temp of circulating mud is a little less than bottom temp. Amount of expansion is $L = L_0\,(1 + 0.0000069\,t)$, where L_0 is length in ft at atmos temp, and L is length due to t° F. Drill pipe suspended in the well stretches from its own wt, but salt water or mud fluid lessens stretch (Fig 31). Under field conditions, multiply results from Fig 31 by 0.666, as pipe friction absorbs about $^1/_3$ of wt.

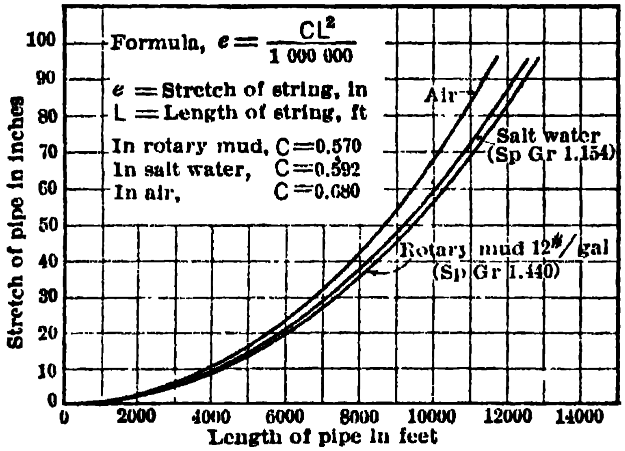

Fig 31. Stretch of Casing, Tubing, or Drill Pipe in Uniform Strings, freely Suspended in Various Flotants, without Float Plug (*Oil Weekly*)

Measurement is best made from top of collar on upper end of a length down to a centerpunch mark close to threads on lower end. After screwing on a length, the distance from the mark to top of collar below is added to previous measurement. For cable-tools, measurement may be made by a weighted mine rope, but the method is subject to errors, due to stretch and slippage on the reel. By using a counting mechanism as a rough check, and placing on the rope calibrated marks at 100-ft intervals, it is possible to reach an accuracy of 1 in 5 000, provided the rope is periodically recalibrated; it should not be reeled up faster than 1 ft per second; cuttings or caved material may prevent the weight from reaching bottom (31).

10. CEMENTING CASING (33)

Chief objectives: to prevent oil or gas from passing up and water from going down outside casing; to strengthen casing against collapse by outside press; to exclude corrosive water from contact with casing; to reduce gas-oil ratio; and to strengthen leaky casing. Cement must be thin enough to be readily pumped. To provide space for cement in a cable-tool hole, diam of which is a little greater than the casing couplings, the hole above the casing seat is under-reamed. Rotary holes are usually enough larger than casing, but all solids back of casing must be removed, as a thin skin of cement may be cracked (33–35).

Dump-bailer method. A large special bailer lowers the cement into the hole, the casing being first lifted 20–40 ft off the bottom, and kept above the level of the cement. For a dry hole, or when it will not stand full of fluid, 20–40 sacks of cement may be placed first, and the casing lowered into it without a plug. The usual practice is to place the cement, and fill casing and hole with water; then put a tight cap on casing and lower it, thus forcing the cement up behind the casing. The same result is obtained by putting a cement plug in the casing shoe, but this is unsatisfactory for large quantities of cement, or if there is a high-pressure flow of gas, oil, or water. TUBING METHOD. Cement is pumped through 2- or 3-in tubing, reaching to within a few ft of bottom of hole; circulation being first established to insure that the cement will rise freely outside the casing. It is prevented from rising inside by packing or a plug, closing the space between bottom of tubing and casing; or, without a plug, the casing is tightly capped and filled with water. After placing the cement, the tubing is flushed out by pumping down water, which returns inside of casing. Water should be kept in the casing until the cement has set. This method requires considerable time for handling the tubing; but, any desired amount of cement can be left in the casing, there is less danger of caving in cable-tool holes due to the smaller volume of wash water, and cement can be placed under a high pressure. CASING METHODS. Cement is pumped through the casing, with or without plugs between the cement and the fluid above and below. Without plugs, the water pumped on top of the cement must be measured, so that the exact position of the cement left inside the casing will be known. The TWO-PLUG or PERKINS METHOD is usual. One plug is long enough to reach up into the casing from bottom of hole, but is tapering at the top, so cement can pass between it and the casing. The other plug, set with a tight gasket on top of the cement, is then forced down by pumping until it strikes a spacer, a stick of soft wood 5-25 ft long, standing on lower plug; amount of cement left inside the casing is thus adjusted. Position of top plug can be checked at any time by the amount of water pumped in. This method is simple, effective, and adapted to both cable-tool and rotary holes. One plug only, placed above the cement, may be used. A shoe guide stops it at the lower end of casing; or the plug is long enough to touch bottom, while its upper end is still inside the casing. Another device is the BAKER FLOAT COLLAR, placed between two casing lengths; if placed on top of the last length, a ball closing against a seat shuts out mud, and so floats the casing into place. As cement is pumped down, the ball drops, letting the cement pass. Cement and collar are drilled out after cement has set. MULTIPLE-STAGE CEMENTING (Halliburton Oil-well Cementing Co) is another method for large-scale work.

Formation-testing permits testing for production without the expense and work of setting casing, or testing cementing for leakage. Fig 32 shows the Johnston tester. Body of tester is above the packer, and the "anchor," a short length of perforated pipe, extends below. Main hole is topped above the formation to be tested, and a smaller hole with a reamed tapered shoulder is drilled with a core-drill. The well is filled with mud fluid and tester is run in on an empty drill pipe. When the packer is seated, it seals the hole below. The fluid below runs through a valve into tester and up into the drill pipe. The formation is thus relieved of wt of the mud column and is practically under atmos press, whence gas or oil will flow into anchor under its own press. After about $1/2$ hr a valve is closed to retain sample in tester and latter is withdrawn after release by equalizing the press above and below.

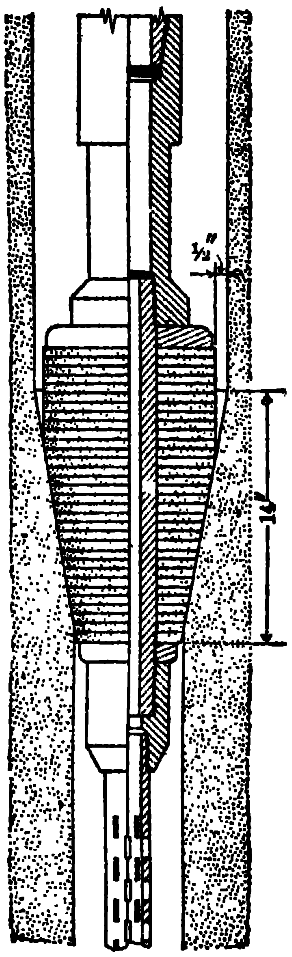

Fig 32. Johnston Formation Tester

11. SAMPLING BOREHOLES (see also Sec 10)

In cable-tool holes, sampling is done with the bailer, which brings up a sludge containing some unpulverized material. The sample is stirred and washed for settling the coarser particles, from which the nature of the strata is determined.

In rotary drilling sampling is more difficult. The circulating mud brings up the cuttings, which, if coarse, are generally caught by vibrating screen or improvised baffles or riffles in the ditch or launder through which the mud flows.

A fairly accurate sample is obtainable by stopping drilling, leaving the bit on bottom and pumping mud through drill pipe to clean out cuttings. The first cuttings showing in the mud come from last stratum drilled. As this procedure requires several hours in deep holes, it is not often used. Time required for cuttings to be brought to surface by the circulating mud may be computed (37) by the formula: $N \quad \frac{D(R^2 - r^2)}{x^2yzE}$, where: N = minutes for cuttings to rise from bottom to surface; D = depth of hole, in; R radius of hole, in; r = outer radius of drill pipe, in; x = radius of pump cyl, in; y = stroke of pump, in; z = number of strokes per min; E = effic of pump, usually 60%. Also, paint or dyes may be placed in the mud and time noted for reappearance at the surface.

Accuracy of samples. As drilling crews, whether cable or rotary, generally try to make speed, samples may be far from accurate. At best, pulverized material is hard to identify, and is frequently contaminated by particles from upper part of hole. As the plastering of a rotary hole with mud tends to seal up the oil sands, productive sands have been drilled through unrecognized. Cable-drilled holes also have passed through an unrecognized oil sand. The need for more accurate samples has caused rapid improvement in core sampling.

Core samples are usually taken of each stratum drilled to determine porosity, permeability, and water-oil ratio. In rotary coring, the bit is attached to the drill pipe; for cable-tools, the core bit and barrel replace the regular bit, and are operated similarly. The holes are 3.75 to 9.75-in; cores, 1.25 to 3-in. Rotary core drills comprise those with the usual inner and outer tubes, and the retractable type. In the first, the inner barrel rotates with the drill pipe, or may be non-rotating. The latter gives a higher core recovery,

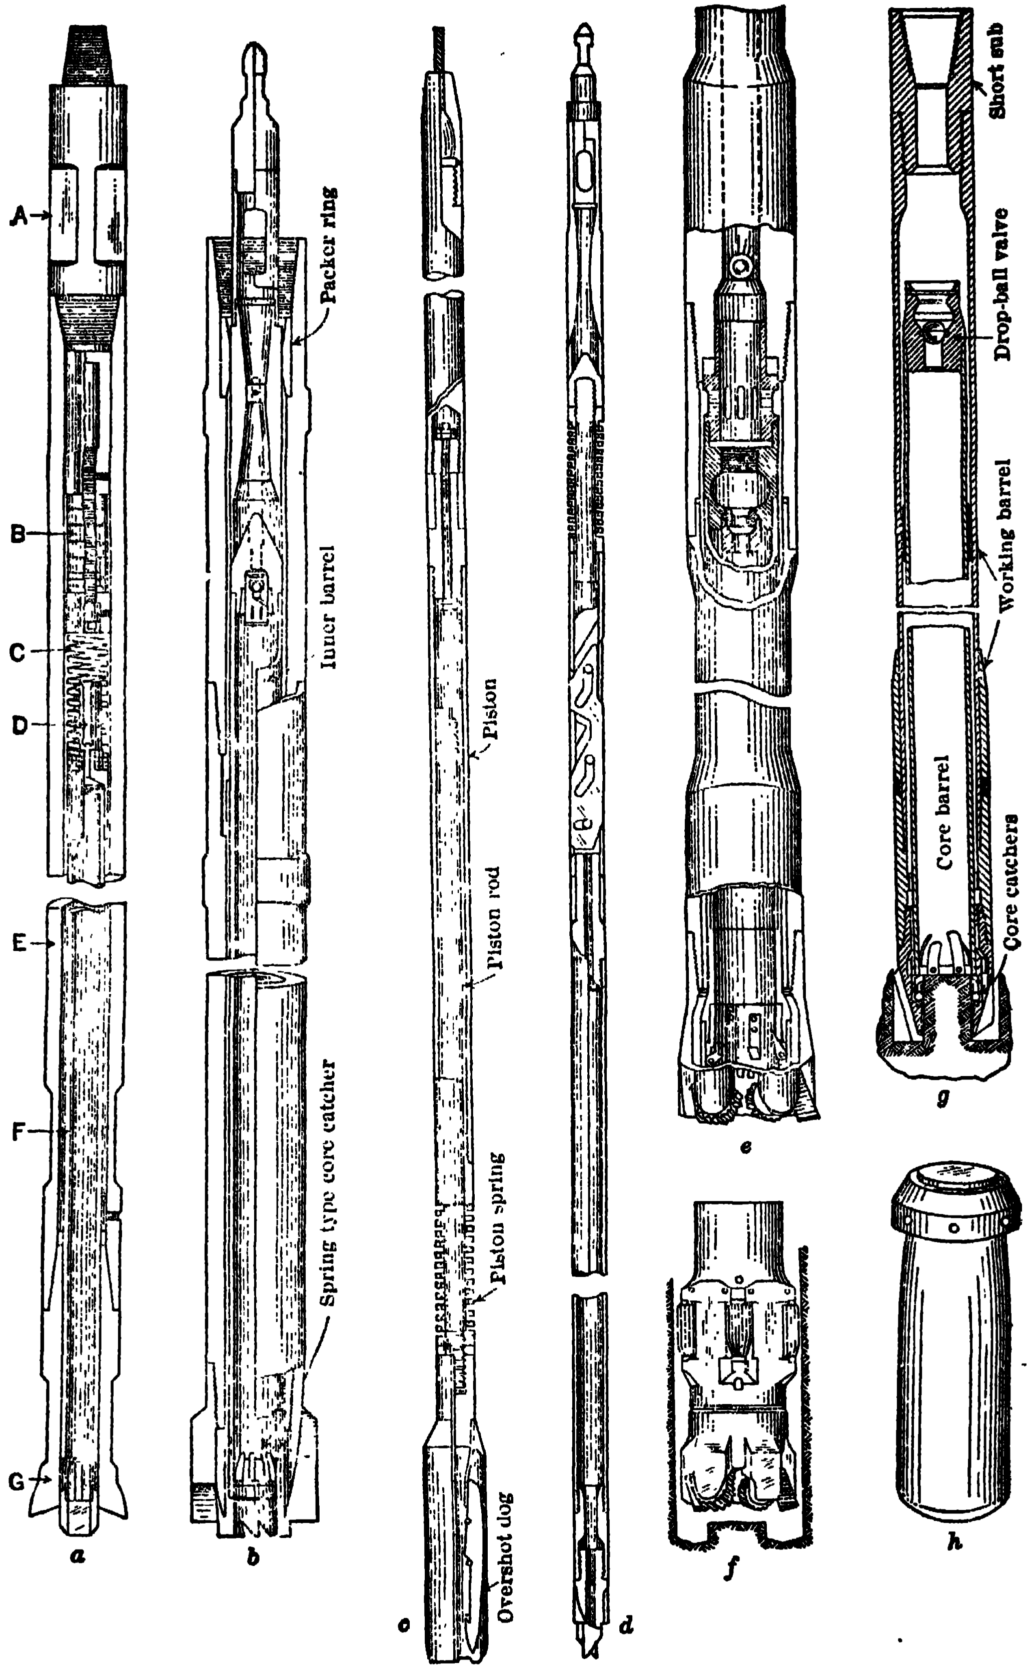

Fig 33. Core Drills for Oil Wells

especially in softer formations, cutting cores up to 5.5-in or larger. The retractable type cuts cores of 1.25-2.5 in. The outer barrel carries a bit cutting a full-sized hole, but has a central opening into which the cutting head can project for taking core. For coring, the barrel is dropped into the drill pipe from the surface, and automatically locks itself on the bit. When core has been cut, an "overshot" (Fig 33*c*) is lowered on a wire line to retrieve the core drill, thus saving the time of making a round trip with drill pipe. About 1 min per 500–1 000 ft is allowed for the barrel to drop through the drilling mud; retrieving speed, 300 ft per min. In soft formations, a main bit may drill several hundred ft, and the retractable core drill be used for all or any part of the distance, without raising the drill pipe. This corer has saved 35 round trips of the drill pipe, in coring 750 ft. Coring speeds are usually 50–75 rpm, ranging from 25 to 110. Fig 33(*a*) shows Elliott cable-tool core drill, in which *A* is upper sub, *B* adjustable weight, *C* spring, *D* valve, *E* and *F* outer and inner barrels, and *G* bit. Fig 33(*b*) is Elliott wire-line retractable rotary core drill, and (*c*) is overshot assembly for retrieving the inner assembly after core has been taken. Drilling assembly (*d*) is to replace inner barrel in (*b*) when no cores are taken. (*e*) is Reed core drill with hard-rock bit; (*f*) same bit with reamer; (*g*) Hughes' core bit for soft rock. (*h*) is core-barrel plug, fastened in lower end of core barrel with light rivets, which shear off when plug strikes bottom of well, the plug rising to top of core barrel and making way for incoming core.

In general, the smaller the core diam, the poorer the recovery, but small diam is necessary at great depths. Most difficult to core are conglomerates and shales, as they break up and wedge in the barrel. In Okla City field, about 50% of length cored is recovered, when larger than 2-in diam. Length of core has only slight effect on percentage recovery (38). Under favorable conditions, nearly 100% core recovery is possible. Recoveries in deep Calif well were: 428.5 ft of core represented by 78.7% recovery; 30 ft of core, 68.1%; 137 ft, 59.1%; 6 ft, 23.1%; 40.5 ft, 88.1%. For costs of coring, see Table 16, 17.

12. CONTROLLED DIRECTIONAL DRILLING

A hole may be drilled vertically, or deflected as desired. Wells are deflected if an oil deposit is under a navigable stream, valuable building site, a restricted area, or where topography is precipitous; or a well may be on the downthrow of a fault, making it desirable to direct the hole across the fault into the oil sand, on the upthrow side. The rig is then set in a convenient location, and the hole deflected as desired.

Directional drilling is done by tools that will produce a curved hole, the position of the bottom being checked at intervals by surveys (Art 24). The tools most used are the following. EASTMAN "REMOVABLE WHIPSTOCK" (Fig 34) is a chrome-steel casting, 5.5–13.5 in diam and 9.5–12 ft long, with a wedge-like point to prevent turning after being set in place, and a tapered deflecting groove along one side. A collar at top, loose around the drill pipe but too small to pass the bit, permits retraction when the bit is withdrawn. If, after the whipstock has been removed, the deflection cannot be increased by controlling weight and using special bits, additional whipstocks are set, say 50–80 ft apart. LANE WELLS "KNUCKLE JOINT" (Fig 35) is attached to lower end of drill pipe. By a universal joint, spring-actuated cam and a square shoulder, a diamond-pointed bit is held at an angle (about 5°) to axis of hole. The bit is spudded at first, the universal joint permitting the knuckle joint to take the new direction. After drilling say 20 ft, the knuckle joint is replaced by a regular bit, and the flexible drill pipe readily takes the bend. Finally the hole is reamed to full size. Kinsbach "casing whipstock" (Fig 36), containing deflecting wedge and locking device, is bolted to drill stem, lowered to desired depth, and oriented. By raising slowly, the locking device is tripped; and by applying weight, bolt is sheared, releasing drill stem. A milling tool is then attached, for cutting a hole through the casing, thus deflecting the well. For an uncased well, Eastman hydraulic bridger (Fig 37) is attached to drill pipe with arms folded, and lowered to depth, then maneuvered until arms spread outward into sides of hole, locking the device in place. A wedge or whipstock is then set on the bridger to cause deflection.

Hall-Rowe method of deflecting boreholes (59), as applied to diamond drilling (Fig 38). A dry wooden plug *A*, grooved to admit water, is pushed down the hole with the rods to the desired point of deflection, and is allowed to swell. Clinometer *B*, with drive wedge *C* attached by copper rivets as shown, is scribed with a reference line in known relation to position of wedge, and contains a glass tube partly filled with dilute HFl, snugly fitted inside. The assembly is lowered to within a few inches of plug *A* and then dropped freely, thus shearing the rivets and driving wedge *C* into the plug. The clinometer is allowed to set for $^1/_2$ hr, then pulled up, leaving the drive wedge behind. Etched portion of glass tube (see Art 24) shows position of liquid surface of HFl when in hole, and this, in relation to reference line, shows orientation of drive wedge *C* after placement, also showing dip of hole. "Deflecting wedge" *D* has a groove of EX diamond bit size (Table 32), cut at a slight angle to axis of wedge and scribed along its center line for orienting. A "pilot wedge" *E* is screwed to lower end of *D* and set so that its flat side will fit that of the drive wedge *C* when *D* is properly oriented. For attachment to drill rod, a special coupling *F* is fixed by copper rivet to the ring at top of deflecting wedge *D*, which is thus lowered into the hole until pilot wedge *E* rests on drive wedge *C*. On being rotated until their flat faces coincide, the pilot wedge drops 2 in into place, orienting *D*. Shearing the copper rivet in coupling *F* drops the rods 1.5 in farther, but stretch in the rods must be taken into account, amounting at 1 500 ft depth to about 2.5 in. Rods are now withdrawn, the ring at top of *D* is reamed off with a rose bit, and a deflected hole drilled along the groove with EX bit and core barrel to a point 3 or 4 ft below *D*. The hole and the wedge *D* itself are then reamed out with an AX pilot diamond reaming bit, and regular drilling resumed. It requires about 5 shifts to complete one wedging operation properly; aver correction per wedge, about 1.5°.

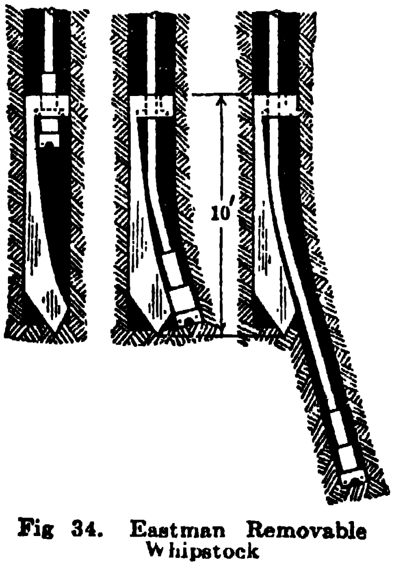

Fig 34. Eastman Removable Whipstock

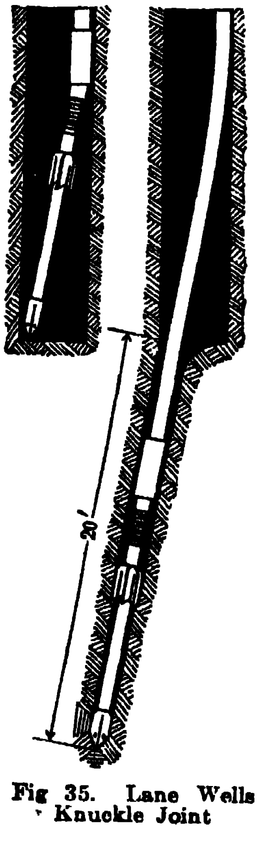

Fig 35. Lane Wells Knuckle Joint

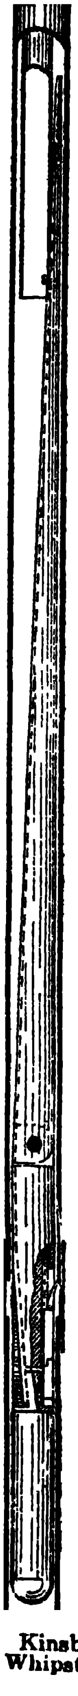

Fig. 36 Kinsbach Casing Whipstock

By using stiff or flexible drill-pipe collars, special bits (Fig 39), or reamers, different speeds of rotation, and varying wt on bit, the degree of deflection can be controlled. A vert hole is difficult to control, as it tends to corkscrew. A drift (deflection) angle of about 6° is most desirable, though it may be as much as 15°. Total deflection may be 50–60° from the vert. Hardness and dip of strata have an important effect on deflection (38, 39). Cost of directional tools and supervision have averaged about $1 000 per well. Assuming $1 200 for extra rig time, the total cost would be say $2 200 for deflecting a 3 600-ft hole. In one case, a 3 600-ft hole was deflected nearly 700 ft horizontally, missing its objective by only 8 ft. A high degree of accuracy is attainable by drilling slowly and making frequent surveys. Most directional drilling and surveying equipment is owned by firms specializing in the work; or equipment may be rented by oil companies. There is a saving in both time and cost by starting directional drilling at the proper point, rather than attempting to drill a perfectly directed hole from top to bottom.

13. COST OF OIL-WELL DRILLING

As no standardized form of accounting is followed, data on costs may be confusing. Actual drilling time varies greatly in different fields, depending upon local conditions and previous experience of the operator. Hence, aver figures should be used only as a general guide. Costs may be segregated as follows: 1, rig and equipment; 2, pipe and fittings; 3, casing and "cellar" connections; 4, production equipment; 5, construction labor; 6, drilling labor; 7, contract labor; 8, water, supplies and rig repairs; 9, fuel and power; 10, circulating fluids; 11, trucking; 12, outside and company rentals; 13, repairs; 14, indirect charges; 15, supervision.

Examples. In KMA field, Tex, where the sands are productive from 400 to 1 700 ft, a well can be drilled and " put on pump " for $2 000. Recent deep drilling disclosed new oil sands at

about 3 700 ft; wells drilled with rotary to 3 650 ft, and completed with cable tools; time, 30 days per well, which may be lessened as drillers become familiar with field. Flowing wells reach stage of delivering to tanks for about $25 000, of which $12 000 is for contractors, and $13 000 for piping, separators and tanks.

In Calif the following figures are for aver conditions: wells of 4 000–4 500 ft, completed in 18–25 days, cost, $35 000; 5 000–6 000, 30 days, $45 000; 7 000–7 500, 35–40 days, $60 000–$65 000; 8 000, 55–60 days, $75 000–$90 000; 10 000–11 500, 75–90 days, $150 000–$170 000. A rig costing about $100 000 should drill 5 wells. Cost of rig and casing, about 1/3 of total; drilling tools, 1/3; drilling and supervision, about 1/3. For depths of 5 000 or 6 000 ft, directional drilling costs from $2 000 for good conditions to $10 000 for bad; surveying, $350–$500.

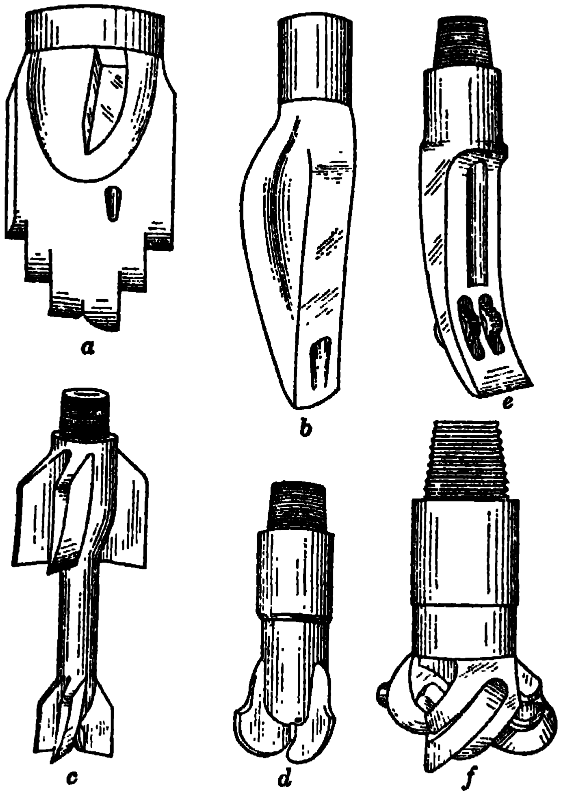

Fig 39. Special Bits for Directional Drilling

In Penn, rotary drilling to 7 500 ft, direct costs were $7.66 per ft, indirect costs, $3.16; total, $10.82 per ft. This is $724.62 per day elapsed time, or $805.21 per operating day. Cost of bits and parts, $2.32 per ft; payroll, $1.81; freight, etc, $0.62; drill stem deprec, $1.37. Gross cost of other wells, drilled 1937–38: cable-tool well, 7 050 ft, in Washington Co, $149 000, or $21.13 per ft; rotary well, 7 502 ft, in Westmoreland Co, $94 371, or $12.58 per ft; rotary well, 6 454 ft, Potter Co, $7.78 for drilling and $1.53 for casing; total, $9.31 per ft.

Table 18. Approx Costs of California Oil Wells

Field	Av depth, ft	Av cost per ft	Field	Av depth, ft	Av cost per ft
Huntington Beach......	4 350	$13	Kern River............	2 800	$13
Kettleman..............	8 800	22	Lost Hills.............	1 500	12
Stockton...............	5 300	13	Mountain View....	5 300	15
Greeley................	7 800	13	Semi-Tropic and Trico..	2 400	16
Torrance Refinery.....	7 200	12			

Cost of "bare" well, excluding production facilities, is about 95% of above figures.

Most wells in Table 23 were drilled in 1938, and represent latest practice. Higher cost of the deeper wells due to more complicated casing problems and harder formations. Wide variation in cost of rigs or derricks; on deeper wells, derricks were moved to new locations, and depreciated approx 10% per move. Now, the derrick is considered part of drilling equipment, and daily rental is charged, based on 1 000 days' life; thus, a $6 000 derrick

(*a*) Routine development drilling in fairly easy formation, with moderate dips.

(*b*) Wildcat (exploratory) well, deepest ever drilled; cost very moderate for such wells. Production or development wells may be drilled here for $15–$17 per ft. Most of strata in the area are easily drilled; dips flat or slight.

(*c*) Routine drilling of development well in hard, steeply-dipping beds.

(*d*) Routine drilling of development well in medium hard sediments; dips moderate.

(*e*) Very difficult area of moderate dips; extremely hard formations for coring. Many fishing jobs caused by drill-pipe twist-offs. (*f*) See casing item.

cost $6 per day; shallow wells have been drilled with portable masts, no derrick cost charged. Wildcat wells vary greatly in cost, of fuel, water, mud and kind of formation; 2 recent wildcats, to 10 000 ft in San Joaquin valley, cost $26 and $8 per ft respectively; in the first large quantities of weight material were used to hold back caving shale, and finally a protective casing-string was set; in the other well, no casing or weight material were necessary. Cost of daily operation for light gas-engine equipment, for drilling to 5 000 ft, averages about $400 per day. Heavy steam drilling equipment, for 10 000 ft costs $600–$750 per day, depending on cost of fuel and water. Extra heavy steam equipment for 15 000-ft wells costs from $750–$1 000 per day.

(a) Misc labor, tools and supplies; freight, hauling, drilling mud, fuel, water, acidizing, shooting, cementing. (b) Chiefly alternating limestone and shale beds, relatively hard. (c) Drilled with cable tools; all other holes drilled chiefly or entirely with rotary. (d) Medium hard sand and shale, very hard dolomitic limestone. (e) Medium hard sands, shales and anhydrite; medium to very hard limestone. (f) Soft sands and shales; heaving shale, salt-water flows and steep dips often cause high costs.

14. PORTABLE CHURN DRILLS FOR PROSPECTING

For placer drilling, light power drills are largely used for depths of 15–30 ft. As shallow deposits become scarcer, deeper, sometimes buried, channels are prospected to 300–400 ft. Lead and zinc deposits are sampled by churn drills to 400–600 ft, as in Tri-State district. For porphyry copper deposits, churn drills may reach 1 000–1 500 ft. Water wells and blast holes are usually within 200–300 ft. Large blast-hole drills grade into "spudders" for oil wells of 4 000–5 000 ft depth.

Setting up. Level rear wheels by blocking, taking wt off front axle by jacks. Caterpillar treads should have ground leveled for them. For the deeper holes a platform in front of drill supports tools and extra bits. Derrick is raised by the aid of engine, and guy wires, if used, are anchored.

Drilling is almost always by spudding with wire lines. Tools are dropped about 60 times per min for placer drilling; quick stroke keeps the gravel in suspension after loosening and avoids pulverizing. In copper and lead-zinc deposits, speed of stroke is 38–50 per min for heavy tools. Some prospecting requires cased holes; blast holes are rarely cased, except at top; tools lighter than for standard rig. For holes deeper than 100–150 ft, jars are desirable. At Miami, Ariz, prospecting holes averaged 600 ft; casing generally needed below 400 ft; bits, 10, $7\,{}^{5}/_{8}$ and 6.25-in; 1 000–1 500 ft holes in porphyry may be started with 23–26-in stove-pipe casing; bottom diam of hole, 4 in.

In Tri-State district, for 400–600 ft, standard bit is 6.25-in, with 26-ft stem and jars; wt, about 2 000 lb (42). When drilling fractured ground, where several strings of casing are needed to obtain accurate samples, holes are started with 8 to 10-in bits and finished with $4\,{}^{7}/_{8}$-in, though the latter lack wt, are slower in drilling, and, if ground is bad, the hole may have to be abandoned to avoid losing tools due to caving (43). In Tri-State mines, underground churn drilling is sometimes done by special compressed-air drills, for prospecting where surface is covered by tailings or buildings; they require only 18-ft headroom for 60-ft holes. In some copper mines, churn drills are set on floor of drift, and need only 12–14 ft headroom, a 50 to 60-ft vert raise being driven for taking the crown sheave. For prospecting copper deposits in difficult rhyolite, a churn drill, starting with 14-in bit, was replaced at 800 ft by a small rotary outfit, making a 9 5-in hole; holes drilled to 1 295 ft, 5-in cores sometimes taken. Material caught on a 60-mesh screen permits identification of rock, and shows whether sulphides are present. A max speed of 82 ft per 8-hr shift has been attained; aver on several holes over 1 000 ft deep, about 30 ft per shift.

Moving. For small drills roads should be about 9 ft wide. Large caterpillar drills, max width 9.75 ft, can climb a 30% grade; speed on level ground, nearly 1 mile per hr; small machines can make 4–5 miles per hr in high gear; 2 miles in low. Non-traction drills are moved by caterpillar tractors, or mounted on auto-trucks; sometimes by the engine winding in a cable attached to a tree. A 6-horse team can pull a 12 000-lb drill on good roads; a 10-horse team, an 18 000-lb drill.

Hollow-rod rig. For shallow boring, holes should be smaller than 4.25-in (the economical limit with cable tools). Hollow rods are then used, instead of rope, for 2 to 4-in holes (45). In the hydraulic method, by means of valves in the rods, cuttings are forced to surface by self-pumping action; in the jetting method (more effective in soft ground) water is pumped down the rods to bring up the cuttings between rods and wall of hole or casing. These rigs drill to 1 000 ft and more.

Bits. To loosen the gravel in placer prospecting, bits are long and thin, compared to blunt, heavy rock bits, which exert a crushing action (see Fig 15). A detachable bit is finding favor; its cutting edge is bolted to body of bit, reducing the wt carried back and forth to blacksmith shop (see Sec 5).

15. DATA AND COSTS FOR PROSPECTING DRILLING

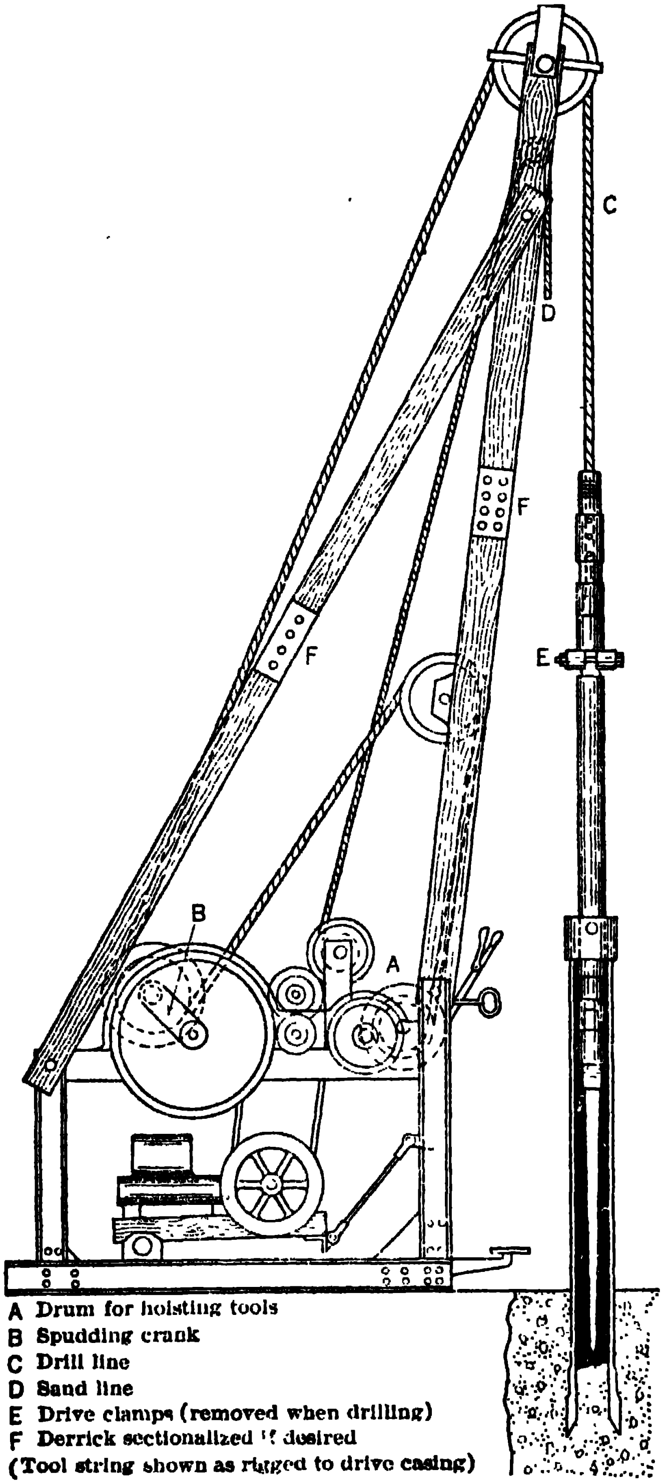
Placer drills. The light Hillman Airplane drill (Fig 40) will drill and handle casing to 75 ft or even more, at rate of about 20 ft per day. Two 20-ft holes per day are often made in shallow testing; at 85¢ per ft in Calif, to $2 per ft in Alaska. Specifications:

Wt of drilling tools, lb........	400	Overall length of frame, ft.....	6
Strokes per min (30–60) aver..	50	Overall width of frame, in.....	37
Length of stroke, in..........	15–30	Diam drive casing, in.........	4 or 5
Heaviest piece (drill-stem) lb..	150	Diam drive shoe, in..........	5.5 or 6.5
3-hp gasolene engine, lb.......	260	Cu in of core sample per ft of hole......................	260 or 390
Longest piece of derrick, ft....	6.5		
Height of derrick from ground, ft	17		

Drill can be mounted on sled runners, or a two-wheel trailer: dismantled, it can be trans-

ported on muleback or in an airplane. Wt without tools, about 1 600 lb; aver cost, with 100 ft of casing and tools, $1 300 fob Seattle.

A larger machine will drill and pull casing to 300 ft, at about 30 ft per day; 26-hp gasolene engine; 28-ft derrick; drive shoe, 7.5 or 9.5 in; wt without tools, for sled or truck mounting, 5 850 lb; with caterpillar mounting, 11 200 lb; wt of tools, 1 000–2 500 lb; cost, with tools and 100 ft of 5 or 6-in casing, $4 500. Keystone No 71 placer drill is an all steel crawler, with 3 speeds. Bit, 5 $^5/_8$ in; wt of string of tools, about 1 200 lb; 25-hp gasolene engine; height of mast, 34 ft. Cost, fully equipped, $5 000–$5 500; wt, not including tools, about 14 000 lb. String of tools: bit, 4 ft 10 in long, 250 lb; drill stem, 4.25 in by 20 ft, 690 lb; jars, 250 lb; wt, complete, 1 350 lb.



A Drum for hoisting tools
B Spudding crank
C Drill line
D Sand line
E Drive clamps (removed when drilling)
F Derrick sectionalized if desired
(Tool string shown as rigged to drive casing)

Fig 40. Light Placer Drill (C. K. Hillman Co)

In testing a placer deposit, actual drilling time may be a relatively small part of total elapsed time. The systematic boring of the Mammoth area, New Zealand (41) was done by 2 petrol drills, powered with 20-hp automobile engines; casing, 6-in, with 7.5-in driving shoe. Holes, 10–20 ft deep; 118 holes drilled in about 4 months; cost, $3.75–$4 per ft; 3 men on each drill. Wages: driller, $4 per day, panner, $3.75, man on gravel pump, $3.25. On a British Col placer (1934), drilling was done with 3 Keystone drills, 1 having capac of 1 500 ft, the others, 300 ft; 1 628 ft of hole cost $2.60 per ft. In 1935, 4 782 ft were drilled, with 6-in casing; cost, $3.42 per ft (including road building). In 1937 drilling cost $2 per ft. Most holes, 200 ft; none deeper than 300 ft.

Base-metal prospecting. In Tri-State district drills are all gasolene, mounted, 5.5–6.25-in spudders, for 400–600 ft holes in shale, limestone and chert; work by contract at $1 per ft aver. The chert wears bits rapidly. Aver speed, 25 ft per day. Costs: wages 55¢; power 6¢; repairs 4.5¢; supplies 18¢; insurance 2¢; taxes 3¢; deprec 2.5¢; total 91¢ (42–44). Underground churn-drilling costs $2–2.50 per ft for 60-ft holes. Solid sulphide ore, drilled with 6-in holes by Armstrong elec drill: depth, 33 ft; speed, 12–18 in per hr; cost per ft, labor $1.08, supplies 5¢, sharpening bits 76¢, misc 9¢; total $1.98. Churn-drill prospecting at Chino mines, Nev Consol Copper Co, N M, in 1930, with

Core rise: in 4-in pipe, with 5.25-in shoe, per ft depth, 22.6 in; in 5-in pipe, with 6.5-in shoe, per ft depth, 21.9 in; in 6-in pipe, with 7.5-in shoe, per ft depth, 20.3 in; in 8-in pipe, with 9.75-in shoe, per ft ft depth, 19.6 in

Sanderson rigs, in fractured, silicified porphyry. Holes started at 13 in, followed by 10, 8, 6, 4.5 and 3-in bits, according to ground and depth. Crew: driller 72¢ per hr; tool dresser 53¢; sampler 52¢. Aver depth: special gasolene rigs, 749 ft, aver cost, $4.15; steam Cyclone drill, 775 ft, aver cost, $4.66; gasolene No 14 traction rig, 363 ft, aver cost, $2.97 per ft. DEEP CHURN-DRILLING, Star electric rig, with standard 85-ft steel derrick for holes averaging 1 000 ft deep in monzonite porphyry. Holes spudded with 26-in cross bit and jars. Stove-pipe casing, 26, 23 and 20-in, placed as needed, followed by regular casing, 15.5, 12.5, 10 and 8-in. Samples taken every 5 ft. Max speed, 5 ft per hr; aver, 1 ft; total cost per ft; $11.41, of which labor was $6.69 and supplies, $4.72. IRON ORE SAMPLING, Mich and Minn. Glacial drift covering varies from a few ft to 300 ft or more; many large boulders. Orebodies often contain layers of taconite, requiring alternate steam churn and diamond drilling. As ore is soft, hard taconite layers are blasted or reamed, to keep casing close to bottom for reliable samples. Light diamond drill is direct connected, or belted churn drill. MENOMINEE AND CUYUNA RANGES. Ore is overlain by greenstone, diorite, diabase and slate. Costs, $1.75 to max of $3.50 per ft when in manganiferous iron ore. On VERMILLION AND MARQUETTE RANGES, costs are $4–$4.50 per ft; MESABI RANGE, $2.50–$3.50 for churn drilling; diamond drilling, $3.50–$4.50 per ft. Rate of drilling, 10–20 ft per shift.

16. BLAST-HOLE DRILLING (see also Sec 5)

Holes are shallow, moves short, and no casing is used. Holes, 9 and 10-in at wide spacing, but 6-in holes often used for quarry and open-pit blasting. Speeds of 9 and 6-in drills are about the same, because the 9-in has heavier tools, stem about 2 700 lb as against 1 500 lb for the 6-in. A steel-frame type (Loomis Machine Co) has capac of 600 ft; safe working load for 31-ft mast, 9 ton; stroke, 13–37 in, is adjusted by a sliding pitman connection to spudding beam; power, gasolene engine, 20 hp at 1 200 rpm. Wt, truck mounting, 8 200 lb; cost $1 945; wheel mounting, 8 800 lb, $2 170; with solid rubber-tire wheels, 8 700 lb, $2 331; with pneumatic tires, 8 500 lb, $2 331; with crawler, 13 000 lb, $3 360; 6-in tool outfit weighs 2 790 lb; 8-in, 3 540 lb. Traveling speeds; 0.5, 7/8, 1.5 and 2.5 miles per hr.

Fig 41 shows tools for drilling and fishing; for bits, see Fig 17; Z bit often used in fissured ground.

Blast-hole drilling, Chino mines, N M, is done with 12 elec drills, caterpillar mounted, 6-in holes. Crew, driller and helper. Collars of holes are cased in shattered overburden; holes usually spaced 20–30 ft, 6 ft from edge of bank; in hard ground, 18 ft apart. When bank is steep and height less than 50 ft, holes may be drilled to 5 ft below grade, to break bottom. In banks exceeding 60 ft, "slope holes" are drilled, in conjunction with toe holes by machine drills. In hard ground and high banks, holes are sometimes staggered, 30 ft apart in each line; holes in front line 50 ft deep, in back line (5 ft behind) 45 ft deep (see also Sec 5).

Drilling speeds in quarries with Bucyrus-Armstrong drills. In traprock, drill 29-T averaged 3.34 ft per hr total time; 4.87 ft per hr actual drilling time, 8-in holes. In hard limestone, with 24-T drill, 5.2 and 6.6 ft, respectively, in 9-in holes. In a hard limestone quarry, Ill, Loomis No 44 and No 2 Clipper drills made in 1937 over 100 000 ft of 6-in holes, averaging 55 ft, at 6 ft per hr actual drilling time. Costs: drilling labor, 16.17¢; incidental labor, 3.33¢; supplies, 2¢; elec power, 3¢; total, 24.5¢ per ft.

Drilling hard siliceous hematite (1937) with 20-T Bucyrus-Armstrong machines, 9-in bits, for hardest ore; smaller type, 6-in bits, for soft. Costs: 9-in holes, $1.89–2.01 per ft, and $0.089 per ton ore; 6-in holes, $1.69–2.28 per ft, and $0.147 per ton ore. Drilling speed, about 2 ft per hr.

17. DIAMOND DRILL

Construction. The boring column (Fig 42) consists of: bit *X*, set with diamonds; core shell *V*, containing lifter *W*; core-barrel *U*; hollow rods *P*, rotating within casing strings *M* and *N*. The drill rod is driven by gasolene engine, mounted on a steel frame; through a swivel, water is pumped into rods, a hose connecting pump and swivel; rods are raised and lowered by a drum and wire rope, the latter passing over a block at top of derrick.

Casing is in 4 standard sizes, EX, AX, BX, and NX, for rods and couplings E, A, B, and N (Table 32). Other slightly different sizes are obtainable. Casing flush on outside when coupled is "flush-coupled casing"; when without couplings, "flush-joint casing."

* Assuming hole 1/32 in larger than bit.

Core-barrels are: single-tube, rigid double-tube, and swivel double-tube. SINGLE-TUBE barrel requires less time to remove core and reconnect the barrel, and in many kinds of rock makes faster progress than double-tube barrels. DOUBLE-TUBE BARREL has an inner tube revolving with outer tube, and the circulating water is carried to bit without coming in contact with the core, to prevent washing of soft core, and reduce grinding between separate pieces of core in the barrel. In the SWIVEL-BARREL, the inner tube is

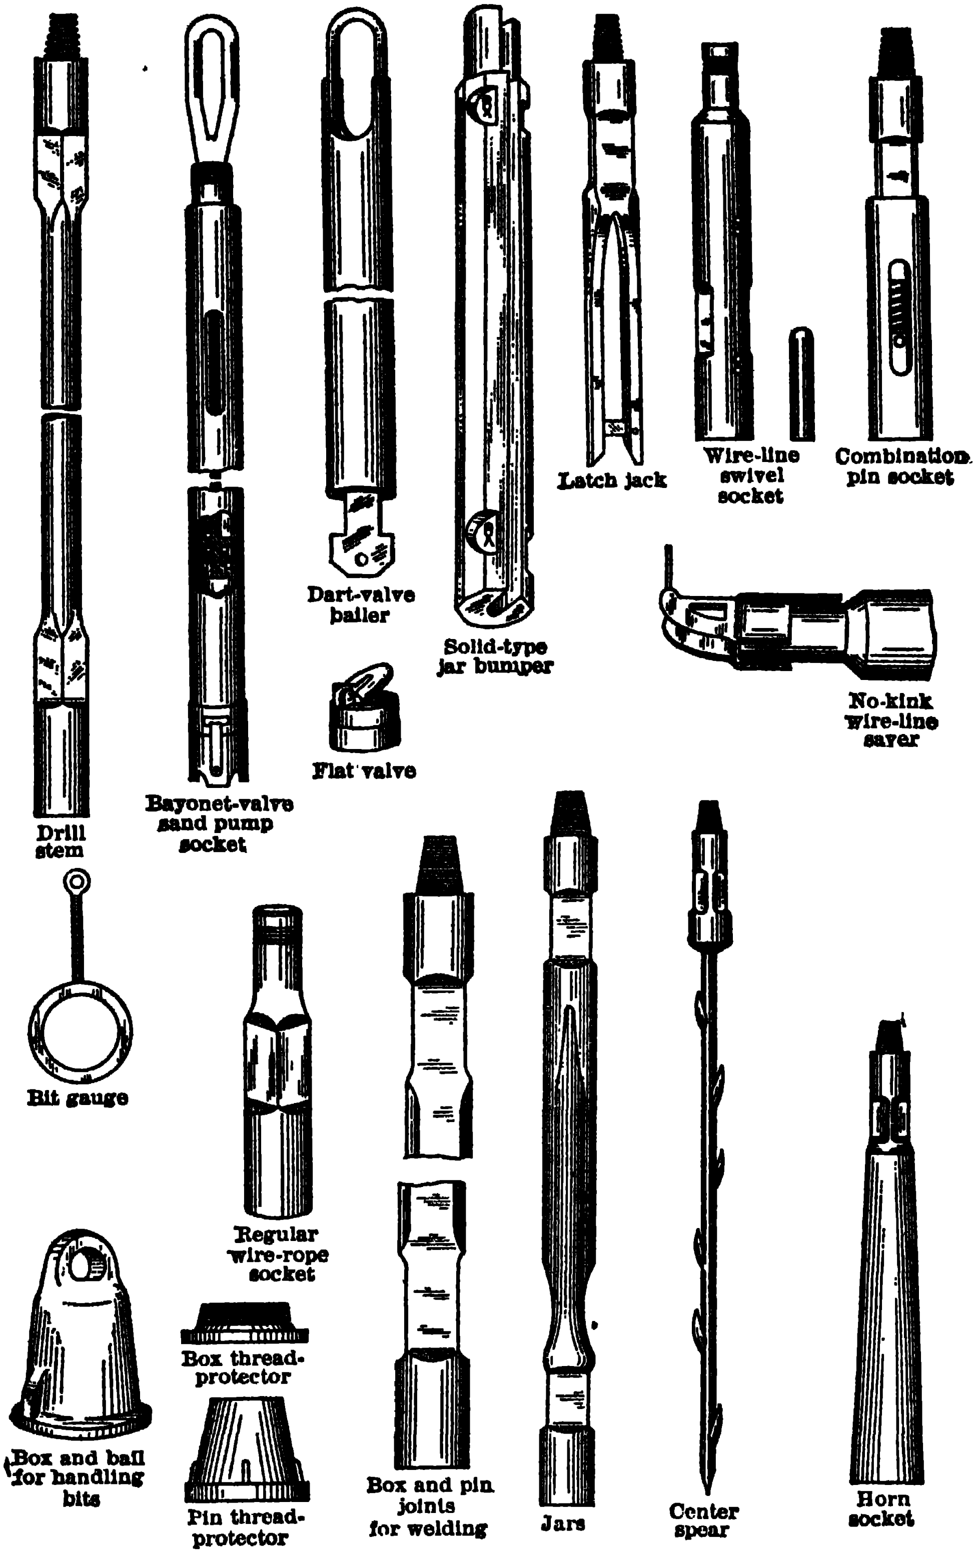

Fig 41. Drilling and Fishing Tools for Churn Drilling (Bucyrus-Armstrong)

mounted on ball-bearings, and as it does not revolve, is desirable for friable rock. Cores larger than standard are obtained with special fittings. For fragile rock, large diam cores are better than small. Fig 43*A* shows the Sprague and Henwood double-tube, ball-bearing barrel; Fig 43*B*, the Sullivan large single-tube barrel for oil drilling. Common lengths of barrel are 20 in, and 2, 5, 10, and 20 ft; longer ones are made.

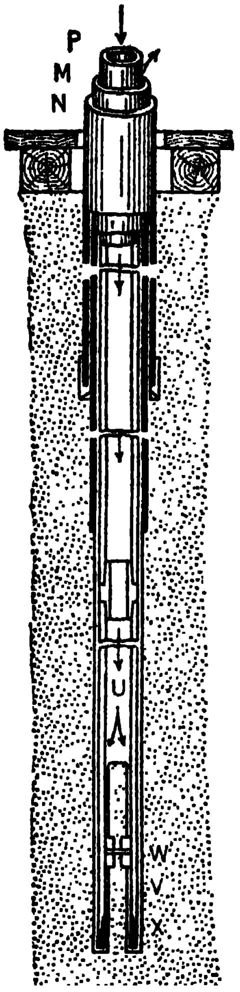

Fig 42. Boring Column of Diamond Drill

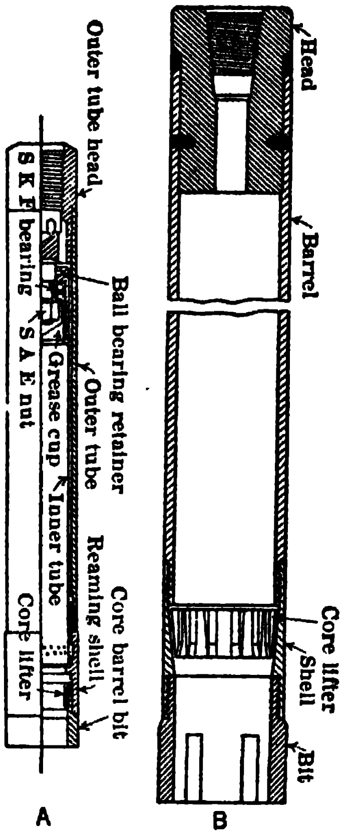

Fig 43. Core Barrels

Rods are cold-drawn, seamless tubing, in standard lengths of 1, 2, 5 and 10 ft, but 20-ft lengths are used for rods of 2 $^3/_8$ and 2 $^7/_8$-in outside diam (Table 33).

Table 33. Diamond Drill Rods

Bits (Fig 44). *A*, blank bit with rounded edge; *B*, round shoulder bit with a large number of stones; *C*, square shoulder bit, with 8 stones, 4 inside and 4 outside; *D*, Kobelite bit, in which stones are first moulded into insert strips, which are then brazed into the bit; *E*, sawtooth bit, hard-faced with Haystellite; *F*, sawtooth bit, face-hardened with borium; *G*, Bade bit, with stones set in plugs, which are then inserted in body of bit; *H*, "castset" bit, made by setting stones in a mould and pouring in molten metal; *I*, sawtooth bit, in which plugs of hard metal are set. Sawtooth and hard-faced fishtail bits may be used in the softer rocks. A solid bit, making no core, may be used for boring in barren strata above ore horizon; its face is slightly recessed;

rim diamonds are set with usual clearance, and holes through bit admit water to face. In soft ore, cores have been taken with a square-shouldered blank bit, with water courses cut in it (Art 18). Diamonds are always set to "cover" one another as bit rotates.

Types of drills range from portable, hand-operated machines for depths of 300–400 ft, to the heavy, engine-driven type for great depths. A recent diamond-drill hole in So Africa is 10 718 ft deep; 2 others, 7 408 and 7 770. Compact drills are made for underground service, and truck-mounted or motorized forms for surface work. With improved bits rotative speeds have been increased from 300 or 400 to 1 000 or even 1 200 rpm, increasing drilling rate by 50% or more. High speed requires changes in design: working parts are enclosed and run in oil; chucks have countersunk bolts; ball-bearings used throughout, and provision made for pressure greasing. The No 22 Sullivan drill has a capac of 1 150 ft with EX fittings (Table 32), or less depth with larger fittings; driven by compressed air, steam, elec, or gasolene engine, these drives being interchangeable. Wt of air- or steam-driven drill, without pump, is 1 390 lb. Fig 45 shows a Longyear UG straight-line gasolene drill, capac 1 500 ft of E hole; wt complete, 1 959 lb; gasolene motor, 20 hp, consumes 8–12 gal per shift; can be moved by fastening the steel cable to a tree and winding it in. Sullivan No 40 drill has a 42-hp Buda engine; capac, 1 500 ft of 3-in core, or 2 200 ft of 2-in core (greater depth for smaller core); hydraulic feed swivel-head has piston travel of 18 in. This drill can be equipped with a 12 or 22-ft Kelly bar for oil-well drilling (Sec 44); mounted on an I-beam frame, which is slid out over the hole while drilling, but is retracted 18 in by a rope and cathead when hoisting or lowering rods; wt complete,

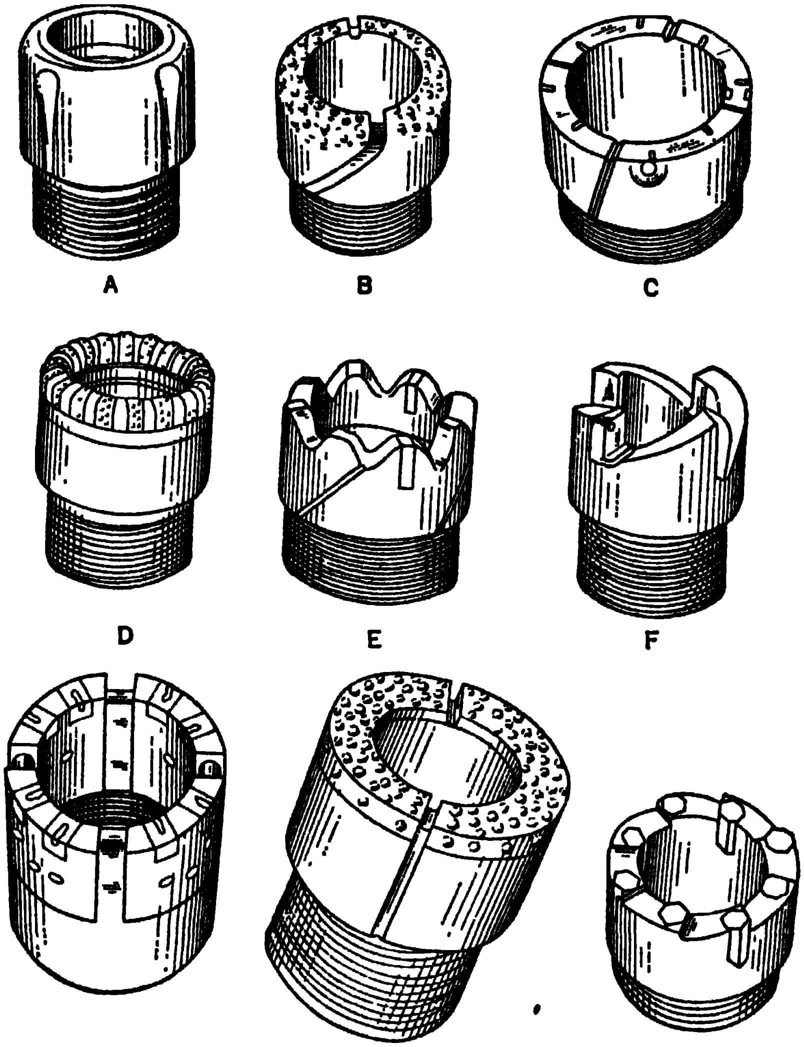

Fig 44. Diamond-drill Bits

8 316 lb. About 70% of diamond drills are driven by gasolene engines; 20% by elec motors; 10% by steam, or, for underground drills, by elec or compressed air. Steam power is familiar to most drillers, easy to handle, and by throttling permits close control over operations; its disadvantages are higher initial cost and boiler upkeep (state boiler codes must be met), difficulty of moving equipment. Department of Forestry, Canada, insists on use of gasolene drills, because of danger of fire from steam rigs (46). For gasolene rigs, cost of fuel and transport are low and drilling can be started promptly.

Feed mechanisms. On hand drills and many small power rigs a positive differential screw-feed is used (Fig 46); hydraulic feed for large drills (Fig 47). Screw-feed. In the swivel-head (Fig 46), the feed-screw spindle *A* is threaded left-handed; rotated by spline-quill *B*, having 3 locked-in splines; spindle rotates with *B*, but is free to move up or down, and is driven by bevel gear *C*, being keyed to *B* and meshing with the drive gear. All rotating parts have ball-bearings. On the lower end of *B* is gear *D*, which drives countershaft *E* by meshing with gear *F*, keyed and locked onto the countershaft. At top of countershaft are 3 feed gears *G*, meshing with corresponding gears *H*, keyed to feed nut *I*, which is threaded to take the feed-screw spindle. The feed gears have different ratios;

sliding key *J*, on shaft *K*, which operates within countershaft *E*, is moved into engagement with any one of the 3 gears by handwheel *L*. When the feed shifter *L* is in its lowest notch it gives the fastest feed; second notch is neutral position; third, intermediate feed; fourth, another neutral; fifth is the slow feed. The rate of feed is varied at will by slowing down, and operating the shifter handwheel. Gears give speeds of 200, 400 and 600 rev of the spindle per in of feed; other gears of 50–1300 rev are obtainable.

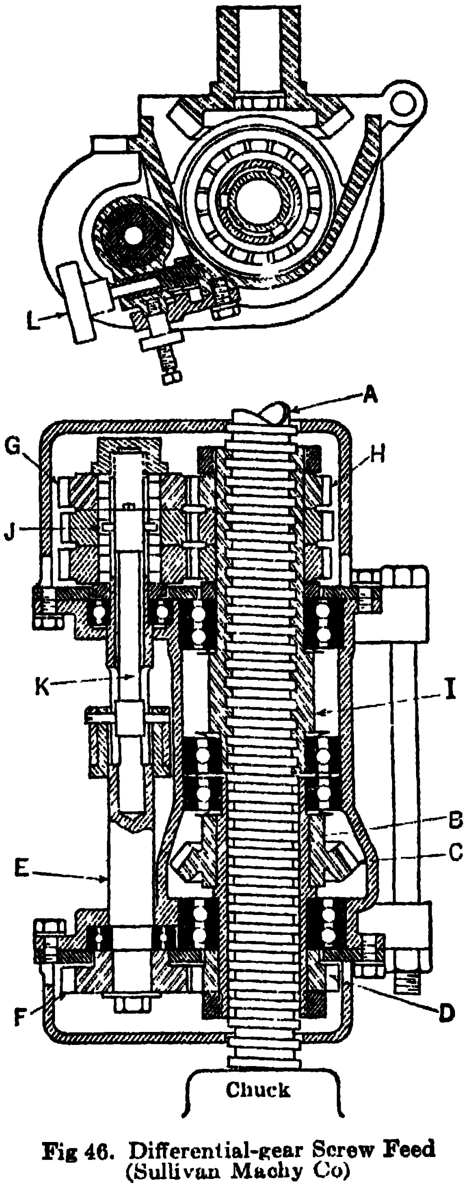

Fig 46. Differential-gear Screw Feed (Sullivan Machy Co)

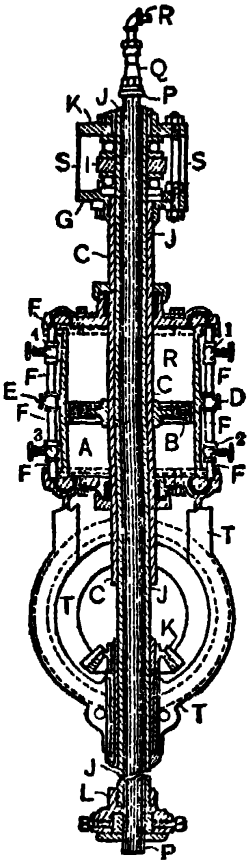

Fig 47. Hydraulic Feed

HYDRAULIC FEED is used almost universally on large drills. In Fig 47, *A* is the hydraulic cylinder, *B* the piston, *C* a hollow piston rod, *D* pressure-water inlet, *E* discharge-water outlet, 1 and 2 inlet valves, 3 and 4 outlet valves. By opening diagonally opposite valves the piston rod is raised or lowered. This motion is transmitted through roller friction head *S* to collar *I*, which is rigidly fastened to hollow drive rod *J*. *J* is rotated by bevel gear *K*, driven from the bevel pinion *T* on crankshaft. The drill rods *P*, passing through *J*, are gripped by chuck *L*, being thus rotated and fed forward. A pressure-gage measures the thrust on the rods. Hydraulic feeds are made also with 2 cylinders, the piston rods being yoked together and the drive rod carried in the yoke. Usual advance per run with single-cylinder feed is 1 ft; with double-cylinder feed, 2 ft. Both screw and hydraulic feeds are mounted on a swivel head, which admits boring in any angular direction.

Differential vs hydraulic feed. Considerable difference of opinion exists as to their relative merits. For any given setup, screw feed gives a constant advance and records the varying pressure on the bit, thus apprising the runner of slight differences in hardness of rock, and of presence of thin seams and small crevices. This information is often invaluable when the core is much broken and its record consequently incomplete. But, in strata of frequently varying hardness, it is necessary to run through soft strata at reduced speed, so that the bit may not be damaged on meeting a hard stratum. With hydraulic feed the pressure is constant, and rate of advance varies more or less automatically as hardness of the rock varies. Thus, danger to the bit in passing from soft to hard rock is lessened. The runner of the hydraulic-feed drill can instantly take advantage of changes in the formation, varying the rate of advance, within the limits imposed by the rock, merely by turning a valve. Three different speeds are the limit with screw feed, unless gears are changed.

Hoisting drum. For small drills the drum is driven by gearing from the crankshaft; in some machines, 2 or more drum speeds are available by use of shifting gears, which form integral parts of engine. For large drills, drum is direct-driven for light loads, but in deep holes, when wt of drill rods may be several tons, a compound gear reduction is provided, the gears being thrown in by a lever when hoisting, and thrown out during drilling. Small belt-driven drills rarely have a hoisting drum, the rods being raised by a rope coiled around a niggerhead.

Table 35. Wire Hoisting Ropes, 6×37 Left-Lay Plow Steel (Sullivan Machinery Co)

1 250	1 7/8	3/8	260	12	1 800	3 1/2	1/2	430	22
2 200	1 7/8	1/2	150	16	2 300	3 1/2	3/8	1 400	14
1 400	2 23/64	1/2	150	20	...	......	....	....	...

Pumps for small belt-driven rigs are single-cyl, usually 3 by 5 or 4 by 5 in; for larger drills, except those driven by steam or air, a 3 by 4-in duplex. For a steam rig, a duplex, boiler-feed pump is common; for the hydraulic type of swivel head, a duplex pump is essential, to provide a constant flow under steady press.

Derricks. A tripod derrick serves for holes to say 600 ft; legs are 4 by 6 in by 22 ft, to give a 20-ft clearance. For holes to 1 000 ft, legs should be 6 by 6 in; height 30 ft. For very deep holes, a steel derrick is preferred (Table 36). A rod length of 40 ft is about the max that can be stood up in derrick without excessive bending; if longer, they should be suspended from crabs on a track in the derrick.

Table 36. Structural Steel Derricks

Height, ft	Base, ft	Top, ft	Capac, lb	Wt, lb	Cost
45	16	4	35 000	4 000	$ 525
66	20	4 1/3	168 000	10 000	790
73	20	"	168 000	10 700	850

87	20	"	168 000	14 200	1 050
94	24	"	168 000	16 100	1 130
122	24	"	367 000	26 300	1 700
136	26	"	367 000	118 000	2 150

Core splitter. Cores are kept in long boxes, marked for future reference. After geological examination, part of a core may be pulverized for chemical analysis. Cores are split by chisel and mallet, or by a mechanical splitter; one half being taken as the sample, the other retained for record. A piece of core is placed in splitter and the blade screwed down tightly; light taps of a hammer notch core on both sides, then a sharp blow splits it. For cores over 4-in diam, a splitter on the principle of the hydraulic jack is obtainable.

18. DIAMOND DRILLING OPERATIONS

Setting up. An area 20–25 ft sq is graded, and drill and pump set on a plank floor. For deep holes or light machines, derrick legs rest on the floor, to counteract upward pressure when drilling. For shelter: in summer, a canvas fly; in winter, a shanty of wood or galvanized iron, which may be sectionalized for moving. To erect a steam rig, with 3-leg derrick and wooden shanty, easy grading, takes say 100 man-hr; to dismantle, say 25 man-hr. Underground setups of a small drill can be made in mine drifts, which should be widened to about 7 ft at the drilling place. Rods 1 ft long can be used, but 5–10-ft lengths save time.

Drilling under water. Drill is mounted on a scow, anchored to bottom, or supported on spuds. If current is too rapid to permit stable setting, a platform is built on piles, or a heavy standpipe is driven from the scow, securely guyed, and the drill set on a platform clamped to top of pipe. Portable drills are set up by blocking the front wheels, securing front of drill with guys, and centering derrick over the drive rod. Two men can make such a setup in 2 to 4 hr, and dismantle in about half that time.

Sinking standpipe is generally done by wash boring (Art 1). On reaching rock the standpipe is chopped or bored in a few inches, to make a tight joint, prevent influx of surface material, and insure return of drilling water to the surface. Sinking standpipe is an uncertain operation. In soft and medium clays and fine gravels, 10–12 ft per hr is not unusual. In bouldery gravel or hardpan, aver speed may be less than 1 in per hr. In rock, speed of sinking standpipe may not exceed drilling rate; in bouldery ground, considerably less.

Drilling. Following is the normal sequence of operations: Slide or swing feed mechanism away from hole. Set safety clamp in position over standpipe. Connect up bit, core shell (with core lifter), core barrel, and 1 length of rod, and lower through the safety clamp until only a few inches project; then grip by the clamps. Screw hoisting swivel into upper end of a section of rods, swing rods into place with the hoist and screw them into the rod joint projecting from the hole. Loosen the clamp and lower the string on the hoist brake until only a few inches project from hole. Tighten the safety clamp, and unscrew the hoisting swivel. Repeat these operations until within a rod length of bottom. Bring feed mechanism back into place. Attach water swivel and lifting bail to the last length; lower it through the drive rod, and screw it into place. Run the feed to highest position, and tighten the chuck. Loosen safety clamp. Connect water swivel to pump and start the pump. Start drill and run downward until pressure shows that bit is against rock. While drilling, adjust feed as necessary. When measurement of rod indicates that core barrel is full, or laboring of pump and engine suggest that it is blocked by broken pieces of core, stop the drill. Keep pump running until water issuing from hole shows that sludge has been well removed. Hoist rods by reversing the operations of lowering. Extract core, and place it in core boxes. Change bit often enough to prevent diam of hole from falling below gage, and to guard against loss of diamonds from wear of the metal surrounding them.

Casing or cement grout is used to support the walls of a drill hole when they cave so as to prevent progress or vitiate samples. Casing is flush-joint tubing large enough to allow the bit to pass. Table 37 gives usual sizes. If hole is continued of same diam below the caving ground, it is reamed before casing is put in. As diamond drill holes are never straight, casing is a difficult operation. Casing is usually twisted and driven down. Sometimes a "casing bit," set with a few diamong chips, is placed on lower end of the tubing, which is then operated as in regular drilling. Cement grout is more and more used instead of casing. In badly caving ground the drill is driven as far as is safe, and the core and sludge saved. Then the grout is pumped down the rods or lowered in a bailer. After it has set, the resulting "plug" is drilled through, and a deeper section of hole is sampled and grouted. Quick setting cements are used. Adding 25% of luminite cement to ordinary cement shortens setting time to about 2 hr.

Table 37. Flush-coupled Casing

Size	Outside diam, in	Inside diam, in		Wt, lb per ft with coupling
		Casing	Coupling	
EX	1 13/16	1 5/8	1 1/2	1.81
AX	2 1/4	2	1 19/32	2 91
BX	2 7/8	2 15/32	2 3/8	5.74
NX	3 1/2	3 1/16	3	7.8

Cementing is usually cheaper than casing, and allows the hole to be started at a given diam without considering possible future support. In shattered ground rods may have to be pulled frequently, due to blocking of core barrel. In soft ground, also, if core is desired, frequent withdrawal is necessary or a double core barrel used. In fissured ground, part or all of the water will be lost. If there is standing water in fissured strata, the sludge will deposit in crevices close to the drill, and re-enter the hole when water current stops. Hence, water must be pumped through the rods during hoisting, and the rods flushed down in lowering. Bran, sawdust, manure, or cement, are pumped down the hole in an attempt to stop the crevices.

Accidents and fishing. Commonest accident is loss or breakage of a diamond. Usual mode of recovery is to send down an old bit, the end of which is filled with wax. The diamond imbeds itself in this and is brought to surface. When the hole can not be cleaned to bottom, for using the waxed bit, a lost diamond may sometimes be recovered by the bailer. The following device has been used. A screen was placed in top of core barrel and a screen clack valve set in an old bit, which was screwed to bottom of barrel. The rods were lowered through a stuffing box and water current reversed. Sludge containing the lost diamond was washed into the core barrel and held between the two screens. In Fig 48, *A* is a casing tap for screwing on casing or rods; *B* and *E*, male and female taper taps for recovering rods: *C* and *D*, for rod couplings; *F*, *G*, combination spear to recover rods or couplings.

Parting of rods in a hole, may be due to fracture, stripping of threads, or unscrewing. If they become unscrewed, it is usually a simple matter to screw them together again. When threads strip or rods break, a recovery tap (threaded inside or outside according to nature of the break) is lowered on a line of rods and manipulated until it engages the broken part. Casing breaks are similarly treated **Jamming of rods** may be due to caving, to a mud rush, to working with worn bit, or to too little clearance between rods and casing. A caving hole usually gives some warning, but casing or grouting is often neglected in the haste for progress. Jamming from a sudden cave can sometimes be averted by reversing and running back the feed without stopping the engine, meantime pumping more water. A mud rush will not often occur while pump is running. If the pump is started before lowering the rods to the bottom, and kept running while hoisting until the rods are above danger zone, jamming will not occur. Pulling jammed rods, when powerful jacks are necessary, elongates the rods, with consequent weakening, and the threads may be stripped.

Loss of bit, due to breakage below core barrel, is a baffling and serious accident. If possible, the bit is picked up by a recovery tap. Difficulty in using a tap is that the bit may lie on its side; furthermore, it offers little resistance to turning, and may turn with the tap. Bits have been recovered by reaming the hole to a size allowing use of a bit large enough to make a core containing the lost bit. If the bit cannot be recovered, the hole is diverted at some distance above it and continued (Art 12). Loss of time due to accidents is often a serious factor in drilling.

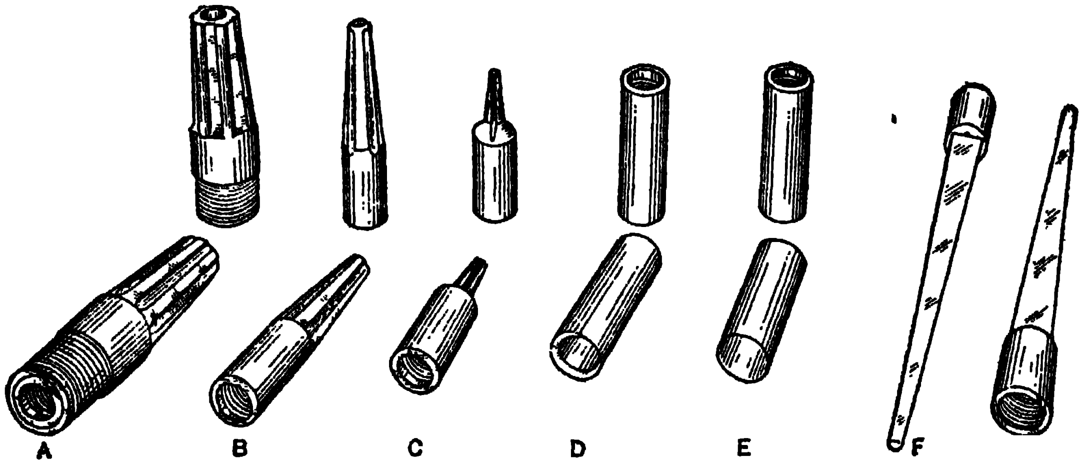

Fig 48. Diamond-drill Fishing Tools (Sullivan Machy Co)

Operating crew of a diamond drill consists of a runner and one or more helpers. The runner should be a good mechanic and repair man, besides being experienced in drilling. By observing behavior of engine, pump, and rods, a good runner can learn much about character of the ground being drilled. This knowledge is valuable as added to the testimony of core and sludge, and furnishing a warning of possible trouble in the hole. Many operators will not entrust the running of an hydraulic-feed machine to a runner who has not had 2 or 3 years' experience as helper on a similar drill, nor give a man work on a deep hole unless he has had experience with shallow ones. In general, less experience is required of runners for screw-feed machines. The helper is fireman and assists the runner in handling rods. A skilled bit setter is usually required, who may act as foreman for as many drills as he can set bits for.

A group of drills will require a general foreman. Team and driver are needed for part or all the time, to haul fuel, attend to water supply, and help in moving. Wages for a runner are usually slightly higher than miners' wages in a given district. Helper is paid usual helper's wages of the district. Bit setter is paid the same or a little more than the runner, minimum wages being $200 to $250 per month. Diamond drill manufacturers have lists of experienced runners and bit setters available for work. These men are paid traveling and living expenses besides regular wages.

Quantity of water per day depends upon: size of drill; boiler consumption; diam and depth of hole; sp gr of sludge; whether rock is hard or soft; whether hole leaks or is tight; and water is saved and reused. Loss of water varies greatly in shattered formations. If no water channels are cut in bit and core barrel, the max size of particle that can pass upward has a diam equal to clearance of the outside diamonds; with water channels, size of particle is determined by clearance between rods and walls of hole. A rising current of 12–18 in per sec is usually sufficient, except for very heavy material, as magnetite or galena. Quantity of water to produce desired veloc. varies with diam of hole and rods (Table 38). With this rising current, the veloc in the small space around the core is much higher, sometimes causing so great a loss of core in soft rocks that veloc must be reduced. In general, much water means rapid drilling and low core recovery; little water increases core recovery at expense of progress, and too little may result in a burned bit. If the hole is tight and nearly all the water pumped down returns to surface, the overflow from sludge box can be reused; loss of water is then about 25%; reused water must be freed from oil. Measurements at 3 drill holes, where all return water was saved, show that 76–80 gal per hr were used; holes, 1.5 in, cores $^7/_8$ in. Drilling a 3-in hole and recovering 2-in core in broken formation when prospecting for coal, required 305 gal of water per hr; in fairly deep drilling, 105–123 gal per hr may be used.

Table 38. Vol of Water Required to Produce a Veloc of 1.5 ft per sec (E. J. Longyear Co)

19. TIME DISTRIBUTION IN DIAMOND DRILLING

Time effic, the percentage of total working time spent in actual drilling, rarely exceeds 60%, and depends on depth and character of overburden, time for hoisting and lowering rods, and delays (Table 39). Time for handling rods depends on depth of hole, and length of rod sections between breaks. Number of lifts depends on nature of ground, kind of bit, and kind and length of core barrel. Uniform rock sometimes cores the full length of barrel; in broken ground, cores break up and tend to jam in the barrel or be lost. Double core barrels (Art 17) tend to overcome this difficulty. A solid bit needs to be raised only to change it. Table 40 shows distribution of delays in 1 200 shifts at United Verde mine (50). Due to 8-hr law, 1 hr aver was taken for traveling to working place and return; adding 0.5 hr for lunch left 6.5 hr. Actual drilling time, 68.88% of total time.

Table 39. Approx Time for Hoisting and Lowering Rods (E. J. Longyear Co.)

Depth of hole, ft	Time for pulling rods, removing core and lowering
500	40 min
1 000	90 "
1 500	2 hr
2 000	2.5 "
2 500	3.25 "
3 000	4 "
4 000	5– 6 "
5 000	6– 7 "
6 000	9–10 "

Reaming EX casing	67.0	1.4
Threading pipe	4.5	0.1
Laying water line	4.0	0.1
General	14 5	0 3
Total	4 644 2	100.0

In drilling 10 192 ft (17 angle holes) in about 12 months (Lupa gold field), most of the work was in sheared rocks (Table 41). Cores were EX ($^7/_8$ in). Time for lowering and raising rods, removing cores and incidental work is included with EX drilling time. Progress was considerably delayed by frequent pulling of the rods, due to core-blocked bits and barrels (51).

In 3 deep holes in So Africa, ratio of actual drilling days to total elapsed time was: 7 408-ft hole, 60%; 7 770-ft, 43.6%; 10 718-ft, 70.7%. Cores: 1 3/8, 2 1/2 and 1 3/8 in respectively.

Table 42. Underground Diamond Drilling, El Potosí Mine (H. A. Walker)

Type of drill	Drilling time, min per ft	Percent of total time				
		Actual drilling	Placing rods	Handling core	Coming, going and lunch	Delays
Small electric	7.3	42.4	10.0	18.8	18.8	10
Small air	7.3	36.0	8.0	27.2	18.8	10
All small drills	7.3	40.8	9.5	20.9	18.8	10
Large 11 SE elec	7.8	46.4	8.1	16.7	18.8	10
Large 6 UGE elec	7.6	50.1	8.0	13.1	18.8	10
Large air	7.2	49.3	8.0	13.9	18.8	10
All large drills	7.5	48.6	8.0	14 6	18.8	10

Table 42 shows results at El Potosí mine, Mex, from Oct 18, 1934, to Mch 16, 1935, with 4 small machines, capac 250 ft, and 3 larger drills of 700 ft capac. The expected performance, ft per shift, is higher than any past averages; but in drilling limestone, under proper power supply conditions, these figures are attainable. Number of ft drilled each time the rods were lowered is assumed as 8 for the small machines and 14 for the large. Using 5- and 10-ft rods should give 62% theoretical core recovery for the small drills and 71% for the large.

20. DIAMONDS, BIT-SETTING, AND LOSS OF CARBONS

Diamonds are of 3 classes: white or slightly tinted crystalline brilliant; less pure crystalline form, known in trade as "bort" or "bortz"; and the opaque, somewhat porous "carbonado" or black diamond, composed of very small diamond crystals in amorphous carbon or graphite, known as "carbon." The white diamond, and similar but imperfect bort, have cleavages along which they can be split, and when cut they refract light brilliantly. Carbon is black, grayish black, or tinged green or brownish. A fresh fracture resembles broken steel. C. E. Wooddell gives a modified Mohs' scale of hardness (Table 43).

Table 43. Modified Mohs' Scale for Different Substances (47)

South American brown bort	10.00	South American carbon	9.82	Fused alumina (3.14% TiO_2)	9.06
South American ballas	9.99	Boron carbide	9.32	African crystallised corundum	9.00
Belgian Congo, yellow	9.96	Silicon carbide, black	9.15	Quartz	8.94
Belgian Congo, white	9.95	Silicon carbide, green	9.13		
Belgian Congo, gray opal	9.89	Tungsten carbide (13% C)	9.09		

Table 44. Prices per Carat of Carbon and Bort (Diamond Drill Carbon Co)

Year	Best quality carbons, 2 carats and over	Best quality small bort, of 0.05–0.20 carat	Fair quality bort
1932	$130–120	$6.50–7.50	From $3 to $7 per carat, depending on quality
1933	115– 70	6.50–7.50	
1934	115– 90	7.50–8.50	
1935	110	7.50–8.50	
1936	70– 65	7.50	
1937	70– 65	7.50	

The scale shows carbons to be below diamonds in hardness, but hardness should not be confused with toughness. White diamond or bort is commonly a single crystal, except "ballas," in which crystallization starts from a central point, making the stone practically impossible to cut; fit for drill bits, but very scarce. Bort splits readily along 3 planes, and is more brittle than carbon. Carbon has no cleavage, hence is less liable to break in hard rock. Selection of good stones requires experience, lacking which, an engineer should buy through a reliable dealer or diamond-drill manufacturer.

Bit-setting is a delicate and important operation. Diamonds must have such clearance that the metal of the bit will not come in contact with the rock, and must "cover" one another, so that no part of the area to be cut will fail to be touched by a diamond at each rev of bit. It was formerly common practice to use a few carbons of large size.

For softer rocks, a square shoulder bit (see Fig 44*C*) might contain: 8 stones, totaling 12–16 carats, and 4 1-carat stones; in the iron regions, 6 or 7 stones aggregating 14 carats, to 16 stones totaling 18–30 carats. Later, the round shoulder bit was developed (Fig 44*A*, *B*), with more and smaller stones, equalizing wear and increasing drilling speed (48). As large carbons are now more costly, the use of smaller sizes, 5–20 per carat, and also of scrap carbon, is increasing. In one type of bit, the number of stones recommended is: EX bit, 50; AX, 60; BX, 80; NX bit, 100. Stones, when set, should project about $^{1}/_{64}$ in beyond the metal of the bit. Soft rocks require larger clearance for good core recovery and to prevent "plugging" or sticking. Cavities cut in the bit are shaped for the individual stones, which are seated with a backing of Babbitt metal or copper, carefully tamped around the stone with hammer and punch. Stones are so set that their cutting surfaces slope away from the direction of rotation. Setting a large number of stones involves so much labor that various mechanically-made bits have been developed. In the "Castset" bit (Fig 44*H*) the stones are placed in a mould and molten bit-metal is poured around them. In the Kobelite bit (Fig 44*D*) the stones are set in a metal powder, pressed or sintered into disks or strips, brazed onto the bit (49); 200 or more stones may be set in this recommended bit. In the "S. A. Produits Boart," 30-40 carats of bort are crushed to a powder and mixed with a metal powder, as iron, formed into a ring and sintered, the ring being soldered to face of bit. The abrasive ring is about $^{3}/_{8}$ in thick, and the bit can be used until most of the ring is worn away.

Tests have shown: that drilling effic increases with rotative speed, but diamond wear reaches a max at about 1 000 rpm; that costs for bits change little between 450 and 1 500 rpm, but are considerably higher above and below these limits; that bits with 40 stones give minimum cost at about 740 rpm, and those with 70 stones at 1 000 rpm; that a bit with 100 stones cuts 50% faster, and has 57% greater durability than a 40-stone bit. Thus, most effic drilling is with bits set with many small stones and run at high speed (49).

Diamond wear depends on hardness of rock, cleavage of minerals composing the rock, shape and quality of diamonds, mode of setting and size of bit, and skill and care of runner. Hard, broken and faulted rock is difficult to drill and diamond loss is high. Runner's lack of skill and care increases breakage and loss of diamonds, rather than wear. In starting a new bit, it should begin rotation a few feet above bottom of hole, and then be fed slowly down to contact with the rock, to seat itself properly, without causing side pressure on outer diamonds. Inferior carbons and bort will serve for soft rock and cost less; but if used in hard rock, rotative speed must be slow to avoid undue breakage (53). Drilling in ground varying from soft schist to massive sulphide, with EX and AX bits, containing 120–150 bort stones of about 20 per carat, loss was .02–.10 carat per ft of hole. In South Africa goldfields, in shear zones of fractured rock containing bodies of quartz and intrusive dikes, the size of bort varied from 6 to 15 stones per carat for face of bit; total number, 45-60 per bit; aver loss .048 carat per ft, in drilling 10 000 ft of hole. Table 45 shows loss of diamonds in different rocks, with bits having 10 carbons totalling 15–20 carats, to 60 stones totalling 12 carats. Bort bits usually had 25 stones of 0.25–0.5 carat each, for outer or gage stones, and about 75 stones, of 0.066 to 0.1 carat, for face ("track") stones (50).

Table 45. Wear on Bits in Various Rocks (50)

Kind of rock	Loss per ft, carats
Black schist	0.002607
Massive sulphide	.004320
Hard massive sulphide	.010244

Hard greenstone	.005757
Quartz	.032585

At Bunker Hill and Sullivan mine, Idaho, a light Mitchell drill for 1 $^{3}/_{8}$-in hole and $^{7}/_{8}$-in core is used both on surface and underground (52). Aver depth of 35 holes, 195 ft. Ground is tilted quartzite beds, but drills fairly well unless sheared and faulted. Bits contain about 40 stones, totalling 6.4–8.75 carats (Table 46).

Table 46. Carbon Consumption, Bunker Hill and Sullivan Mine (52)

No of bits	Aver ft per bit	Carats per bit		Total carats	Loss, carats		Percent loss	Carbon cost per ft
		Range	Aver		Total	Per ft

21. RECOVERY OF CORE

Core recovery may reach 100% in hard uniform rocks. It is lowest in loose, soft, cleavable and broken rocks, where, unless the drill is run almost dry, and rods are raised every few inches, recovery may not be more than 10%. Vibration of rods causes low recovery. For good recovery in hard rock the drill should be run with low speed and heavy press; in soft rock, the reverse. Recovery is invariably less in upper than in lower portion of holes, due to decomposed rock near surface.

Table 47. Core Recoveries (E. J. Longyear Co)

Table 48. Core Recovery at United Verde Mine (50)

Kind of rock	Percent recovery
Black schist	85.5
Quartz porphyry	88.8
Hard quartz porphyry	94.0
Diorite	87.8
Greenstone	79.2
Hard greenstone	87.1
Massive sulphide	93.6
Hard massive sulphide	95.3
Quartz	88 3

Size of hole is determined by the depth to be bored, and purpose of hole. To obtain a core in soft, friable minerals, as coal and salt, the inside diam of bit should not be less than 2 in. For hard rock or ore, a $^{13}/_{16}$-in to 1 $^{1}/_{8}$-in core is large enough. If the stratum or orebody to be sampled lies deeply, the hole must be begun larger than this for larger and stronger rods, and to give room for casing without excessive reaming, should casing be necessary. At United Verde mine, Ariz (Table 48), holes were 25–2 200 ft deep: 79% from 5° below horiz to 12° above; 84%, from E to AX size; 14%, AX to N; and 2%, N size or larger (50). In the Lupa goldfield, So Africa, (Table 41), core recovery for 9 762 ft of EX hole, including 50 ft of surface weathered rock, was 92.5%; excluding weathered rock, 95%. In deep holes on the Witwatersrand (7 400–10 718 ft), core recoveries were 92 and 97.3% for 1 $^{1}/_{8}$-in core, 96.4% for 2 $^{1}/_{8}$-in core.

22. SPEED AND COST OF DIAMOND DRILLING

Speed is affected by: kind of rock and surface covering; depth, direction, and situation of hole; quantity of water in hole; kind of drill, fittings, and accessory outfit; core requirements; labor, climate, and continuity of work; percentage of delays. Rate of advance is higher in uniform rock than in alternating hard and soft strata; low, in shattered and fissured rocks. Hard uniform rocks that core well drill faster than soft rocks which grind up in the core barrel. Caving decreases speed. With proportionate increase in weathered surface covering, there is usually a fairly consistent decrease in speed and increase in delays; bouldery formations also decrease speed. Since many factors affect drilling rate, a complete record of each case is needed fully to interpret results; there is great difference between actual and overall drilling rate.

Table 49. Progress in Diamond Drilling from Surface (E. J. Longyear Co)

No of holes	Depth of holes, ft	Progress per shift, ft	
		While drilling	Overall
6 in limestone	200–1 000	28.6	17.2
shale	1 000	33.1	21.1
iron formation	1 200	10.1	7.2
gypsum	1 000	22.6	13 3
clay	300	23.0	16.1
traprock	1 200	12.2	9.3
norite	1 000	18.4	12.6
serpentine	300	21.4	14.3
basalt and granite	1 000	9.1	6.2
porphyry	600–2 000	9 0	6 2

Table 49 includes contracts on which steam drills were used; more modern gasolene, air or elec drills give higher speeds; 40-70 ft per 8-hr shift underground is not uncommon. Gasolene surface drills, with their high rotative speed and freedom from delays, make old drilling rates practically obsolete.

Table 50. Typical Diamond Drill Costs per Ft

Material	Clay	Gypsum	Limestone	Limestone	Limestone	Limestone	Shale	Norite (nickel)	Porphyry (copper)	Porphyry	Iron formation

Total	$0.42	$0.50	$1.04	$1.29	$1.65	$1.30	$1.74	$1.36	$1.57	$2.48	$1.83

Between the horiz and vert, the inclination of the hole has little effect on speed. In the same formation, holes pointing upward drill slower than those pointing downward, because of the awkwardness of arrangements at mouth of hole. Occurrence of much water in such a hole adds to inconvenience in drilling, and tends to retard progress.

Whether the drill is working underground or on surface makes no appreciable difference in speed, once the drill is set up. Moving is usually more difficult underground, but the moves are likely to be shorter and several holes are often drilled from one setup. Holes drilled from scows into subaqueous strata always advance more slowly than those in similar formations where the drill can be set up firmly. Rate of advance per drilling hr increases with size of drill. But, rate per working hr may be greater with a light than a heavy drill, when holes are shallow and moves frequent.

In rock which cores well, the longer the core barrel used the faster the advance. In soft friable rocks, if high core recovery is essential, use of double core barrel will increase speed. Taking cores 2 in and smaller, size of core has no appreciable effect on speed, provided drill is not working beyond its rated capacity. Larger holes will drill more slowly. Holes drilled with a solid bit advance faster than those with an annular bit, unless the hole is of large diam. Best quality of carbons, well set, gives fastest progress.

Holes drilled by contract usually show higher speeds than those on company account, unless great difficulties are met and contractor can not finance added expense. Bonus system is sometimes successful. The danger in contract and bonus systems is that unless a minimum percentage of core recovery is stipulated increased speed may be gained at expense of core recovery. Unfavorable climate, cold or tropical, retards drilling. Drilling 24 hr per day usually gives a greater speed per working hr than one-shift work. In the latter, time is wasted in starting up, and usually also at end of shift, due to fact that it is unsafe to leave the drill with the rods in the ground (see also, Prospecting, Sec 10).

Drilling at Phelps Dodge United Verde Mine. Most diamond drilling is "short-hole" work, 100–500 ft deep, for delimiting known ore areas, prospecting stope walls, determining structure or geological formation, and to aid locating development headings. Occasional long holes, 1 000–2 200 ft, are drilled for prospecting outlying ore areas. Ground drilled varies from soft chlorite schist and metamorphosed quartz porphyry to hard rhyolite-porphyry, diorite and massive pyrite carrying quartz and jasper; highest speeds are in massive sulphide ores. A Boyle BBU drill is used for short holes, with E bits; Longyear UG drill, in harder ground, for depths of 200–1 000 ft; Sullivan C hydraulic drill, for deeper holes. The ES $^9/_{16}$-in bit is used where depth requires surveying, and 1 $^7/_8$-in bit for holes that may require grouting or casing. A Wright bore-hole surveying instrument is used for holes over 500 ft deep, to check deviation in bearing and inclination. Core boxes with corrugated removable metal trays carry core to the diamond drill shop. Representative sections of core from holes of particular interest are kept as a permanent record; otherwise, the entire core is sent to assay office; part of the pulp is saved for future analysis.

Max footage at United Verde (1930) was 33 376 ft, by 5 to 6 drill crews, 1 foreman and 2 bit setters. Present work is done by 1 crew, with foreman who sets bits and supervises other work. In holes averaging 250 ft, footage is 40 ft per shift in aver schist or porphyry, and 25 ft in hard sulphide. For 1 500-ft holes, with setups permitting 20-ft changes of rods, footage is 10 ft per shift. Bort is generally used in all kinds of ground; carbons sometimes for outer ("gage") stones in broken quartz or siliceous sulphide. Bort loss, 0.02–0.1 carat per ft. Cutting edges of bits are rounded and set with bort averaging 20 stones per carat. The E bit (1 $^7/_{16}$ in) averages 120 stones and requires 7 hr for setting; the ES (1 $^9/_{16}$ in) bit usually has 100 stones, 6 hr for setting; the A (1 $^7/_8$ in) bit takes 150 stones and 9 hr aver for setting. Recovery of stones from used bits, aver 50%. Costs in Table 51 are direct only, not including cost of cutting stations or overhead. Wages: runner $6.95, helper $5.67 per shift. About 60% of foreman's time was charged to drilling.

Table 51. Cost of Drilling 6 922 Ft of Hole in 1937, United Verde Mine

Labor	$0.82
Carbon	0.31
Supplies	0.02
Compressed air and water	0.02
Miscellaneous	0.02
Total	$1.19
Number of holes	58
Aver depth, ft	119
Max depth, ft	507
Ground classification:	
Hard siliceous sulphide	6.3%
Aver sulphide	31.9
Schist	27.5
Porphyry and diorite	34.3

Note.—Total carbon loss for above holes, .031 carat per ft; max in any month, .098 carat.

Drilling in Lupa Goldfield, Tanganyika, Africa. About 10 000 ft of hole were bored in 1 year. As water was unfit for boilers, Longyear UG-A screw-feed drill with Ford motor was used; rated capac, 1 100 ft of EX hole. Water pumped, 3 000 gal per hr. Total equipment cost, including rods, casing, bits, core barrels and fishing tools, was about $12 500, fob North Bay, Canada. Wages: bit setter, $275 per month, and drill runner, $200, both plus expenses; native helpers, $2.50–$4.50 per month, plus food; 2 8-hr shifts, 6 days per week, with 1 driller and 3 helpers. In 1 year (1934–35), 17 angle holes totaling 10 192 ft were bored by contract, on a cost-plus-15% basis, the company furnishing equipment. Rocks drilled: weathered, 4.4%; diorite, 55.2%; sheared rocks, 30.5%; aplite and diabase dikes, 7.1%; granite, 1.9%, quartz veins, 0.9%. For core recovery, see Art 20. Holes were 120–1 325 ft deep. Drilling was delayed considerably by core-blocked bits and barrels, due to: fractured rock, small angle of intersection of holes with joint or bedding planes, fragments of rock falling to bottom of hole, and crooked core barrel. Bits had 12–16 bort outside, and 10–14 inside, 6–8 stones per carat; face of bit, 22–30 stones, 10–15 per carat. Reaming shells had 3 rows of 12 stones each, increasing slightly in clearance in each row, and averaging 3 or 4 per carat. EX bits averaged 54.8 ft of hole per bit; AX casing bits, 6.6 ft; AX steel-set casing bits (hard cutting teeth), 6.3 ft; EX reaming shells, 600 ft per shell. Aver diamond loss, 0.048 carat per ft, cost $0.335. Holes surveyed by hydrofluoric acid method (Art 24) every 50 ft; aver deflection in 600-ft holes, 1° per 100 ft. Costs, including wages and living expense of drillers, diamond loss, gasolene, oil, native wages and food, general supplies, and office expenses, were $1.837 per ft; to which add $1.938 to cover 50% of plant, traveling expense of crew from Canada and return, transport of machinery, insurance, housing, machine shop and a 15% local operating fee; total cost per ft, $3.775 (51).

Drilling at Noranda Mines, Canada. E rods are used for holes to 1 000 ft, with space for 5-ft pulls to 200 ft, 10-ft up 600 ft, and 20-ft pulls for greater depths. Drill is a Longyear UG; rods, 5 and 10 ft long; reamer, 2.5 in long, outside diam $^5/_{16}$ in; double-tube core barrels, 5, 7 and 10 ft long; diam of core, $^{15}/_{16}$ in; core recovery, 97%. As drilling was not on contract, more stress was laid on core recovery than speed. Four machines drilling in massive sulphide, rhyolite and diabase during 1937, averaged 21 ft per 8-hr shift, including time for moving and setting up; aver depth of holes, 250 ft; max speed, 60 ft in an 8-hr shift. Wages: runners, 73¢ per hr; helpers, 56¢. Estimated cost per ft during one year: material (mostly parts), 18¢; labor, including setting bits, 80¢; bort and carbons, 23¢; overhead, including compressed air, 31¢; total, $1.52. Bits set with bort, 12–15 stones per carat; reamers, with carbons of 0.25–0.5 carat each. For special work a Longyear Prospector Drill was used, with 5-ft rods, $1\,^{1}/_{16}$ in outside diam; reamers, $1\,^{1}/_{8}$ in long, outside diam, $^{15}/_{64}$ in; bit $^{7}/_{8}$ in long, $^{5}/_{8}$-in inside diam; core barrel, 5 ft; diam of core, $^{5}/_{8}$-in; core recovery, 97%. Drilling speeds for 4 000 ft averaged 25 ft per 8-hr shift; max footage, 40 ft. Costs not available.

Witwatersrand, So Africa. Table 52 gives details of the deepest holes yet bored by diamond drill (contract costs from Sullivan Mach'y Co, So Af). In other deep holes, in the Far East Rand Areas, the formations comprised about 700 ft of dolerite, sandstones and shales, followed by dolomite, amygdaloidal diabase, quartzites, volcanic breccia and hard slates, each sometimes of great thickness but flat dip. Sullivan N and P drills were used, with 60-ft derricks; 3 8-hr shifts, 6 days a week. Holes were started vertically with 3-in bits; casing, $2\,^{7}/_{16}$ inside diam; then 2.25-in to 2 000–3 000 ft and $1\,^{7}/_{8}$ in to 5 000 ft. Speeds varied greatly: in dolerite, max for 24 hr, 149–186 ft; max for 1 month, in dolerite, quartzite, shale and breccia, 1 295–1 357 ft; for 1 year, with 4 machines, 4 925 ft, 1.5-in holes (54).

U S Bureau of Reclamation. Diamond drilling for possible dam sites, Texas, with Longyear, Sullivan, and Knight and Stone machines. In easy limestone, 4 700 ft were bored at aver of 21 ft per 8 hr; aver depth, 150 ft. Time includes water testing every 10 ft, and driving casing through as much as 50 ft of overburden, and moving from hole to hole. For holes 40–100 ft deep, in fractured gneiss, core recovery was 65–100%, cost over $3 per ft. Nine holes, in limestone, aver 100–150 ft deep cost about $1 per ft; others, up to $1.87 per ft. At Marshall Ford dam, a Sullivan air drill bored 27 000 ft, at a cost (to contractor) of $0.35 per ft; other shallow holes, $0.68 per ft. At Grand Coulee dam, diamond drilling was contracted at $2.95 per ft for 84 vert holes, and $3.50 for 15 angle holes, all in hard granite.

Climax Molybdenum Co (1937–38) drilled 12 467 ft of 1.5 to 2 $^3/_8$-in exploratory holes (Table 54) in granite and schist; range of depth, 200–1 540 ft, aver 600; aver speed, 14.81 ft per 8-hr; core recovery 50%.

Salt beds of western Texas and New Mex. Diamond drilling was done by contract (1927–29) to depths of 1 000–2 750 ft, to test potash content of beds; cores, 2.5-in. As KCl is soluble, a saturated solution of common salt plus MgCl was used instead of water. Total footage, 20 400 ft; core recovery, 98%.

Kennecott Copper Corp, Alaska, has done much exploratory diamond drilling by contract, mostly in dolomite, all underground work. Nearly all holes are at angles of 5–10° to horiz. For 60 800 ft of 1.5-in hole ($^7/_8$-in core), aver cost from 1920 to 1931 was $2.15 per ft. Later costs (1937) are about the same.

Sullivan mine, Kimberley, B C. Underground diamond drilling by contract in chert, quartzite and massive sulphide ore (pyrhotite, galena and sphalerite). Cores, $^3/_4$ in for holes less than 200 ft. Costs, $2–$2.12 per ft.

Homestake mine, So Dak. The orebody, a steep-dipping replacement in schists, slates and quartzites, is best prospected by horiz holes across the strike. All drilling is now done underground; parallel holes, 100 ft apart, and 50–450 ft deep (Table 55).

Table 55. Underground Diamond-drilling Costs, Homestake Mine, S D

(*a*) Nearly all horiz holes, from 7 by 7-ft drifts; (*b*) including all delays for moving; (*c*) includes bonus; (*d*) includes charging off new equipment; (*e*) oil and supplies; (*f*) compressed air; (*g*) includes an inclined hole from surface, 1 018 ft deep; (*h*) carbon bits only; (*i*) cast bort bits, except in broken ground.

El Potosí mine, Mex. In 1934, 58 726 ft of holes were drilled with electric machines, which saved 8¢ per ft over air-driven drills. Table 56 gives costs.

Matanuska coal basin, Alaska. Core drilling in sandstone, and clayey shale that clogged bits and required frequent pulling of rods. Speeds: shale, 2.5–6 ft per hr; sandstone, 10 ft; aver, including pulling of rods, 1.3 ft per hr; 8 holes, 676–1 820 ft; contract price, $4.25, plus $3 per ft of core recovered (58).

Star mine, Rhodesia. Zinc silicate orebody, in limestone and schists (60). Drilling bad in schist; good in limestone; 10 700 ft of hole; aver depth, 275 ft; aver per shift, 11.76 ft; core recovered, 74%. Table 57 gives costs.

Table 56. El Potosí Mining Co, Mex (H. A. Walker)

	Cost per ft (1938)	Cost per ft (1934)

	$0.5064	$0.4220
Total footage....	45 129 (*a*)	80 128 (*b*)

(*a*) Includes 9 275 ft elec drilling; (*b*) 58 726 ft elec drilling; (*c*) lost bit increased cost 7.4¢ per ft.

Phelps Dodge Corp, Morenci branch, Ariz (Apl, 1938). Data on 11 holes of 750 ft aver depth: total aver working hr, 574; contract price, \$3.50–\$3.69; total aver cost, including eng'g, sampling and general expense, \$6.03. Casing, 25% of all holes. Drilling was in shattered ground, largely monzonite granite.

Purchase vs rental of prospecting drills is a question usually decided by local conditions. If only a few holes are necessary, renting or contract work often preferable; for a large amount of drilling, purchase of equipment may be cheaper (57).

Total	\$4.247

23. SHOT-BORING WITH CALYX DRILL; SHAFT BORING

Construction. Like the diamond drill, the bit is rotated by hollow rods, driven by an engine and gearing on the surface. Chilled-steel shot, $^1/_{16}$ and under, to $^1/_8$-in, are the abrasive medium. Fig 49 shows bit for small holes. The shot, fed into the rods with the wash water, pass to the inner periphery of core barrel and bit; thence under the bit, some being crushed, others remaining unbroken and are rolled around under its edge. Diagonal slots in the bit allow passage of wash water to the annular space outside, without displacing and lifting the shot. The sludge collects in a hollow cylinder ("calyx"), above the core barrel and open at the top. As the rods are of smaller diam than the calyx, the veloc of the rising water is decreased, permitting deposition of the coarser sludge in the calyx (Fig 50); to carry this material to the surface would require a large quantity of water under high press. In large machines, the wt of rods gives sufficient press on the bit; in smaller sizes, added press is applied by a rack feed and hand wheel. Speed of rotation, 50–100 rpm. Instead of using a mechanical core lifter, as in the diamond drill, the drill core is gripped by wedging it in the barrel with angular pieces of quartz, dropped through the rotating rods. Inclined holes can not be more than about 35° off the vert, as the shot tends to run to lower side of bit. A complete Calyx-drill outfit, delivered in the West, costs \$8 000-\$10 000.

The Calyx drill can bore holes from a few inches diam to 6 ft or more. An important application is the boring of mine ventilating shafts and chutes for ore and waste (for the latter, see Sec 10, Art 23). A bored shaft will often stand without support, where shattering of walls by explosives in usual shaft-sinking methods would require timbering; hence the advantage of boring a ventilating shaft, leaving smooth walls, without fire hazard. Early methods for holes of large diam involved actuating the drill from surface;

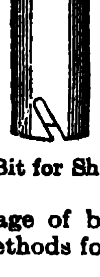

Fig 49. Bit for Shot Boring

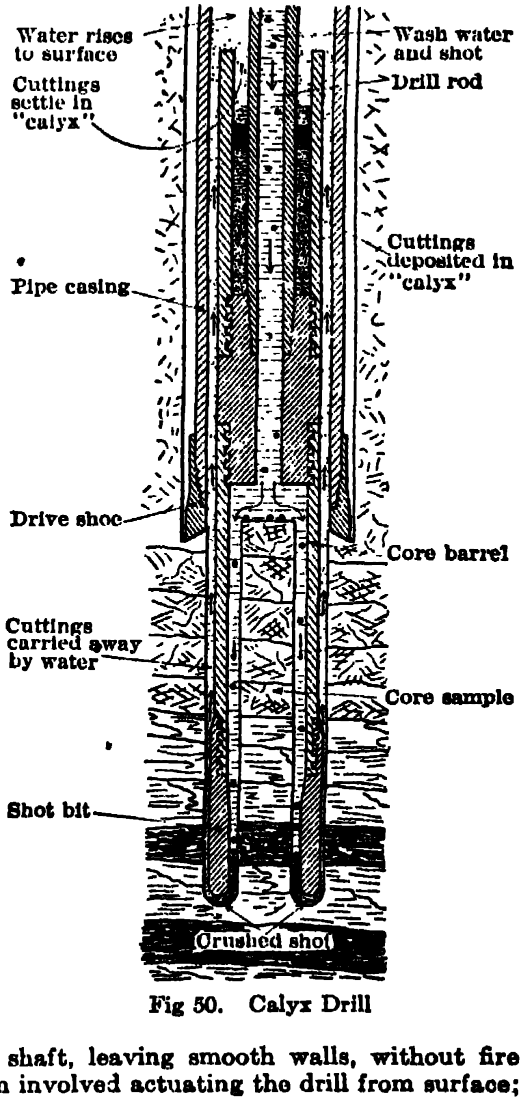

Fig 50. Calyx Drill

but a recent drill designed by Newsom (64, 81) has driving mechanism and operator in a cage just above core barrel at bottom of hole (Fig 51).

Zenith mine, Minn (65, 81). Vert ventilating shaft, 5.5 ft diam, through 15 ft of alluvium by hand, 1 193 ft bored in rock; total depth, 1 208 ft; elapsed time, 7 mos. Formations: greenstone, some quartzites, chert and diorite. Surface plant: stiff-leg derrick, 60-ft boom, working load 30 ton, impact load 95 ton; main hoist, 200 hp, normal line pull 13 200 lb, rope speed 450 ft per min; man hoist, 25 hp; power-cable reel with 25-hp motor; air-hose reel with 11-hp motor; air compressor at 40 cu ft per min for ventilation. Drill (Fig 51): 100-hp motor; speed of core barrel, 52 rpm; wt on cutting shoe, about 6 ton; length inside core barrel with new shoe, 15 ft 2 in. Core puller, inside length 8 ft; bailer; man cage (for 2 men); muck bucket. Aver drilling rate, 5.8 ft per day; best week, 77 ft; aver per drilling cycle, 8.46 ft. Shot consumption for 714 ft of hole, 32 lb per ft. Total man-hr, 15 320; direct crew man-hr, 11 044; crew-hr, 4 933 total, 4.13 aver per ft, of which 0.39 for setting and removing drill, 0.96 drilling, 1.05 bailing, 0.53 mucking broken cores, 0.48 pulling cores, 0.12 changing drill shoes, 0.60 lost time. Operating cycle: drill lowered to bottom, power cable and air hose lowered; operator went down, tightened jackscrews against wall of hole (Fig 51) to resist motor torque, connected cable and hose, and drilled until core barrel was filled, or until stopped by some operating condition; he then disconnected cable, released jackscrews and went to surface. Drill raised and inspected; sludge and water bailed from hole; operator went down, broke off core with hand-driven wedges, and returned; core puller lowered (Fig 52) and core lifted; hole again bailed, and operator went down to remove broken rock and inspect bottom; his return completed the cycle. Direct cost per ft: labor and supervision, $12.16; power and supplies, $7.34; total, $19.50.

Idaho-Maryland mine, Calif (earlier instance of same method). Shaft, 5 ft diam, 1 125 ft deep. Best day's progress, 10 ft; in 30 days 150 ft were bored; aver cost per ft, $23.67.

Examples of operating large drills from surface (U S Bureau of Reclamation): (*A*) An Ingersoll-Rand WS3 machine bored a 3-ft hole 29 ft deep in gneiss, in 27 shifts; cost per ft, $24.19. Badly fractured rock and a flow of water made drilling difficult. (*B*) In dolomite, 2 holes 46 and 56 ft deep were drilled by same machine in 36 shifts; cost per ft, $23.60. (*C*) In limestone, an Ingersoll-Rand W-3 machine drilled 993 ft of hole (2 of them 92 ft deep), including moving, laying pipe lines and setting up, at aver of over 3 ft per shift; cost per ft, $12.56. Of this total, 211 ft cost $8.12 per ft. (*D*) Grand Coulee Dam: 8 holes, 3-ft core, 386 ft aggregate depth, were bored at an aver speed of 0.33 ft per hr actual drilling time; cost per ft, $31.40; shot used, 9 130 lb. (*E*) Kennett Dam: 2 36-in holes, total depth 187 ft, cost $26.63 per ft; shot used, 4 650 lb.

24. DEVIATION AND SURVEYING OF BOREHOLES

Deviation or drift. Few diamond or rotary drill holes exceeding 100 ft deep are straight; deviation is least in cable-tool holes. In general, deviation increases with depth; also, holes bored at only a slight angle to dip of strata tend to parallel the bedding planes. Surveys to 3 000 ft of 8 deep holes on the Rand showed that: at 1 000 ft, all holes were nearly plumb; at 3 000 ft, 2 were over 25° off plumb (54). At the Britannia mine, B C, horiz holes drilled toward an underlay footwall curved downward, those toward the hanging wall curved upward; holes drilled obliquely to hanging wall curved downward; thus, holes tend to become normal to dip and strike (Fig 53). Holes have been started as much as 25° off true direction in order to reach given objectives (67). Deflection generally seems to vary inversely as length of core barrel (68); worn or short core barrels, or light rods, or excessive press on bit, aggravates tendency to deflect. Drift of oil wells has caused so much trouble that holes are regularly surveyed to keep deflection under control, and successful directional drilling depends on accurate survey methods to determine both drift angle (deviation from vertical) and bearing. Methods and instruments commonly used for oil-well surveys may be classified as follows;

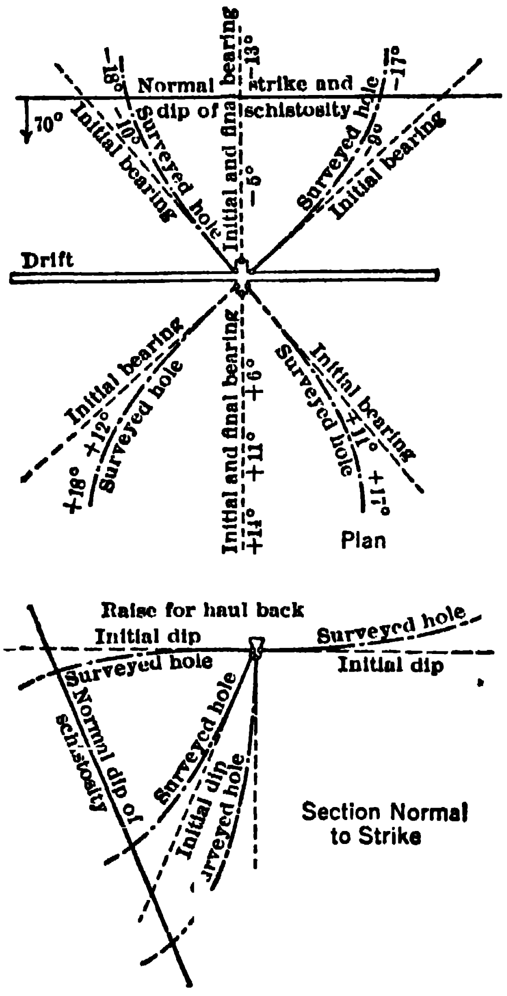

Fig 53. Deflection of Horizontal Diamond-drill Holes in Shear Zone (*E & M Jour*)

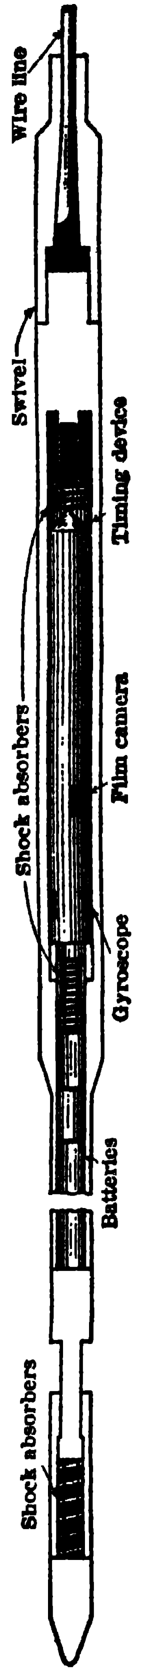

Fig 54. Surwel Gyroscopic Clinograph

Surwel Gyroscopic Clinograph (Fig 54) is used in either an open hole or casing. Readings of drift angle and bearing are taken at any desired interval, going down or coming up, thus giving check readings. The instrument, electrically operated, maintains a fixed bearing, set beforehand, as desired; it carries a non-magnetic watch, compass dial and thermometer. An elec film camera, operated at will, with double lenses and timing contact, records time in seconds, temp, and inclination from the vert; capac, 50 ft of 16-mm film, 1 000 records. Instrument weighs 45 lb, its protective steel case, 1 300 lb. It is lowered on a $^9/_{16}$-in wire line, or on the drill rods. The error of closure between two check surveys, in and out, should not exceed 1% of well depth. Time for a round trip in a 9 500-ft well is about 3.5 hr on wire line, or 7.5 hr on drill rods.

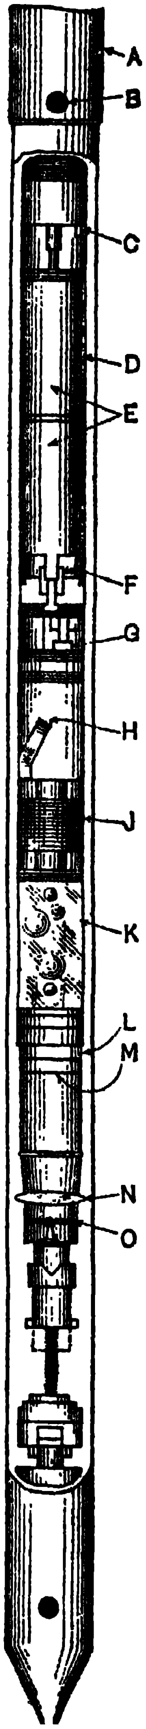

Photo-magnetic instruments record on sensitized paper disks the drift angle (indicated by a delicate plumb bob), and the compass bearing. They do not give reliable compass readings inside casing, but, if lowered 8–10 ft beyond casing, are practically free from magnetic interference. There are 2 forms: MULTISHOT INSTRUMENT (Fig 55) has recording film for a number of observations; SINGLE-SHOT INSTRUMENT makes one record only (Fig 56), disk *a* reading to 5° within 5 min, disk *b* reading to 24° drift, within 20 min. Position of plumb bob image, the *x* mark on concentric circles, shows drift angle. Bearing is read by drawing a straight line from center of disk through *x*, or intersection of plumb bob cross hairs, to rim of disk on which bearings are printed. Disks are available for drift angles up to 70°, but accuracy decreases somewhat as drift angle increases. A single-shot instrument is loaded in daylight from a clip of sensitized disks. Time of lowering is set beforehand on the instrument watch, which closes an elec contact when taking record, a synchronized watch being used at surface. On return to surface, the developed disk is available within 2 or 3 min. In some deep borings, where bottom temp may reach 250–300° F, it is difficult to use photo films. At about 240° the camera must be cooled.

Instruments recording drift angle only make a photo record, or mechanical record in form of a punch mark, or graphic record in form of a curved stain on a paper scale. They are run into well like the preceding, or dropped through the drill pipe, and recovered by raising the pipe. When dropped into the well, this "Go-Devil" type has protective spring guides on outside of its casing. TOTCO DRIFT RECORDER makes a punch mark on a disk with concentric circles to show drift angle. It can be raised from the well at 3 000 ft per min, thus saving time in deep holes. The recording mechanism comes to rest in less than 10 sec after reaching its position in the well.

Syfo Clinograph (Fig 57). The orifice chamber 4 is filled with a definite amount of fluid, which passes slowly through orifice 6 into delivery chamber 7, filling this chamber slowly until the upper bend of delivery siphon 8 is reached. The siphon action causes part of the liquid to discharge into recording chamber 12, and to rise quickly into upper bend of recording siphon 13, discharging thence into receiving chamber 16. The inflow into 12 is faster than the discharge, causing liquid to rise above bend in 13 to a point midway between top and bottom of recording paper 11. Liquid remains in this chamber less than 30 sec, and then drains out, thus eliminating danger of splashing the chart when raising instrument. Liquid leaves a stain with a sharp line of demarcation on recording paper, in form of a sinuous curve; vert distance from high to low point, as measured by the scale printed on the paper, gives angle of deviation from the vert.

Oriented core barrel (Eastman Oil Well Survey Co) takes a core, while simultaneously, with a single-shot instrument, making a photographic record of drift angle and bearing. The device makes a groove in the core, in line with a marker which shows in the photograph, thus correlating core with survey data.

Orientation of drill pipe at the surface. If the pipe is allowed to turn freely while being lowered, and is raised a few feet on touching bot-

Fig 55. Eastman Multishot Instrument. *A*, Drill-pipe sub. *B*, Orientation hole. *C*, Locking pins. *D*, Inner barrel. *E*, Batteries. *F*, Shock absorber. *G*, Start and stop switch. *H*, Contact-actuating clock. *J*, Electric motor. *K*, Film box. *L*, Lighting unit. *M*, Camera. *N*, Condensing lens. *O*, Compass on gimbals

tom and then lowered again, the orientation at the bottom is fairly close to the measured orientation at the surface (69). Rotation at surface is measured by sighting a distant point, and then measuring the turn of each section of pipe as lowered. In one hole having a drift angle of about 24° (at which friction of drill pipe in hole would have great effect) the survey at a depth of about 4 050 ft gave a bearing of N 36° 15′ W, as against a magnetic bearing N 35° 45′ W. Although this method is quite satisfactory, the magnetic method is usually preferred (70).

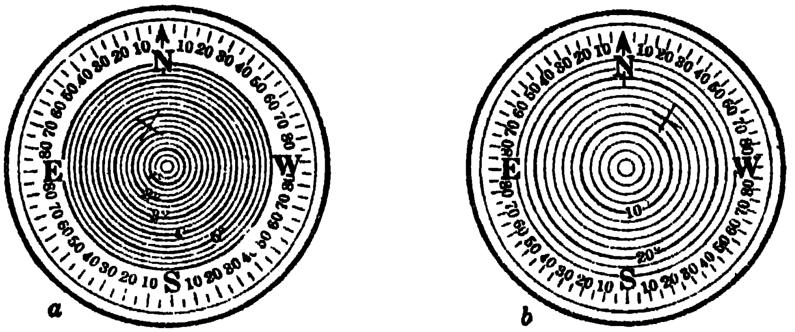

Fig 56. Photo Records (Lane Wells Co)

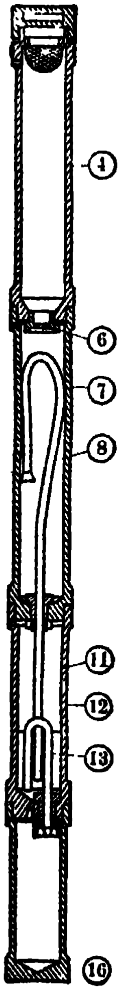

Fig. 57. Syfo Clinograph

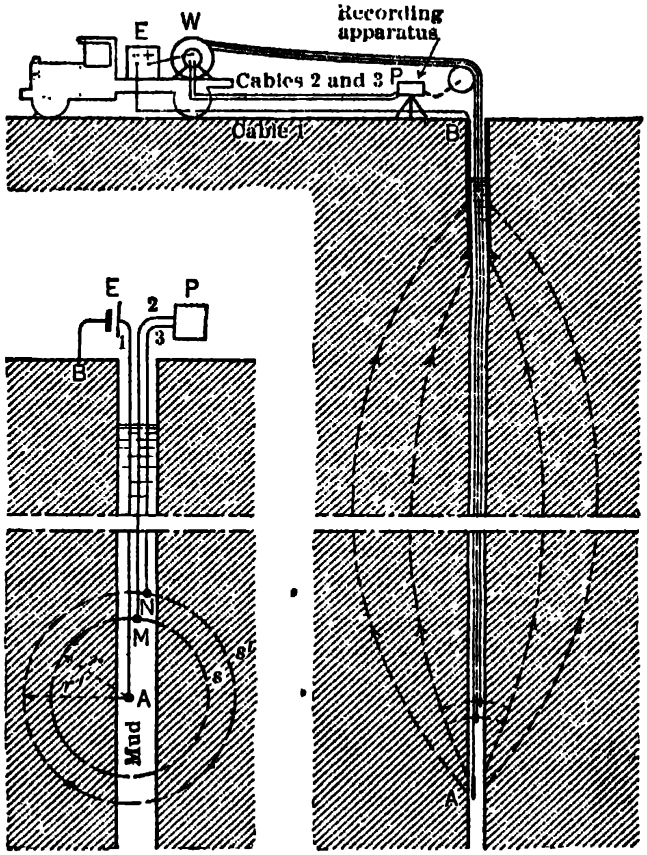

Fig 58. Diagram of Electrical Coring

Electrical coring (Fig 58) (" electrical logging ") is used to determine the resistivity and porosity of the formations through which wells are drilled (71). The conductivity of stratified rocks is not the same in all directions; hence, if an elec current flows into stratified ground, the surfaces of propagation are not spheres but ellipsoids, the axes of revolution of which are perpendicular to the plane of stratification, whence the direction of dip of

the formations can be determined. The principles of electrical and magnetic geophysical prospecting have also been applied with some success to the survey of boreholes (for details, see Bib 71, 72 and Sec 10A).

Borehole surveying is largely done by surveying concerns on basis of rental charges for equipment or service fees. Among them are: E. J. Longyear Co, Eastman Oil Well Survey Co, and Lane-Wells Co; some of them combine surveying with controlled directional drilling. **Rental charges range from $4.50 or $5 per day to $150 per year,** with a certain minimum fee; **surveying charges, $16–$20 per hr** of actual work, plus a standby charge and transport costs.

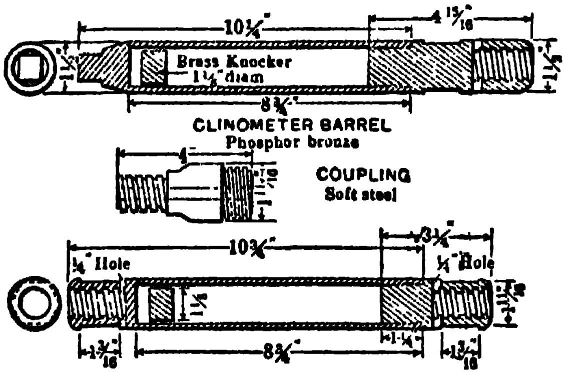

Fig 59. Two Types of Hydrofluoric-acid-bottle Container

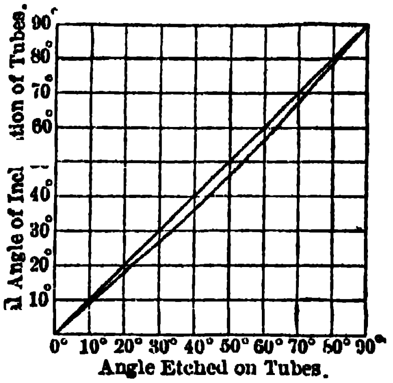

Fig 60. Curve of Capillarity Correction

Following are descriptions of several older methods of borehole surveying that are still useful.

Hydrofluoric-acid method is the simplest for determining deviation from the vertical only. Apparatus consists of small wide-mouth bottles with rubber stoppers, supply of hydrofluoric acid, a metal container for the bottles, and a goniometer. The bottles should be of constant diam outside and inside, throughout their length. Inside diam should be as large as diam of hole permits. By using a phosphor-bronze container, a bottle 1 1/8 in outside diam can be used in an *E* hole (Table 32). Walls of bottle should be about 1/32 in thick; stopper, tight fitting. Containers are of steel, bronze, or brass (Fig 59), bored to receive the bottle with snug fit. They are made in 2 parts, which screw together with fine threads, to exclude water, and are packed with lead or have carefully machined surfaces to insure a tight joint. A leak may cause collapse of the bottle, due to pressure of water in a deep hole. Containers are lowered into the hole by a wire; or attached to the end or in the middle of a string of rods, in which case they are threaded on one or both ends for rod connections. In operation, the acid is diluted according to depth of hole and time required for lowering the container, the aim being to allow the bottle to reach the desired place in the hole before any considerable etching takes place. The bottle is left at this point long enough to allow a line to be etched. Strength of acid and time for etching are best determined by experiment on the spot. Container is then withdrawn, bottle washed out, and angle of deviation measured by goniometer. The angle thus measured indicates a deviation from the vertical that is too small; due to CAPILLARITY, which causes the acid to rise on upper side of bottle, so that the surface of the acid at rest in the inclined tube, when in the hole, is not truly horizontal. Amount of error varies with angle of inclination, diam of bottle, and strength of acid. It is a max when the bottle is inclined 45°; is larger in bottles of small diam, and increases with the strength (and resultant viscosity) of the acid. Fig 60 is a curve for 1 1/8-in bottles and dilute (1 to 12) acid. For the strength of acid and diam of bottle used a curve should be plotted, giving correction for any given deviation.

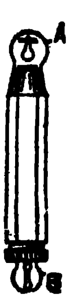

Fig 61. MacGeorge Gelatine Tube

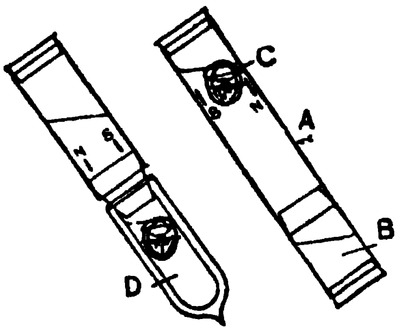

Fig 62. Maas Borehole Compass

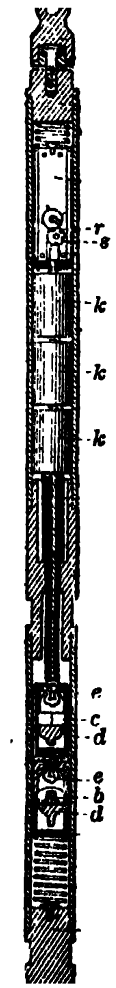

Fig 63. Oehman's Apparatus

Gelatine method (MacGeorge's). Apparatus consists of a container as above, and a tube to fit it. The tube (Fig 61) contains in the upper bulb A a small compass and in the lower bulb B a glass plummet, both floating in gelatine. The gelatine is heated in the bottle until it is liquid, then placed in the container, lowered to the proper point in the hole and allowed to set. When the tube is withdrawn it is placed in a goniometer with vert and horiz circles, the compass needle is brought into the meridian, the plummet made vert, and the amount of vert and horiz deviation read.

Maas borehole compass employs a combination of the above methods. It consists of a 1 1/8 by 6-in tube A (Fig 62), in one end of which is placed dilute hydrofluoric acid; in the other a gelatine solution and a small compass C. For holes so deep that the gelatine would set before the compass is in position, a small thermos bottle D contains the gelatine and compass, and a 3-in tube is used for the acid.

Photographic methods. OEHMAN'S APPARATUS (Fig 63) (73). Plumb bob c and magnetic needle b, have an electric light e above each, and photographic paper disks below on gimbals d, d. Clockwork r, s completes the circuit with battery k at a set time, at which the shadows of plumb bob and needle are photographed in the positions they take according to the deflection of the borehole. J. S. OWENS (74) has devised an instrument that gives a series of clinometer and compass readings recorded on sensitized paper by electric lights, the recording mechanism being controlled by clockwork. One insertion gives simultaneous records of essential data for each point in hole surveyed. F. Humphreys (75) describes a photographic instrument which records position of a plumb bob clinometer in relation to the quadrants of a compass. A line through the centers of plumb bob shadow and image of compass dial gives direction of drift, the distance between these centers showing drift angle on the graduated circles. The instrument is not designed for deviations greater than 35°. The Wright surveying instrument uses radio-active matter to affect a photo film (for details, see Bib 76).

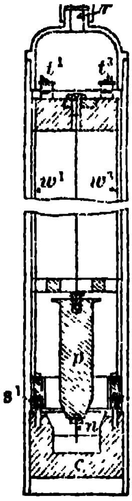

Fig 64. Transmitter of Briggs' Clinophone (after Redmayne)

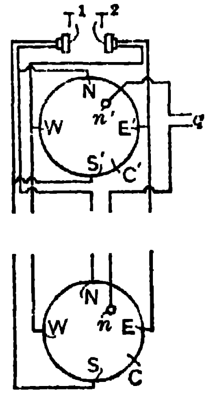

Fig 65. Diagram of Electrodes in Surface Receiver of Briggs' Clinophone

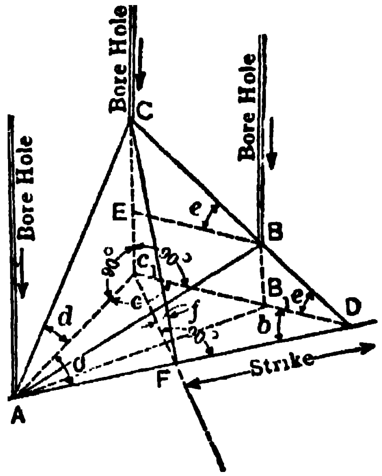

Fig 66. Computation of Borehole Data

Briggs' clinophone was designed for very accurate surveys of boreholes for the freezing and cementation methods of shaft sinking (Sec 8). Tests show that errors in readings seldom exceed 1 min. The transmitter (Fig 64) comprises: plumb bob p, with a needle n at the end dipping into vulcanite cup c, in which are 4 electrodes N, S, E, W of platinum foil. Each electrode connects at upper end to a plug and socket s' and s^3, and these in turn to upper terminals t', t^3, etc. A central terminal is electrically connected to needle n. A 5-strand cable passes through gland r to a receiver at the surface, which has 4 similar electrodes N′, S′, E′, W′, in a cup c' which, with cup c, contains weak salt solution (Fig 65). Needle n' is fixed in a metal holder. Alternating current is supplied through wires q. Telephone transmitters T', T^3 on surface are connected separately to N–S and E–W directions.

On lowering instrument into the hole, after plumb bob p and needle n are at rest the operator moves needle n' until the sound in both telephones is the same. Needle n is then in same position in cup c as needle n' in the hole in cup c'. The position of n' is recorded by a scale on bottom of c'. The instrument is oriented by the rods used to lower it, which have scarfed joints, thus making practically a solid rod, and any rotational movement of the transmitter in the hole is indicated at the surface. As a check, the rods can be turned through 180° and readings taken also on return trip. Readings are taken rapidly, the only time lost being that for the plumb bob to come to rest. The instrument is very accurate for small deflections; for greater deflections, the plumb bob is shortened.

Kiruna method (77) uses the electric deposition of copper from solution to make a mark within a cylinder, instead of etching by HFl. Used successfully in Sweden.

Use of survey results: (*a*) determination of dip and strike of a stratum or orebody cut at 3 places; (*b*) determination of dip from the core, the strike of the stratum or orebody being known; (*c*) determination from drill core of the true thickness of stratum.

Strike and dip. Theodore Simons (78) gives a convenient method of calculating strike and dip from 3 holes. In Fig 66, A = lowest point at which vein is cut; B = point of intermediate elevation; C = point of highest elevation; B_1 and C_1 = projections of B and C on horiz plane through A; d = angle of inclination of line connecting A and C; e = angle of inclination of line connecting B and C; c = horiz angle between above lines; b = angle between line of strike and extension of horiz projection of line connecting C and B; f = angle of dip; $m = \tan d \div \tan c$; $n = 180° - c$. Then $\tan b = \sin n \div (m + \cos n)$, from which the strike is obtained, and $\tan f = \tan e \div \sin b$.

Dip of a bed. E. E. White (79) gives a method for determining the dip of a bed from a hole not at right angles to the strike of the bedding, knowing this strike and the direction

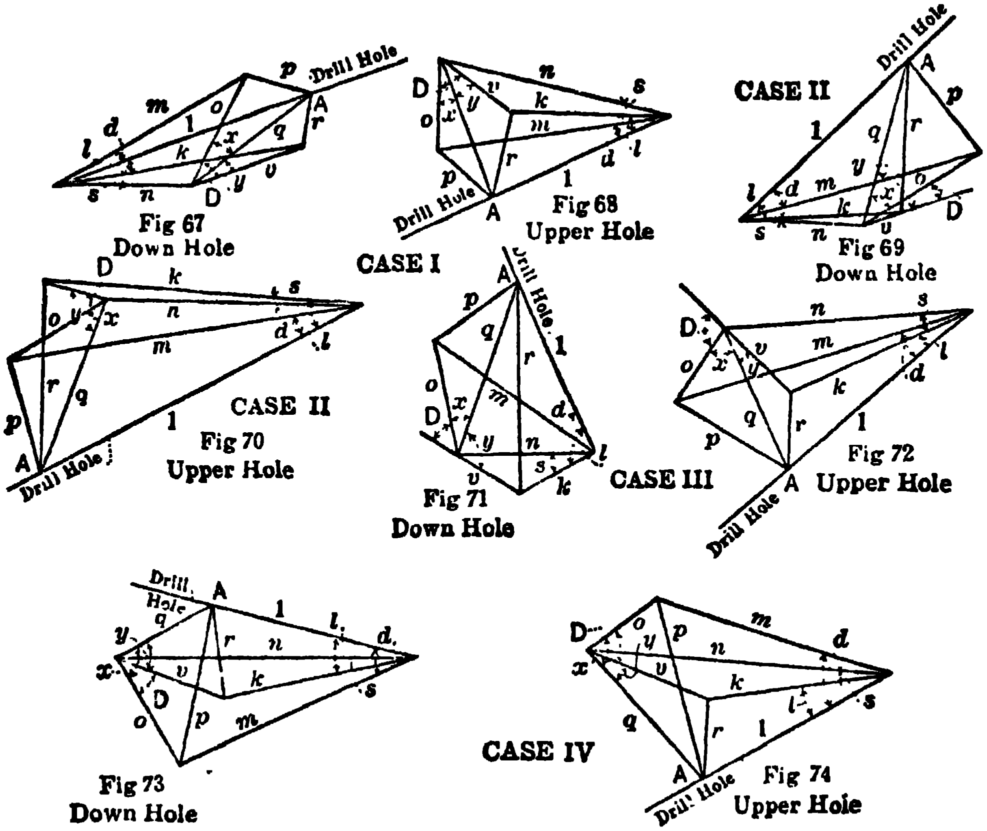

Fig 67–74. Various Combinations of Drill Hole and Bed (*E & M Jour*)

of the hole. In Fig 67, I = inclination of hole from horiz; d = angle between bedding and axis of hole, as obtained from core; S = difference in strike between bedding and hole; D = true dip of strata; p = length of a perpendicular from any point A on the hole to the bedding plane; r = length of perpendicular from A to the horiz plane through the intersection of the hole with the bedding plane; *mon* represents a bedding plane; *kvn* is a horiz plane through the intersection of the hole with the bedding plane; *qop* and *qvr* are planes through A perpendicular to n. If length of hole from A to point of intersection with the bedding plane is taken as unity, $\cos I = K$; $\cos d = m$; $\cos S = n \div K$; $\sin I = r$; $\sin d = p$; $n = \cos I \cos S$; $o = \sqrt{m^2 - n^2} = \sqrt{\cos^2 d - \cos^2 I \cos^2 S}$; $q = \sqrt{o^2 + p^2} = \sqrt{\cos^2 d - \cos^2 I \cos^2 S + \sin^2 i} = \sqrt{1 - \cos^2 I \cos^2 S}$; $x = \sin^{-1}\frac{p}{q} = \sin^{-1}\frac{\sin d}{\sqrt{1 - \cos^2 I \cos^2 S}}$; $y = \sin^{-1}\frac{r}{q} = \sin^{-1}\frac{\sin I}{\sqrt{1 - \cos^2 I \cos^2 S}}$.

Four cases arise: $D = x + y$, when beds dip in same direction as the hole, but more steeply (Fig 67, 68). $D = y - x$, when beds dip in same direction as the hole, but less steeply (Fig 69, 70). $D = 180 - y - x$, when beds dip in opposite direction to the hole, and more steeply than a plane perpendicular to the plane through the hole and the strike line of the beds (Fig 71, 72). $D = x - y$; when beds dip in opposite direction to the hole, and less steeply than a plane perpendicular to the plane through the hole and the strike line of the beds (Fig 73, 74).

J. N. Justice (40) gives a method for determining true thickness of a bed, knowing its dip, the direction of the hole as surveyed, and distance penetrated by the hole through the bed. In Fig 75, AB = plan of portion of hole in the bed; CAD = line of strike; EB = projection of strike line through B; AE is perpendicular to CAD; d = angle of dip; F = angle between direction of dip and direction of hole; P = apparent angle of dip; T = true thickness; $A''B$ is known in length and direction from the core and survey. The derived formulas are: $\tan P = (AE \tan d) \div AB = \cos F \tan d$; $T = A'A'' \cos d = A''B (\sin a \cos d - \cos a \cos F \sin d)$; $AA'' - AA' = A''B \sin a - AB \cos F \tan d$.

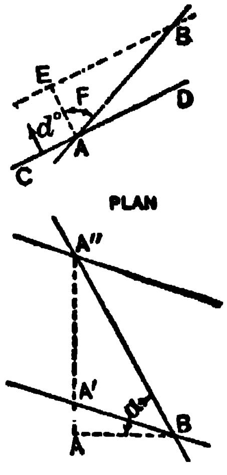

Fig 75. To determine Thickness of Bed

25. CHOICE OF BORING METHODS

Chief factors: (a) depth of hole; (b) speed and information desired; (c) first cost of outfit; (d) operating cost; (e) character of materials penetrated; (f) transport facilities.

For shallow work in earth or soft rock, a hand rig is preferable; for holes over 50 ft deep, or in hard rock, a power rig should be used, unless first cost, including transport, outweighs the saving. Speed generally increases with size and wt of rig, except that in shallow holes and frequent moves the time for dismantling, moving and setting-up may offset speed. The question of operating cost is so closely related to purpose of the work, character of strata penetrated and labor available, that each case must be considered separately. In hard, shattered rock, churn drills are preferable to diamond drills. Small rotary drills will bore ground that can not be satisfactorily penetrated by churn drills, but the question of sampling by rotary coring is not yet fully worked out. Large rotary outfits can go to greater depth than cable-tools. Diamond drills have been successful in sampling ore where no core could be made, the sludge being saved and assayed. To secure information as to physical character of ore or rock, a core drill is necessary.

PROSPECTING, DEVELOPMENT AND EXPLOITATION OF MINERAL DEPOSITS

1. DEFINITIONS

Mining includes surface operations, as quarrying in open cuts and the working of placers, as well as underground work. In a given mineral deposit, mining operations may be divided into 4 stages:

Prospecting, or the search for minerals.

Exploration, or the work of exploring a mineral deposit when found. It is undertaken to gain knowledge of the size, shape, position, characteristics, and value of the deposit.

Development, or the driving of openings to and in a proved deposit, for mining and handling the product economically.

Exploitation (mining), or the work of extracting the mineral.

These terms are used loosely. It is often difficult to distinguish between prospecting and exploration, or between exploration and development, as the different kinds of work insensibly shade into one another; an arbitrary differentiation between them is usually established at a given property. Confusion also arises when the terms are extended to describe operations on a property containing several orebodies. In such cases, prospecting for new orebodies is a part of exploration. In certain mineral deposits, prospecting and exploration are done in one operation by boring; as in the disseminated lead ores of S E Mo, and in those Mesabi iron ores and gold placers that are mined by open-cut methods.

Prospect is a mineral property before exploration has proved it to be worthy of development.

Since methods of prospecting and exploring a mineral deposit are based largely on its geological characteristics, a genetic classification of mineral deposits is invaluable (Art 3; Sec 2, Art 17). Methods of development and mining are determined largely by the shape and position of a mineral deposit. From this standpoint ore deposits are classified as:

Veins. Tabular-shaped deposits of non-sedimentary origin, usually dipping at high angles.

Beds. (1) Tabular deposits, lying conformable to the stratification of inclosing rocks; (2) detrital or sedimentary superficial deposits.

Masses. Large orebodies of irregular shape standing at any angle. Fig 4 shows outline of a massive orebody.

The following terms are commonly used in metal mining (letters refer to Fig 1–5). For coal mining terms, see Art 102 *et seq.*

Hanging wall or " hanging." Ore limit or wall-rock on the upper side of a dipping orebody (*h*); called " roof " in bedded deposits.

Footwall or " foot." Ore limit or wall rock on the lower side of a dipping orebody (*f*); called " floor " in bedded deposits.

Shaft. A vert or inclined opening, giving access to and serving the various levels of a mine (*d*, *c*); an " inside " shaft is one which does not open to the surface; a flat or low dipping inclined shaft is called " slope " in coal mines.

Crosscut. A horiz opening, like a tunnel, and running through country rock or ore at a considerable angle to the strike of formation or orebody (*g*).

Drift. A horiz opening, lying in or near the orebody, parallel or nearly parallel to its strike (*k*).

Level. The horizon at which an orebody is opened up, and from which mining proceeds. The term is often used in the same sense as " drift," or to cover all horiz workings on one horizon. Thus, the drifts and crosscuts in Fig 2 would be called the 1st level, or the workings on 1st level.

Winze. An opening (*m*) like a small shaft, sunk from an interior point in the mine.

Raise (Cornish, " rise "). A shaft or winze excavated upward (*l*) as for connecting adjacent levels. Terms winze and raise are used interchangeably to describe a completed opening as at (*n*), Fig 1.

Tunnel. Technically defined as a nearly horiz underground passage, coming to surface at both ends. In mining, the term is used also for such a passage open to daylight at only one end. Tunnels may be crosscut tunnels (*p*), Fig 5, or drift tunnels (*r*), Fig 1; the term " adit " is also used to describe any tunnel with one end open to the surface, although formerly limited to tunnels driven primarily for drainage purposes.

Stope. An underground excavation (*s*, Fig 1) resulting from actual mining of ore, as distinguished from other excavations in ore, as drifts, crosscuts, raises, winzes. The verb "to stope" is used loosely, but usually to denote the general plan and work of breaking ground in stopes.

Back. The ore between a level and the surface, or between 2 levels; also designates the roof of a drift, crosscut, or stope.

For comprehensive glossaries of mining terms, see Bib (1).

PROSPECTING AND EXPLORATION

2. CONDITIONS WARRANTING PROSPECTING

Search for mineral is largely guided by knowledge of the geological associations and peculiarities of known orebodies. It is done chiefly by miners who have absorbed the details of ore occurrence in mines where they have worked. However, they are keen observers, and have been responsible for most ore discoveries. Some deposits have also been found by inexperienced men, and some famous orebodies have been found accidentally. Crane (2) lists 130 gold and silver mines in the U S, of which 11 were discovered by chance. See also Bib (479).

Theoretically, the trained economic geologist should make the best prospector, but the chance of finding commercial orebodies is so small that such men can not afford to prospect unless employed by mining corporations. Engineers generally direct the work of exploration, and scientific prospecting is commoner than formerly. Economic geology aids by indicating favorable localities and eliminating unlikely ones. Most plans for exploration are based (often unconsciously) on theories of origin of the orebody concerned (Art 3).

Cost of prospecting and exploration should be kept low on account of the high risk involved. Simple methods should be employed and unnecessary expenditure for equipment avoided. It is impossible to estimate the cost of strictly prospecting work; while fairly accurate unit costs for trenches and test pits can be obtained, the required amount of such work can not be determined in advance. Closer estimates are possible for systematic exploration. Examination of a mineral property generally gives an idea of the amount and kind of work required to prove its value. The estimated cost of this work, compared with geological possibilities, furnishes a measure of the risk involved (Sec 25).

Presence of outcrops warrants prospecting, to determine whether shoots of commercial ore exist at any points along them. Since exposed outcrops of well known types of orebody have now been fairly thoroughly prospected in all but the most inaccessible regions, the field for prospecting at present lies in search for new or rare types, or for those orebodies the outcrops of which are covered. However, air transport has expanded the fields open to prospecting of the older sort, besides making it possible to develop and exploit outlying discoveries, as in northwestern Canada, New Guinea and central Africa (646).

In arid regions, surface exposures of rocks are often covered with a black or brown stain (MnO_2), known as "desert varnish." In such cases, if an orebody and the adjacent rocks are equally resistant to erosion, outcrops can not be distinguished unless pieces are broken off. There are undoubtedly exposed outcrops of this kind which have not been found. Their discovery is fortuitous, or results from patient detailed tracing of float (Art 4) (502).

Presence of float, as pieces of ore, or specks of metal or ore minerals, justifies prospecting. Such discoveries must be considered in connection with local geology. Thus, it is useless to seek the source of quartz float in a schist or slate area where individual quartz stringers are too small to be of economic value.

Favorable geological conditions. Many data have been collected about geological associations and characteristics of different types of orebody. Recognition of these characteristics in a new district warrants prospecting. Conversely, geological conditions may prohibit prospecting; thus, search for coal is useless in igneous formations. Common associations and characteristics of orebodies are given in Art 3. It is important to note that geological conditions at one place may be superficially similar to those at another and yet not be accompanied by workable ore deposits. Many geological conditions affecting occurrence of oil and other mineral deposits are recognizable from the air, with or without photography, but interpretations are more trustworthy if based on previous acquaintance with the ground. Features most clearly recognized: contacts between different formations and general character of each; faults; folded structures; quartz and other outcrops; oxidized cappings. For cost of aerial exploration, see W. E. D. Stokes, Jr, Bib (103).

Ancient workings and dumps of ore, waste, or slag exist in different parts of the world, and lead to prospecting in their vicinity. Much historical information about old EUROPEAN and SPANISH-AMERICAN mines is available. Occasionally, an old book or record has afforded a clue to the location of an ancient source of mineral. Reasons advanced for the abandonment of ancient mines are: (*a*) wars or attacks by savages, (*b*) pinching out or faulting of orebody, (*c*) occurrence of water, (*d*) lack of technical knowledge on the part of the ancients. *a*, *b*, and *c* may be valid reasons; water in particular prevented mining much below groundwater level. Most old workings show evidence of skilful mining (3); the ancients did not work orebodies the metallurgy of which was unknown. No development was done in advance of mining; frequently, the cost of acquiring property was merely the cost of prospecting. The slave labor used was the only capital invested, and did not disappear when the mine was abandoned or exhausted. The purchasing power of metals was higher than at present. In such circumstances the ancients could work small, irregular, and low-grade orebodies. The existence of old workings is not conclusive evidence of the existence of ore workable under present economic conditions.

G. R. Carey (4) in 1901 investigated ancient workings in RHODESIA, where there are numerous outcrop workings on auriferous quartz veins of which there is no written history. Aver depth of workings, 30 to 60 ft, occasionally 100 ft; in most cases mining had been confined to narrow pay streaks; aver stope width, about 2 ft. Indications were that the ore had been crushed, sorted, and washed. The following conclusions from this work are suggestive: (*a*) Length of old workings = length of pay shoots at the surface. (*b*) Strike of vein is shown by course of the workings. (*c*) Dip of vein is toward the steeper bank of the old excavations (since hanging wall over an open cut breaks down under long weathering), and may be determined from dip of the footwall bank of the excavation. (*d*) Width of vein can not be determined from, but is usually less than, the width of the old workings. Very narrow veins are indicated by narrow workings, with small dumps containing much waste. (*e*) Grade of pay shoots, vague, but above aver grade of dumps, if high values be rejected. (*f*) Large and numerous dumps in comparison with size of workings, especially dumps containing large pieces, indicate low-grade ores. Small, sparse dumps along strong workings indicate that whole vein was worked as payable, and that its grade was probably good. Roughly, the value of a vein is proportional to the ratio between extent of old workings and extent of the dumps. (*g*) No light is thrown by old workings on permanence of the vein or on its gold values in depth.

3. GEOLOGICAL DATA FOR PROSPECTING AND EXPLORATION

By Alan M. Bateman, Professor of Economic Geology, Yale University

a. Introductory

Most mine exploration rests upon geological theory or knowledge as to probable position, form, size, extension, mineral character, or value of an ore mass. Correct geological knowledge frequently enables one or more of the above features to be determined in advance of exploration, often with considerable accuracy. In some cases geology furnishes no clue, and exploration is necessarily blind. Following are some common conditions under which geology may aid in exploratory work, with methods by which results may be secured (see also Sec 2).

Sources of information: (*a*) PROCESSES OF ORIGIN OF A DEPOSIT determine its form, size, and geological position, the mineralogy and value of its primary ore, the probability of its occurrence in undeveloped districts, and success or failure of exploration for more ore in a partly developed district. Production of ore masses is only one of many effects of ore-building processes. Other effects, if recognized, may assist in discovering ores. Favorable indications do not insure ore occurrence, but, if they are entirely lacking, ores of the type not indicated will almost certainly not be found. (*b*) PROCESSES OF SUPERFICIAL ALTERATION acting on an orebody after its formation. These yield inferences from nature of outcrop as to what lies beneath a barren gossan, the value of undeveloped orebodies, depth to which developed ores may be expected to go, and often the presence or absence of any orebody at all. (*c*) TIME OF FORMATION OF A DEPOSIT, relative to other geologic events, determines the time relation between undeveloped ore masses and faults, intrusive rocks, metamorphism, sediments, and all geologic events that have occurred in a given district, and promises to yield valuable data. (*d*) KNOWLEDGE OF DISTURBANCES THAT HAVE AFFECTED AN OREBODY subsequent to its formation is useful when a deposit has been faulted, drag-folded, or affected by regional metamorphism. Faulted portions of orebodies may often be located. If effects of metamorphism are not too profound, the origin of the deposit may still be determined and used as under (*a*). In extreme cases of metamorphism, geology furnishes little aid.

Materials of mineral deposits and their formation. Mineral deposits are localized concentrations of special substances of the earth's crust; some are of common rock-making minerals. Of the 1 400 mineral species, about 30 are common rock-forming minerals and 200 occur in mineral deposits.

Metalliferous deposits consist of: (1) ORE MINERALS, containing one or more metals; they are mostly metallic; one or more metals may be obtained from a single mineral, or the same metal from several minerals; they are PRIMARY OR HYPOGENE, and SECONDARY OR SUPERGENE. (2) GANGUE minerals, usually discarded; mostly non-metallic minerals or rock; some are utilized, as rock gangue for road metal, fluorspar for flux, quartz for abrasive, calcite for soil dressing. (3) ORE, a mixture of ore minerals and gangue, from which metals may be extracted at a profit. Whether material is ore or worthless depends upon value of product and cost of extracting and marketing it; also upon content of byproducts or gangue minerals that can be utilized. Quantity of metal varies from 0.00016%, in case of some gold ores, to 60% for iron ores. Some ores have common metal associations, as Ag and Au, Ag and Pb, Ag and Co, Zn and Pb, Cu and Ni, Fe and Mn, Sn and Wo.

Non-metallic deposits consist of solids, liquids, or gases, and are mostly used in their natural state. They are mainly common substances, as fuels, rocks, sands, salts, and various non-metallic minerals. The deposits, gem stones excepted, consist mainly of the desired materials, which must usually be "processed" for market.

The materials of mineral deposits are formed by: (1) CRYSTALLIZATION FROM MELTS, as magnetite; (2) SUBLIMATION, as sulphur; (3) DISTILLATION, as petroleum; (4) SUPERSATURATION, as nitrates; (5) REACTION OF GASES WITH OTHER GASES, LIQUIDS, OR SOLIDS, as cassiterite, sulphur, magnetite; (6) REACTION OF SOLUTIONS WITH OTHER SOLUTIONS, GASES, OR SOLIDS, the commonest process, giving rise to most ore minerals by direct deposition, replacement, oxidation, reduction, adsorption or catalytic action; (7) PRECIPITATIONS BY BACTERIA, as iron and manganese oxides; (8) UNMIXING OF SOLID SOLUTIONS, upon cooling, as ilmenite from magnetite; (9) COLLOIDAL DEPOSITION, as manganese; (10) WEATHERING PROCESSES, placers, clays, bauxite.

In formation of most ore minerals, water has played the dominant part. Their deposition is greatly influenced by temp and press; a drop in temp or press commonly causes deposition of minerals in solution.

Stability of minerals. Most minerals change state in response to environment, and thus are indicators of geological conditions. High-temp minerals perish at the surface and take forms stable under the new conditions, like pyrrhotite to limonite; surface minerals change to stable forms at depth, as clay to mica or garnet; some are persistent, as gold or diamond. Other minerals change molecularly; chalcocite formed above 91° C is isometric, but on cooling changes to orthorhombic; below 91° C it forms directly as orthorhombic; isometric chalcocite, therefore, indicates primary origin.

Geologic thermometers. The above conditions yield geologic "thermometers," which indicate conditions of formation of ores and help diagnose ore deposits. They are established as follows: (1) DIRECT MEASUREMENTS, as of fumaroles; (2) MELTING POINTS, as stibnite at 546° C or bismuth at 271° C, which means that the Cobalt, Ont, ores containing Bi must have been formed below that temp; (3) DISSOCIATION, as calcite at 900° C or pyrite at 610° C; (4) INVERSION POINTS, as "high" quartz (a high-temp variety formed above 573° C) changes below 573° C to "low" quartz; isometric chalcocite changes to orthorhombic below 91° C, and argentite changes to the lower-temp form of acanthite at 179° C; (5) EXSOLUTION (separation from solution with lowering temp); cubanite and chalcopyrite exsolve at 450° C, bornite and chalcopyrite at 475° C, and covellite and chalcocite at 75° C; (6) RECRYSTALLIZATION, as native copper at 450° C and silver at 200° C; (7) LIQUID INCLUSIONS, as Tri-State sphalerite, formed between 115° C and 135° C, thus indicating a hypogene origin; (8) CHANGES IN PHYSICAL PROPERTIES; fluorite loses color at 175° C.

Magmas, rocks, and ores. Most metalliferous and many non-metallic deposits result from igneous activity: (1) some igneous rocks are themselves ores, as corundum syenite, and magnetite porphyry; (2) certain ores are closely related to igneous rocks, as nickel to norite; (3) some igneous intrusions are bordered by contact metamorphic ore deposits; (4) mineral deposits are also formed from volcanic emanations, fumaroles and hot springs; (5) veins are clustered in zonal arrangement outward from igneous intrusions.

When a magma begins to crystallize it undergoes differentiation, yielding basic, intermediate, and silicic fractions. Normally, basic minerals crystallize first and sink in the melt to form basic fractions. Magnetite, chromite, platinum and nickel generally accumulate with such basic fractions and may form ore deposits within the intrusive. As the basic minerals are subtracted, the residual "rest-magma" becomes progressively more silicic, and granitic magmas eventually become rich in silica, alkalies, and water; some may be squeezed into fissures to form pegmatites, containing many valuable minerals. With progressive crystallization the final aqueous extracts gather the metals and rare elements. These mother liquors constitute the magmatic solutions that give rise to most of the valuable mineral deposits.

The result of differentiation is to yield: (1) IMMISCIBLE SULPHIDE LIQUIDS, which settle and form magmatic sulphide deposits; (2) CRYSTALS of silicates and oxides, forming igneous rocks or ore deposits; (3) GASEOUS EMANATIONS, which escape and carry out valuable substances; (4) RESIDUAL LIQUIDS, containing metals. Gaseous emanations may react upon invaded rocks to produce contact metamorphic deposits, or may escape outward with their load of metals, later to condense and mingle with meteoric waters to form mineralizing solutions. Residual liquids may leave the magma as liquids and also constitute metallizing solutions. Thus, the magma may yield mineral deposits within itself and supply gases and hot liquid solutions to form the multitude of contact metamorphic and hydrothermal deposits that are the offspring of magmas.

Classification of mineral-forming processes. Recognition of mineral-forming processes and the resulting deposits is the basis upon which prospecting, exploration, and to some extent, development, depend. It is only when these processes are understood that assumptions and predictions as to geologic position, form, size, continuity, character of ore beneath croppings, and often their value, are reliable. Following table classifies mineral-forming processes rather than ore deposits, and is not opposed to the classification in Sec 2, Art 17. It is the basis of the practical considerations that follow.

Classification of Mineral-forming Processes

Process of formation	Resulting mineral deposit
Magmatic concentration	Syngenetic magmatic deposits (early and late)
Sublimation	Sublimate deposits
Contact metamorphism	Contact-metamorphic deposits
Replacement	Massive, lode, and disseminated replacement deposits
Filling of cavities	Fissure veins, and other cavity fillings
Sedimentation	Sedimentary iron, manganese, phosphate, coal
Evaporation	Saline deposits
Residual concentration	Residual deposits; oxides of aluminum, manganese, iron
Mechanical concentration	Placers
Oxidation and supergene enrichment	Oxidized and secondary enriched deposits
Metamorphism	Metamorphic deposits, asbestos, talc

b. Magmatic Concentrations

Origin is due to magmatic processes during consolidation; some, like nickel and diamond, are large and rich. Some ores, like magnetite, may form also by processes other than magmatic, but others, like Cr and Pt are formed only by magmatic processes. The orebody may constitute the whole of an igneous intrusion, as in the magnetite bodies at Kirunavaara, Sweden; more commonly, the useful mineral constitutes a relatively small part of the igneous mass, and occurs in disconnected, isolated masses near its borders or center. They originate by differentiation; some represent segregations of early formed crystals; others, injections of concentrated melts; others injections of residual liquid melts; and others injections of accumulations of segregated immiscible liquids.

Type	Process	Example
I. Early Magmatic:		
A. Disseminated crystallization	Crystallization in situ	Diamond pipes
B. Segregation	Fractional crystallization	Chromite deposits
C. Injection	Concentration and injection	Kirunavaara, Sweden
II. Late Magmatic:		
A. Residual liquid segregation	Fractional crystallization residue	Taberg; Iron Mt, Wyo
B. Residual liquid injection	Filter pressing	Adirondack magnetites
C. Immiscible liquid segregation	Concentration of immiscible liquid	Insizwa, Africa
D. Immiscible liquid injection	Same, with injection	Sudbury offset deposits?

Recognition. Magmatic deposits are composed only of magmatic minerals; labradorite and olivine are formed in no others. Typical hydrothermal minerals, as rhodochrosite, barite, sericite, chlorite, are absent. They are associated with an igneous rock of which they are a part or the whole, are never surrounded by a halo of typical hydrothermal wall-rock alteration, and constitute a small group of ores, each associated with its own rock type. They are distinguished from contact metamorphic deposits by absence of contact metamorphic minerals, and from replacement deposits by absence of hydrothermal minerals and alteration.

Occurrence. Magmatic concentrations occur as irregular marginal segregations, rarely as central segregations, also as dikes and irregular intrusive masses. Some are stratiform with enclosing igneous bodies, as the platinum and chromite deposits of the Bushveld, So Africa. They occur only in association with the mother igneous rock.

Valuable products. Some of the valuable magmatic mineral products are:

Deposit	Minerals	Parent Rock
Native Metals		
Pt	Pt, and with chromite or Ni-Cu-Co sulphides	Peridotite family
Pt metals	Osmium, iridium, palladium, etc	"
Au, Ag	By-product metals	"
Oxides		
Fe	Magnetite, some hematite	Syenites, anorthosites
Fe-Ti	Titaniferous magnetite	Gabbro family
Ti	Ilmenite	"
Cr	Chromite	Peridotite, serpentine
Al	Corundum	Nepheline syenite
Sulphides		
Ni-Cu	Chalcopyrite, pentlandite, polydimite, sperrylite with pyrrhotite, some pyrite	Norite
Ni	"	"
Cu	Bornite and chalcopyrite	Silicic rocks
Precious Stones		
Diamond	Diamond, garnet	Kimberlite
Garnet	Pyrope, almandine	Ultra-basics
Peridot	Peridot (olivine)	Peridotite

Practical applications. Segregations are marginal in position and irregular in form. Only those of large horiz dimensions are likely to extend far below the surface. New ore can be expected only in or adjacent to parent rocks, and marginal positions afford greatest possibility for exploration.

Extensions in depth are generally unlikely to exceed surface dimensions in case of segregations; tonnage possibilities can not safely be predicted on surface showings. Stratiform layers may have great extension along strike and in depth, as the Bushveld deposits; dikes and large injections may reach considerable depth. The walls are not generally abrupt, but merge into parent rock; hence exploratory workings in transitional portions are unpromising. Underground exploration for new ore masses not revealed in outcrops is hazardous; surface exposures are apt to equal or exceed the size and number of masses found in depth. In all igneous deposits, the primary minerals near surface generally persist to max depth of deposit; changes in tenor with depth are accidental rather than zonal.

Search for orebodies in undeveloped districts. Igneous deposits are not accompanied by an obvious aureole of rock alteration; the only indications available to the prospector

are actual ore, and the kind of igneous rock with which such ores are generally associated. These are valuable guides; their absence throws suspicion on any reputed occurrence; search for diamonds in Arkansas was initiated by discovery of the correct type of rock. Common associations are given in the preceding paragraphs. The correct rock mass being discovered, search should be made particularly about its margins. Peripheral igneous bodies bear a definite relation in size to the parent igneous rock, since large orebodies can not be concentrated from small rock masses. If size of the igneous mass can be determined it affords a clue to size of possible ore masses. Some sulphide bodies lie in embayments of igneous bodies, hence such places should be prospected.

Magmatic orebodies occurring as dikes differ from ordinary dikes only in their mineral content; their expectation in a district can not be predicted by geologic features; they are " where you find them." Dikes of ore, though rare, are particularly reliable bodies upon which to count for persistence in depth. They can be recognized by: (*a*) igneous minerals; (*b*) lack of accompanying rock alteration; (*c*) included irregular fragments of country rock, not crusted by ore minerals, as in cavity-filled deposits.

c. Sublimation

This very minor process accounts for certain deposits associated with volcanoes and fumaroles; they have been directly volatilized by heat and subsequently redeposited in the same form at lower temp and press. Sublimates deposited around volcanoes are rarely present in commercial quantities. Sulphur of this origin has been mined in Japan, Italy and Mexico.

d. Contact Metamorphism

Contact metamorphism or pyrometasomatism (648) gives rise to distinctive ore deposits, where certain igneous rocks invade carbonate rocks. The deposits are characterized by an assemblage of diagnostic high-temp minerals resulting from reaction of the magmatic vapors on the host rocks. The characteristic features of such deposits are: (*a*) proximity to intrusive, (*b*) calcareous host rock, (*c*) distinctive mineral association, (*d*) intimate associations of ore and gangue minerals. The new minerals result from recombinations of former minerals, accessions from the magma, and combinations of both. The accession minerals (including ore minerals) are deposited by metasomatic replacement.

Minerals of contact metamorphic deposits (common minerals marked with asterisk).

Minerals partly of recrystallization and partly accessions

*Grossularite garnet
*Andradite garnet
Axinite
Tourmaline
*Wollastonite
*Scapolite
*Epidote
*Hedenbergite
*Diopside
Augite
Forsterite
*Tremolite
*Actinolite
Hornblende
*Vesuvianite
*Spinel
Gahnite

Mineral accessions from intrusive rock

*Specularite
*Magnetite
*Chalcopyrite
Bornite
*Sphalerite
Pyrrhotite
Molybdenite
Arsenopyrite
Galena
Cassiterite
Willemite
Pyrite
Tetradymite
Altaite
Scheelite

Original rock minerals

Clay Quartz Calcite Dolomite

The most diagnostic minerals are lime silicates, magnetite, and specularite with sulphides, in intimate relationships. Common types of deposits and mineral associations are:

Metal	Chief metallic minerals	Examples
Iron	Magnetite, hematite	Cornwall, Pa
Copper	Chalcopyrite, bornite, pyrite, pyrrhotite, magnetite	Morenci, Ariz Cananea, Mex
Zinc	Sphalerite, magnetite, pyrite, pyrrhotite, galena	Hanover, N M
Lead	Galena, sphalerite, magnetite, chalcopyrite, pyrite, pyrrhotite	Inyo Co, Cal
Tin	Cassiterite, wolframite, magnetite, pyrrhotite	Saxony
Tungsten	Scheelite or wolframite, molybdenite	Mill City, Nev
Molybdenum	Molybdenite	Yetholin, Australia
Gold	Arsenopyrite, native gold	Hedley, B C

Practical considerations. Contact metamorphic deposits are mainly confined to certain rock types. They are not associated with extrusive rocks, such as rhyolite or andesite, but only with granular, deep-seated intrusives; they are rare with extremely silicic or basic rocks and are most common with intermediate types, as monzonite, granodiorite and diorite. Position of deposits is influenced by faults and by dip of host rocks; such channelways conduct vapors outward from intrusive. They are usually confined to within 100 ft of intrusive contact (Fig 6); hence search should be directed to marginal areas, or where channelways extend outward, as at Rochester, Nev; large roof pendants included in intrusive are particularly favorable sites for ore, as at Mackay, Idaho. Inferences from outcrops as to form and size are unreliable, because orebodies are so irregular in form. Orebodies are irregularly distributed in contact aureole and generally unconnected; hence much exploration is required and predictions of extensions far beyond exposed places are unsafe. Irregularities in tenor are common, and aver grade is low.

e. Replacement

This is the dominating process of mineral deposition in epigenetic deposits. It is a gradual process of simultaneous solution of minerals and rocks, and of deposition in the same space, volume for volume. Thus, a cubic meter of limestone may be replaced by a cubic meter of sulphides, which often retain the limestone structure. The interchange is not molecular, but is of molecular proportions. Replacement is accomplished by liquid or gaseous solutions and almost any rock may be replaced by ore, although carbonate rocks are most susceptible; it is helped by fractures or schistose structures in the host rocks; takes place at normal temperatures (supergene enrichment) and at low, intermediate, and high temperatures. Replacement bodies are commonly surrounded by a halo of rock alteration, particularly those in igneous rocks. Replacement bodies may be massive, lode-fissure, or disseminated.

Criteria of replacement: (*a*) structure of original rock preserved in ore; (*b*) unsupported nuclei of original rock surrounded by ore (such as could not have remained suspended in an open cavity); (*c*) doubly terminated crystals that have grown freely on all sides; (*d*) crystals and ore faces intersecting original rock structures. Distinctions: from magmatic deposits by above criteria and hydrothermal mineralogy; from contact metamorphic deposits (emplaced by replacement) by lack of contact metamorphic mineral assemblages and presence of hydrothermal minerals (these two types grade into each other); from cavity fillings by above criteria and lack of crustification and vugs.

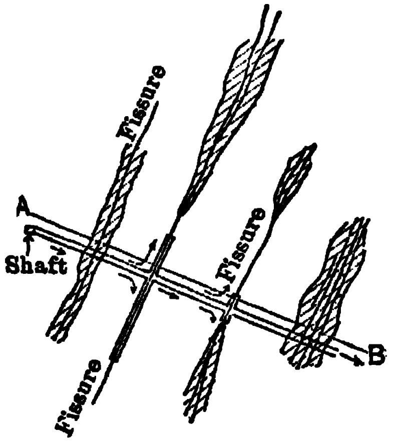

Fig 7. Plan of Flat Shoots in Thin Sedimentary Layers. (Arrows show Direction for Crosscuts and Drifts)

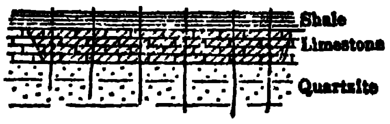

Fig 8. Narrow Bed between Unfavorable Formations (Replaced along Fissure Zone so as to give Deposit a Bedded Form). Cross-sec

Features affecting search for and exploration of replacement bodies. The form and size, often not predictable, are controlled by: (*a*) homogeneity of rock; (*b*) form and structure of host rock; (*c*) number and distribution of channels of access; (*d*) mode of replacement. Since replacement can not occur without entry of solutions, channels of access are important guides to ore sites; an orebody may occur where a fissure intersects a congenial bed of limestone; thus more ore may be expected where similar fissures intersect the same bed. Form of replacement masses in homogeneous rocks like limestone is generally determined by arrangement and distribution of minute fissures. In non-homogeneous rocks, like alternating beds of lime and shale, flat shoots develop in the limestone where it is intersected by fissures (Fig 7); closely spaced fissures result in wide bedded shoots (Fig 8). Replacement may begin in disconnected centers, causing disseminated deposits; if continued, the centers coalesce to form a large solid orebody. Such ore boundaries are generally sharp (Fig 9–12). For full discussion, see Bib (649).

Search in sedimentary rocks. Most replacement deposits in sediments are localized by fissures that cross favorable beds; the ore spreads out within beds on either side of fissure, giving rise to tabular-shaped bodies (Fig 12). Undersides of impervious beds are particularly favorable. Search should be made by following fractures toward a favorable bed, and crosscutting in that bed normal to trend of fissure system (Fig 7, 12). SEARCH IN IGNEOUS ROCKS should be conducted along fracture zones, or within areas of intense hydrothermal alteration.

Outcrops of replacement bodies. Replacement veins are irregular in outline; outcrops may not be commensurate in size with underlying orebodies. Disseminated replacements in igneous rocks are confined to, limited in size by, and have extent of, the fractured area in which they are localized. Replacements in sedimentary rocks generally have greatest extension parallel to bedding planes; hence, in flat rocks, outcrops are large in proportion to volume of ore. Inclined beds, as at Leadville, Colo, outcrop only where the edges of including limestone are eroded; slight outcrops then often represent large deposits and justify search in depth. Mineralized fractures should be followed downward to favorable beds where lateral exploration can be carried on. In vert beds, replacement bodies often have an adequate outcrop, which represents expectations below.

Examples of some replacement deposits. In the following are given, first the ore, second the type, and third the location. IRON: magnetite, Dover, N J, Lyon Mt, N Y; hematite, Iron Mt, Mo. COPPER: disseminated, porphyry coppers, Utah Copper; lode, Kennecott, Alaska, Magma, Ariz; massive, Bisbee, Ariz, Noranda, Que, Boliden, Sweden. LEAD: massive, Leadville, Sullivan, B C; lode, Coeur d'Alene, Idaho, Tintic, Utah; disseminated, S E Mo. ZINC: massive, Flin Flon, Manitoba, Silesia; lode, Franklin Furnace, N J. GOLD: lode, Homestake, S D, Kirkland Lake and Porcupine, Ont. SILVER: lode, Cerro de Pasco, Peru, Park City, Utah. TIN: pipes, Transvaal. MERCURY: lode, Almaden, Spain. MOLYBDENUM: disseminated, Climax, Colo, Utah Copper, Utah.

f. Cavity Filling

This consists of deposition from solutions of ore minerals in pre-existing openings in rocks. The kinds of cavities that are filled and the resulting mineral deposits are:

Cavity	Deposits
Fissures	Fissure veins
Shear zones	Shear zone deposits
Joints	Ladder veins
Tension cracks	Stockworks
Saddles	Pitches and flats Saddle reefs

Cavity	Deposits
Irregular caves	Cave deposits
Channels	Cave deposits
Gashes	Gash veins
Breccias	
Volcanic	Pipes
Collapse	Breccia fillings
Tectonic	"
Pores	Disseminated
Vesicules	Vesicular fillings

Cavity-filling deposits generally display comb structure or crustification, consisting of layers of different minerals on or about country rock (Fig 13), with crystals projecting toward former opening; vugs are common. Minerals are typically hydrothermal, ranging from normal- to high-temp minerals; commonly, intermediate to low. Cavity-filling deposits grade into replacements, usually accompanied by some replacement of walls or included country rock (Fig 14). The replacement part may constitute the bulk of a deposit; hence, prompt recognition of this feature is desirable.

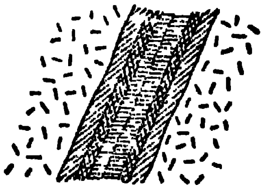

Fig 13. Single Filled Fissure

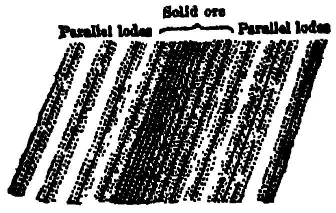

Fig 14. Replaced Sheeted Zone

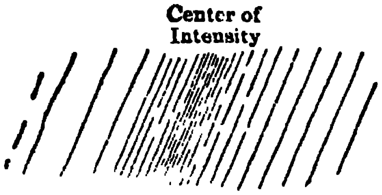

Fig 15. Sheeted Zone (Cross-sec), showing Largest Number of Cracks at Seat of Heaviest Movement

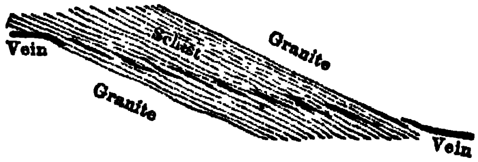

Fig 16. Vein dividing into Lenses *en echelon* on passing at Small Angle through Cleavable Formation

Fissure veins are the most important type of cavity filling. Their formation involves formation and filling of fissure, which may occur simultaneously or be separated by long time intervals. Varieties: (*a*) simple filled cracks; (*b*) sheeted zones (Fig 15), consisting of closely spaced parallel cracks filled with ore; (*c*) single, fat lenses, commonly in schists (Fig 16); (*d*) composite, wide zones of nearly parallel fissures connected by diagonals (Fig 14).

Physical details. Most fissure veins are narrow and inclined. When exposed at surface, the outcrop is straight or curved, depending upon dip of fissure and surface relief. Veins are seldom planes; usually of complex curvature, and characterized by pinches and swells (Fig 17), branches, horses or included masses of country rock, anastomosing (Fig 29), and brecciation. Walls are *frozen* or *free*, and may be marked by selvage or gouge, or they may be commercial, that is, ore grades into country rock with no definite wall.

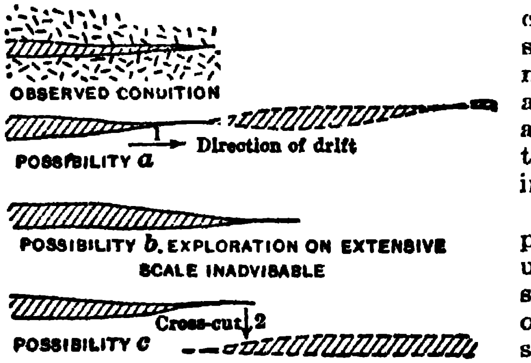

Fig 17

Practical considerations. Prospecting, exploration and development are often based upon assumption that fissures continue considerable distances along the strike observed at one point. This leads to errors in locating shafts, adits, or crosscuts to intersect vein, and in locating claims with respect to vein apex. Knowing the aver strike reduces risk in predicting extensions from a single exposure; trenching, and observation of aver strike should precede selection of sites for openings. Aver trend of other fissures in district is suggestive. If bedrock is covered, surface exploration for continuation of a fissure may be guided by projecting its apex on to a topographic map (see Art 5). Dip of fissures has little relation to their size or continuity. Most fissures have high dip (50°–90°); the North Star vein (dip about 20°), Grass Valley, Cal, is an exception. It is not true that veins of low dip are never wide. Dip may vary greatly; projections of dips observed at only one point are unsafe unless attested by geologic habit of other fissures of district. Fissure veins generally have small displacement; large faults in a district are not often mineralized; much exploration has been wasted on them.

Fissure systems. Except in case of a few large veins, like Comstock Lode, **fissure veins seldom occur alone. The strains that produce fissures of small displacement generally find relief in many cracks. Fissures of approx same trend form a system. There may be**

several systems in a district; intersecting systems may be of different age and displace each other, as at Butte (Fig 18), or may be COGNATE, formed contemporaneously due to same cause (Fig 19, 20). Varieties of cognate systems: (*a*) parallel, (*b*) intersecting, like cleavage in augite (Fig 20), (*c*) fan-shaped, (*d*) radial, as at Cripple Creek, Colo.

Practical considerations. It is often erroneously assumed that the wall of a vein means the limit of metallization. Since parallel fissures are common (Fig 21, 22) crosscutting is advisable, especially in early stages of development, and has yielded fruitful results, as at Camp Bird, Colo, and Kennecott, Alaska.

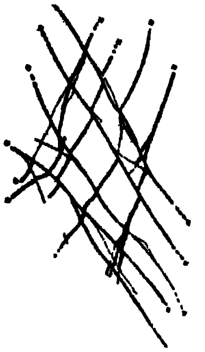

Fig 18. Superposed Vein Systems of Different Ages, Butte

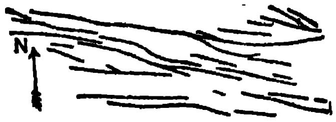

Fig 19. Vein System; Fissures All Cognate. (Part of a System in Harz Mts)

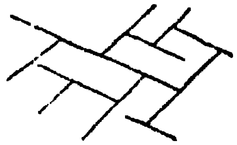

Fig 20. Two Intersecting and Mutually Alternating Systems, Forming a Cognate Group

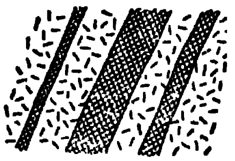

Fig 21. Large Filled Fissure with Parallel Lodes

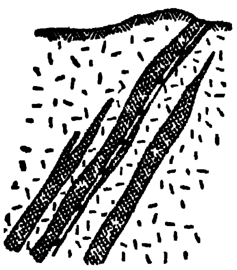

Fig 22. Two Parallel Lodes overlooked through Insufficiency of Lateral Exploration

Fissures of same system are generally of same age and mineralization; those of cognate groups are mineralized alike. Fissures of different systems usually have different minerals, ores, and values (Freiberg, Saxony); veins of different ages may also have different ownership rights. Younger fissures pass through and fault earlier ones, and such intersections do not carry same apex rights as junctions of cognate fissures. An intersecting cognate system (Fig 20) will be mineralized alike; two different intersecting systems will be mineralized unlike. Relative ages may be determined by: (*a*) relation to rocks of known age, one cutting a porphyry and the other cut by it; (*b*) if of different ages, one generally faults the other in same direction; ore of older is crushed and dragged, and ore banding of younger passes through older (Fig 23). Termination of one vein against another does not imply faulting, since the two may be cognate (Fig 20); (*c*) in contemporaneous cognate fissures the ore bands will not be broken, but turn from one into the other (Fig 24). These may suffer post-mineral movement simulating different ages.

Fig 25. Fissure Deflected by New Formation, due to Small Angle of Incidence
Fig 26. Fissure, first Deflected, then Entering New Formation
Fig 27. Fissure at Small Angle of Incidence may enter thus without Change

Effects on fissures of change in formation. Since rocks fracture differently, fissures generally change in passing from one formation into another (Fig 25–32). This change is often for the worse, since initial exploitation usually starts on widest and richest portions. A fissure meeting a new formation at a low angle of incidence may be deflected (Fig 25) or refracted (Fig 26); rarely, there is no change (Fig 27). The higher the angle of incidence, the less the probable change (Fig 28). Passage into a more brittle rock causes spraying (Fig 29); into less rigid rocks, pinching (Fig 30–31); into tough rocks (shales), dying out (Fig 32); and angling into a fissile rock causes an *en echelon* dispersion into lenses (Fig 16).

Practical considerations. A geologic map, showing formations in path of fissure vein along strike and dip, permits predictions as to expected behavior. Any change in formation may produce a physical or mineral change in a fissure vein. Outcrops of veins restricted to one of several equally exposed formations indicates the latter are unfavorable. Most favorable are homogeneous formations, as monzonite. A fissure vein can not enter a rock later in age than itself, for example, an intrusive andesite.

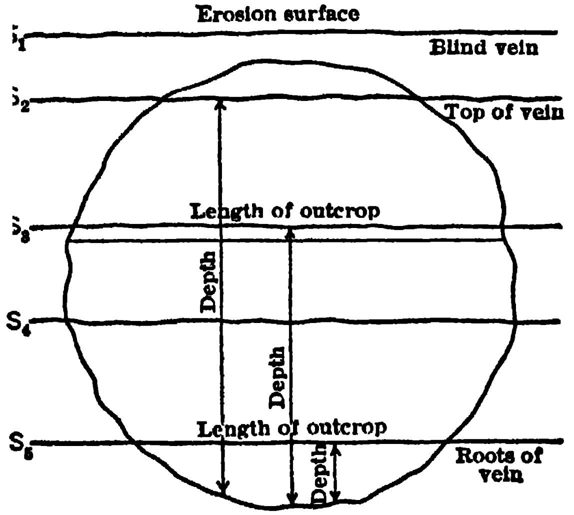

Fig 33. Longit Projection of Fissure, Showing Relation of Length to Depth, Depending on Depth of Erosion. S_1, Erosion Surface Gives Blind Vein; S_2, Depth Greater than Length; S_3, S_4, Erosion Revealing Medial Sections, with Depth Approx Half the Length; S_5, Roots of Vein, Length Greatly Exceeding Depth

Fissure veins terminate within a homogeneous formation by: (1) abutting a fissure or fault (Fig 18); (2) splitting into diverging stringers (Fig 29); (3) pinching to a mere crack (Fig 30). The possibilities of pinching are (Fig 17): (*a*) a pinch intervening between two swells, (*b*) a final termination, (*c*), continuing as an overlapping *en echelon* fissure. In the last case, crosscutting is advisable. Terminations in non-homogeneous formations are shown in Fig 29–32.

Predictions as to depth. Deep exploration and estimates of ore tonnage and life of mine depend upon predictions as to expected depth. If no change of formation is indicated, low-temp and press minerals often mean shallow depth, while medium- to high-mean greater depth. Strong fault fissures commonly extend to depth, weak ones are apt to be shallow. As a rough rule, the depth will equal about half the length, depending upon the depth of erosion. Shallow erosion may fail to expose a " blind " vein; progressively deeper erosion may reveal the top, medial portion, or roots of a vein. If the top is exposed, the depth may equal the length; if the medial portion, half the length; if the roots, less than half the length. This is based on assumption that fissure veins originally are roughly circular, lens-shaped bodies (Fig 33). With erosion surface at S_2, the depth is practically a diam; at S_3 or S_4, the outcrop is a diam and the depth a radius; at S_5, the outcrop is a chord and the depth only part of a radius. Depth of erosion may be estimated by: (*a*) top of vein is indicated if enclosing formation has not suffered much erosion, as in Boulder batholith, Mont; (*b*) rarely, fault scarps may indicate recency and lack of erosion; (*c*) extent of associated placers may roughly measure the amount of erosion; (*d*) contrast between zone of secondary enrichment (see later) and primary ore permits an estimate of amount of erosion; a thick zone of rich secondary sulphides overlying low-grade primary ore means extensive erosion of upper part of vein; (*e*) district habit of veins may afford a clue; all veins of Cobalt, Ont, are shallow.

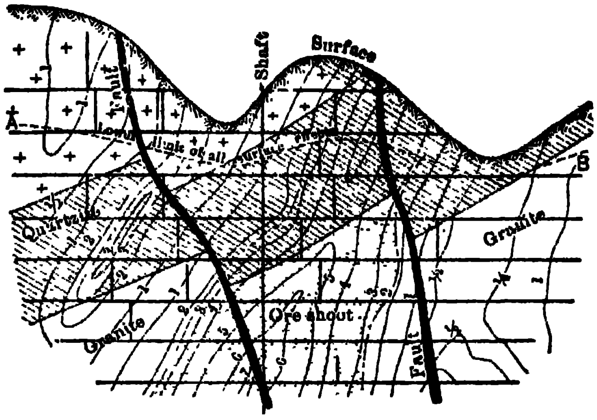

Fig 34. Assay Sec on Plane of Vein, Showing Lines of Equal Widths of Vein Filling. High Values (Shaded Areas) Correspond to Relatively Great Widths, and Show that the Two are in Some Way Related

Ore shoots. Commercial minerals of most veins are concentrated in ore shoots of various shapes and sizes. Common types: 1, open space, due to available open space, or "swells"; 2, intersection, due to vein intersections; 3, impounded, due to damming of solutions by impervious barriers; 4, wall-controlled, due to effect of wall rock upon precipitation; 5, structure-controlled, due to decrease of temp and press; 6, recurrent, due to successive periods of metallization; 7, unsolved, includes many. RECOGNITION by mineralogy, assays, and plotting of distribution.

Geological assay maps help determine localization and expectation of shoots and aid exploration. Plot a longit sec of vein, showing rocks, fissures, oxidized, enriched, and primary zones, vein widths by contours, and outlines of ore shoots (restricted to primary ores, Fig 34–36). The superposition may show a definite relation between ore shoots and influence of wall rock, as within diabase dikes (Fig 35) (hence other dikes suggest places for exploration); or to intersecting fissures (Fig 36), showing that other fissures of same system may also localize shoots; or to widths of fissure (Fig 34). If vein occupies a fault fissure, the geology of both walls may be plotted on separate tracings, which can then be shifted over each other until the geology coincides, thus giving the fault displacement (both walls are on same drawing in Fig 34–36). Shoots may be independent of above causes; then the only guiding rule for search is that they are apt to recur at fairly regular intervals.

TIN: Llallagua and Huanuni, Bolivia; Cornwall, Eng. ANTIMONY: Hunan, China MERCURY: New Idria, Cal. TUNGSTEN: Kiangsi, China.

Other important cavity filling deposits. SHEAR ZONES are wide zones of fracturing impregnated by ore minerals. They constitute large and important deposits of Cu, Au, Zn and other metals. Mostly, replacement deposits. LADDER VEINS are short, transverse, cooling-joint cracks in dikes.

Transverse lengths are no greater than width of enclosing dike, but longit lengths may be great. Where closely spaced, the dike as a whole may be worked, as at Morning Star, Victoria. Stockworks are masses of rock traversed by a network of small veinlets, so closely spaced that the whole mass may be mined. Their typical habitat is in upper part of a stock. Stockworks make large deposits of Sn, Au, Cu, Pb, Zn and other metals. Most of the world's lode tin comes from stockworks, that at Altenberg, Ger, being 3 000 ft across. Saddle reefs are openings occurring when alternating competent and incompetent beds are folded into close anticlines. A vert cross-sec resembles that of a saddle. Leg-lengths, 100–300 ft; a single axis was horizontally followed for 3 000 ft in Bendigo, Australia, where 300 million dollars in gold were produced from such deposits. Saddles occur one below another; at Bendigo, mining has reached 4 600-ft depth. Pitches and flats are tension cracks accompanying gentle warping in sediments. Wisconsin lead and zinc ores are examples. Solution cavities in the form of caves, galleries, and gash veins are a source of Pb, Zn, Cu, Hg and many other ores. They occur only in soluble rocks, generally resting upon an insoluble rock. Breccia fillings are spaces in breccias occupied by ores: (*a*) volcanic breccia pipes (Bassick mine, Colo); (*b*) collapse breccia deposits, due to collapse of rock overlying a large solution cavity; these are common in Utah, Ariz, Colo, and Mex, and contain large deposits of Cu, Zn and Ag-Pb ores; at Bisbee, Ariz, they form a crackled surface area, 1 000 ft above the ore; (*c*) tectonic breccias, resulting from tectonic stresses; these contain large Zn deposits in Tenn. Pore space fillings are found where rock pores are impregnated, as by Cu, vanadium and radium minerals, and oil in sandstone. Vesicular fillings are the filling of lava vesicles or blow holes, as in Lake Superior amygdaloidal copper deposits. Exploration should follow the tops of lava flows.

g. Sedimentation

Sedimentary processes (650) give rise to commercially valuable deposits, as Fe, Mn, Cu, uranium, phosphates, sulphur, magnesite, bentonite, building stones, cement rocks, commercial clays, and coal. The world's largest reserves of Fe, phosphates, and clay are of sedimentary origin. The deposits are relatively thin, but widely distributed; those of Fe, as the Clinton ores of the U S, and the " minette " ores of Central Europe, occur over hundreds of square miles.

Practical considerations. Such deposits vary little in thickness or grade over short distances; hence relatively few openings are necessary to delimit ore and estimate values. A single ore bed may be repeated in outcrop by folding or faulting. Exploration is guided by fixing the position of beds in the geologic column and by revealing the structure from surface mapping.

h. Evaporation

Evaporation of bodies of marine, lake, and subsurface waters yields commercial deposits of salt, gypsum and anhydrite, potash, nitrates, borates, sodium carbonate, sodium sulphate, lime, and travertine (651). Salt, gypsum, potash, and nitrate deposits support large industries. When sea water is evaporated to about $^1/_2$ its volume, Fe_2O_3 and $CaCO_3$ are deposited; to $^1/_5$ vol, gypsum or anhydrite; to $^1/_{10}$ vol, common salt; next, magnesium sulphates and chloride; and lastly the bittern salts, including potash. Evaporation of 1 000 cu ft of sea water yields only 0.7 cu ft of gypsum. When common salt is not underlain by gypsum it means that a cut-off body of sea water has been shifted or tilted into another basin after the gypsum has been deposited. Potash deposits (as Stassfurt, Germany, and New Mex basin) represent enormous concentration by draining into residual settling pools. The U S potash basin, recently developed, has an area of 40 000 sq miles, of which 3 000 are known to contain sylvite, carnallite, or langbeinite; present potash mining is centered in 33 sq miles near Carlsbad, N Mex.

Practical considerations. Statements given for " sedimentation " above apply also to marine products of evaporation. Salt and gypsum alternate in layers; they also alternate with potash beds. Beds are generally horiz, and search is made by vert drilling.

i. Residual Concentration Deposits

These result from removal of undesired materials and accumulation of an insoluble residue of desired substances by weathering. Requirements: (*a*) rocks containing valuable minerals that are insoluble; (*b*) climatic conditions favoring chemical decay; (*c*) gentle topography, on which residue can be retained (erosional plateaus are especially favorable); (*d*) long-continued crustal stability, to allow quantity accumulation. In one case, the residue is an accumulation of a pre-existing mineral that has suffered no change (iron oxide in limestone, liberated by solution of limestone and accumulated as a residual deposit of iron ore). In another case the residual mineral is caused by weathering, as the feldspar of a syenite decomposes to form bauxite, which accumulates to form a deposit. Source materials: (*a*) pre-existing deposits, as siderite that yields iron oxide ore; (*b*) disseminated minerals in rocks, as iron or manganese oxides in limestone or chert; (*c*) rock minerals that weather to new constituents, as clays, bauxite.

Residual iron ores result from solution of enclosing limestone or chert, and accumulation as hematite or limonite; as at Lake Superior and Mayarí, Cuba; also Appalachian brown ores.

Residual manganese deposits are the source of most manganese. They are the accumulation of: (*a*) manganese oxides disseminated in limestone or dolomite (southern U S); (*b*) of manganese silicates in crystalline schists (India, Gold Coast, Brazil); (*c*) of former manganiferous deposits (Butte, Mont).

Bauxite deposits result from special conditions of tropical weathering of aluminous rocks, free from quartz, upon old erosion surfaces. Such weathering is lacking in the soils of temperate regions. Aluminum silicates break down, forming the bauxite, gibbsite, boehmite and diaspore; silica and iron are removed in solution and bauxite accumulates. Deposits of Arkansas come from nepheline syenite; those of France and Southern Europe are beds and pockets from limestone impurities; those of Guiana and Gold Coast are blankets from crystalline schists; those of Russia are transported bedded deposits.

Residual clays result from weathering of aluminous rocks. They consist of kaolinite, halloysite, and impurities. Orthoclase breaks down to form aluminum silicate, and soluble potassium carbonate and silica. The kaolins or china clays come from pegmatite dikes; other industrial clays, from other rocks.

Other residual products include zinc, tin and nickel ores, kyanite, barite, phosphates, tripoli, and ochers.

Practical considerations. Search for these deposits must be confined to present or ancient erosion surfaces. As they are mostly flat blankets they can be explored by vert drilling or test pits. They usually contain impurities, which affect their value.

j. Mechanical Concentrations (Placers)

Placers result from weathering of enclosing rocks or gangue, releasing valuable substances which are then concentrated by water or air. Stream, beach, eluvial, and eolian placers are thus formed. For concentration, the ore minerals must be of high sp gr, chemically resistant and durable. The common placer substances are Au, Pt, cassiterite, magnetite, chromite, ilmenite, native Cu, precious and semi-precious stones, zircon, monazite, and phosphate. The materials are derived from: (*a*) commercial lodes (Mother Lode) Cal; (*b*) non-commercial lodes (veinlets of cassiterite); (*c*) sparsely disseminated minerals (Pt grains); (*d*) rock-forming minerals (magnetite, zircon); (*e*) former placers. The most favorable sites for placers are where weathering is deep and topographic relief exists. Stream placers form pay streaks on stream bottoms where swift water slackens, as below rapids, canyons, and inside of meandering curves. Pay-streaks may become buried by stream meandering. Former stream placers may be left as BENCH gravels or HIGH-LEVEL gravels, that have been covered by lavas, and later exposed by stream canyons with different courses.

Eluvial placers are those formed in regions of deep decay, just below the outcrop of the source lodes, where streams have not worked them (gold and cassiterite). BEACH GRAVELS form on sea beaches (gold at Nome, Alaska, and zircon, monazite, and ilmenite in India). EOLIAN placers have been concentrated by the wind in Australia.

k. Oxidation and Supergene Sulphide Enrichment

When ore deposits are weathered, surface waters oxidize many minerals and yield solvents that dissolve other minerals. Thus, the upper part of a deposit becomes oxidized and leached down to the water table, forming the OXIDIZED ZONE. The metallic content of the down-trickling solutions may be precipitated beneath as sulphides, to form the SUPERGENE SULPHIDE ZONE. The unaltered lower part is the PRIMARY ZONE. The upper parts are thus impoverished and the lower enriched. Outcrops must be interpreted in the light of these changes; if the ore in shallow surface workings is primary, no abrupt change may be expected below; if secondary, lower-grade ore may be expected beneath it. Supergene enriched ore may give way beneath to rich primary ore, as at Bisbee, Ariz, or to valueless protore, as at Ray, Ariz. A knowledge of superficial changes and ability to recognize secondary ores, and the characteristics of orebodies beneath superficial zones, are invaluable aids in prospecting, exploration and development.

Oxidation and solution in oxidized zone (652). On weathering, most metallic minerals are leached or altered to new compounds which require metallurgical treatment different from the original materials. Deposits containing sulphides and arsenides are most susceptible. Water and oxygen act on pyrite to form H_2SO_4 and $Fe_2(SO_4)_3$; the latter attacks pyrite to form more ferric sulphate, which dissolves Cu, Zn, and Ag, forming soluble sulphates of these metals. In the presence of MnO and NaCl it also dissolves Au. The oxidized zone thus becomes impoverished in these metals. Some of the iron sulphate hydrolyses to limonite, which remains behind and forms a rusty gossan or capping.

Gossans and cappings are indicators of what lies beneath. Other stains than limonite may persist and signify their source minerals. Discovery of gossan warrants exploration. Gossans result from massive deposits; cappings from disseminated or porphyry deposits; both are called croppings. In croppings, the iron of sulphide derivation may become fixed at the site of the original sulphides, forming INDIGENOUS limonite, or be dissolved and removed, forming TRANSPORTED limonite. The former indicates the previous presence of Cu; the latter, the lack of it, pyrite predominating. The explanation is that Cu accelerates formation of the insoluble ferric iron, while free acid, yielded by pyrite oxidation, tends to keep the Fe in soluble ferrous state, so that it can be transported. Recognition of the two types of limonite provides inferences as to character of underlying ore. Indigenous limonite occupies the voids vacated by sulphides; it is never outside of the voids; its structure indicates the kind of predecessor sulphide. It is compact, hard, and has subdued colors. Transported limonite has moved outside of the voids; in presence of reacting gangue it is precipitated as a halo around the void and floods the rock; in inert gangues it may move far, forming paints and crusts in cracks. FALSE GOSSANS are formed by transported limonite which, distant from its source, has met precipitating agencies such as carbonates. They lack indigenous limonite and do not overlie ore. Copper likewise may migrate from its original site and be precipitated by limestone as copper carbonates. Such stains are deceptive because they do not overlie ore; they show no voids, no indigenous limonite, and no indigenous copper carbonate.

Inferences as to hidden deposits (653). FORM AND SIZE of gossan are generally the same as those of underlying deposit; a fissure-vein gossan is of obvious shape; irregular replacement or contact deposits also give irregularly shaped gossans; sheeted lodes may be indicated by sheeting in the gossan. The outline of "porphyry" deposits can be determined by mapping features characteristic of copper in capping. The gossan may be much larger than original deposit, due to "mushrooming" or spilling over of Fe_2O_3 from original sulphide site. CROPPING MINERALS, if present, give positive clues as to mineral content. Their absence does not indicate lack of ore beneath. Specks of relict sulphides often persist in quartz. Stains of Cu, Mn, Co, Ni and Mo may indicate corresponding minerals. VOIDS, if lacking, indicate absence of underlying ore; if present, their abundance indicates former sulphide abundance, and shape may indicate minerals, as pyrite and galena cubes, or arsenopyrite spears. LIMONITE COLORS are indicative: seal brown, maroon, and orange colors indicate Cu; yellows and brick reds, pyrite; deep browns and yellowish browns, chalcopyrite; orange to chocolate, chalcocite or galena; tan to brown, sphalerite. LIMONITE STRUCTURES (653) are quite diagnostic. Indigenous limonite assumes various boxwork structures, as "course cellular" indicating chalcopyrite; "fine cellular," bornite and chalcopyrite; "cellular sponge," sphalerite; "relief limonite," chalcocite. (For fuller description, see Bateman: Economic Mineral Deposits, Chap 5). ROCK ALTERATION distinguishes primary and supergene metallization. Much sericite indicates much primary metallization; if this is highly kaolinized it indicates extensive supergene alteration with expectation of sulphide enrichment.

Factors controlling and limiting oxidation. Lack of oxygen generally occurs at the water table, but oxidation may extend lower, along fractures in regions of relief; or a rising water table, caused by valley fillings, faulting, or change to humid climate, may drown an oxidized zone. Change to arid climate inhibits oxidation. If erosion is too rapid, oxidation cannot keep pace; if time is too short, oxidation will be limited; cold climate is unfavorable. Permeable rocks aid it; dense rocks retard it. Faults deflect, impound, or cause deep oxidation. Oxidation ceases by refrigeration, burial, and depletion of oxygen by abundant sulphides. Oxidized zones may become stranded above water level, as at Bingham, Utah, or drowned beneath it, as at Miami, Ariz, or in Rhodesia. DEPTH OF OXIDATION may reach 3 000 ft (Lonely mine). In humid regions of low relief it is generally shallow; with high relief, shallow to medium depth. In glaciated regions, post-glacial oxidation is negligible, but in areas protected from deep glacial erosion it may be deep, as at Kennecott, Alaska (2 800 ft). In arid regions it may be very deep under old or mature topography, and shallow under youthful topography.

Ore deposition in oxidized zone. Metallic solutions generated by oxidation may, in passing downward, undergo precipitation in the zone of oxidation, and oxidized compounds of the metals may thus be deposited toward bottom of the zone. These include carbonates, silicates, oxides, or native metals of Cu, Zn, Pb, Ag and others. For example, $CuSO_4$ meeting $CaCO_3$ yields $CuCO_3$ and $CaSO_4$. Modes of precipitation: (*a*) EVAPORATION AND SATURATION, yielding efflorescences; at Chuquicamata, Chile (654), large copper deposits consist of antlerite, brochantite, chalcanthite and krohnkite; (*b*) OXIDATION AND HYDRATION, yielding goethite and $PbSO_4$; (*c*) REACTIONS BETWEEN SOLUTIONS such as NaCl and Ag_2SO_4, yielding silver chloride; carbonated solutions, by which $PbSO_4$ is changed to $PbCO_3$, and carbonates of Cu and Zn are formed; also Cu_2O, CuO, Cu and Ag; Au in $Fe_2(SO_4)_3$ solution is deposited by reduction to Fe_2SO_4; (*d*) REACTION WITH GANGUE OR WALL ROCKS: Cu solutions with $CaCO_3$ yield Cu carbonates; with colloidal silica, chrysocolla; zinc sulphate similarly yields smithsonite and calamine.

Generalizations. Common ore minerals diagnostic of oxidized ores are carbonates, silicates and sulphates of Au, Zn and Fe; oxides of Cu, Co, Mo; chlorides, iodides, and bromides of Ag; and $PbSO_4$, $PbCO_3$, MnO_2 and boxwork limonite. Native Au, Ag, and Cu may be of oxidation or of hypogene origin. If given ores are oxidized, it follows that: (*a*) such ores will change in character in depth; (*b*) tenor will change in depth; (*c*) oxidized ores will be superficial; (*d*) metallurgy devised for oxidized ores will not apply to underlying ores; (*e*) extraction plans should be deferred until volume of ore is delimited; (*f*) future life of a mine generally depends upon what lies beneath the oxidized ores.

Supergene sulphide enrichment. Metals in solution that escape capture in the oxidized zone trickle down to where there is no available oxygen (generally the water table), and there undergo deposition as supergene sulphides, forming the zone of secondary enrichment. Progressive erosion allows deeper oxidation, releasing more metals to be added below. Rich primary ores are made richer, valueless protore is made commercial. Primary ore may be enriched to 10 times its original metal content. The process applies chiefly to copper and silver ores.

Requirements for supergene sulphide enrichment: (*a*) preceding favorable oxidation; (*b*) downward moving erosion surface and water table; (*c*) sufficient time; (*d*) primary minerals that, upon oxidation, yield enough $Fe_2(SO_4)_3$ and H_2SO_4, as pyrite will, but chalcopyrite will not; (*e*) primary minerals susceptible of undergoing supergene sulphide enrichment, as Cu and Ag will, but Pb and Zn will not; (*f*) permeability of deposit or host rock; (*g*) absence of precipitants in oxidized zone (in limestone, Cu is fixed as carbonate and no supergene sulphides can form); (*h*) zone of no available oxygen; (*i*) underlying precipitants in form of sulphides, etc, because supergene sulphides are deposited only by reaction with them, and not on quartz, etc. If underlying precipitants are lacking, no supergene enrichment occurs.

Mode of precipitation. A metal in sulphate solution is precipitated by one of lower solubility than itself. The relative solubilities of common sulphides, the least soluble first, are: Hg, Ag, Cu, Bi, Pb, Sb, Zn, Ni, Co, Fe, Mn. Thus, Cu will be precipitated by any below it, but by none above; Mn is not precipitated by any of the group. This explains the commonness of supergene sulphide zones of Cu and Ag and lack of Mn; Zn should form such zones but does not; Ni may do so, but most deposits are in glaciated regions. Deposition is by replacement of the primary sulphides. Some reactions are: $CuSO_4 + ZnS = CuS + ZnSO_4$; $14\ CuSO_4 + 5\ FeS_2 + 12\ H_2O = 7\ Cu_2S + 5\ FeSO_4 + 12\ H_2SO_4$; $CuSO_4 + CuFeS_2 = 2\ CuS + FeSO_4$; $Ag_2SO_4 + ZnS = Ag_2S + ZnSO_4$. Thus, a gossan containing evidences of Cu should, under favorable erosional and climatic conditions, have an underlying enriched zone.

Degree of enrichment. INCIPIENT enrichment, characterized by thin coatings or microscopic veinlets of supergene sulphides, indicates weak enrichment or the bottom of the enriched zone. PARTIAL enrichment is where about half the primary minerals are replaced. COMPLETE enrichment (rare) is where primary minerals are largely replaced. Residual nuclei, however, indicate character of primary ores. SELECTIVE enrichment, where only certain selected minerals or grains are replaced, indicates weakness or bottom of zone. PERVASIVE enrichment is where all primary sulphides, grains and veinlets are replaced, indicating vigorous enrichment.

Factors influencing enrichment: (*a*) WATER LEVEL generally controls the top of enrichment, which in turn conforms to topography at time of enrichment (650). Enrichment rarely occurs above the water table but extends hundreds of feet below it. A sinking water table favors completeness; a rising one stops it. (*b*) HOST ROCKS must not be reactive; carbonate rocks inhibit enrichment; fractured, friable, permeable ones favor it. (*c*) FAULTS, if enclosed and impervious, protect underlying ores from enrichment; they also conduct enriching solutions deep into primary zone. (*d*) TOPOGRAPHY. Tops of enriched zones controlled by water level conform to the then existing topography. Most zones are out of adjustment with present topography. At Morenci, Ariz, enriched zone is related to earlier mature topography, but recent uplift caused canyon-cutting too fast for enrichment to keep apace. Enriched zone may be related to older topography buried beneath lavas and favorable for exploration. (*e*) RATE OF EROSION. Most favorable conditions for rich, thick, enriched zones are equal rate of oxidation and lowering by erosion, the two continually progressing downward. Too rapid erosion cuts through the enriched zone; if slow, the zone is thin. (*f*) TIME OF EXPOSURE TO WEATHERING must be great enough to provide thick zones; post-glacial time is too short. (*g*) PRESENCE OF MINERALS YIELDING SOLVENTS is essential, as iron sulphides; lacking these, solvents for metals are not generated.

Cessation of enrichment is caused by: (*a*) burial beneath thick sediments or lavas, as United Verde Ext, Ariz; (*b*) submergence beneath water level; (*c*) change of climate from (1) humid to rainless, (2) semi-arid to humid, thus raising water table near surface; (3) temperate to cold, causing

refrigeration of water level, as Alaska, Siberia; (*d*) bottoming of ore; (*e*) complete enrichment, by which practically all acid-yielding yellow sulphides (pyrite, pyrrhotite, chalcopyrite) have been converted to supergene sulphides; further oxidation then only converts secondary chalcocite into copper carbonate, as in part of Inspiration deposit, Ariz. Thickness of enriched zones attains hundreds of feet; 3–8 ft at Ducktown, Tenn, 150–400 ft at Ray, Ariz, 450 ft at Magma, Ariz, 1 400 ft at Bingham, Utah. At United Verde Ext mine, Jerome, Ariz, is a fossil-enriched zone 400 ft thick overlain by 450 ft of oxidized zone, the latter buried under 750 ft of sedimentaries and lavas.

Recognition of supergene enriched deposits is essential to intelligent exploration and development, to determine what part of enriched zone is revealed, expectable ore above or below, and tenor and character of primary ore in depth. Criteria are: Zoning. The 3 zones, oxide, supergene sulphide, and primary, are characteristic. Supergene zones must be distinguished from primary enriched zones; former show abrupt mineralogic changes and are generally related to a recent topography, but latter could have a topographic relation to surface existing at time of first metallization. Gossans. Enriched ores generally leave some evidence in the gossan, such as rock alteration, stains, and character of limonite boxwork previously discussed. Erosion must have been sufficient to release enough metal to produce enrichment. District habit is also helpful. Mineralogy. Sooty chalcocite is the only diagnostic mineral. Other minerals, as chalcocite, covellite, or argentite, are common but also occur under primary conditions; however, if associated with kaolin or other supergene products they become diagnostic. In general, chalcocite, covellite, or argentite in abundance in upper part of sulphide zone, but diminishing with depth, is a safe indication. For other minerals see adjoining Table. Curves. Curves of copper assays against depth from drill holes (Fig 37) are characteristic. If curves of Fe or S content are superimposed, these cross the Cu curve at top and bottom of enriched zone. Microscopic criteria are generally conclusive. Texture of supergene sulphides is characteristic. Also, the microscope will reveal if supergene sulphides have replaced only FeS_2, indicating lean pyrite protore beneath; if they replace abundant galena, bornite, and chalcopyrite, commercial primary ores may be expected.

Common Indicative Ore Minerals

Metal	Minerals generally of primary origin	Minerals usually of secondary (sulphide) enrichment origin	Minerals usually originating in oxidized zone
Copper	Chalcopyrite Bornite *Enargite *Tetrahedrite *Tennantite	Chalcocite Covellite *Sooty chalcocite	Native copper *Malachite *Azurite *Brochantite Antlerite *Atacamite *Chrysocolla *Cuprite *Tenorite
Silver	*Tetrahedrite *Tennantite	Native silver Argentite Pyrargyrite Proustite Stephanite Polybasite Pearceite	*Cerargyrite *Embolite *Bromyrite
Gold	Native gold Gold tellurides	Native gold	Native gold
Zinc	*Sphalerite Willemite	Wurtzite	*Smithsonite *Calamine *Hydrozincite
Lead	Galena		*Cerussite *Anglesite *Pyromorphite Leadhillite
Iron	Pyrite Marcasite *Pyrrhotite *Arsenopyrite Magnetite Hematite *Specularite Siderite	Marcasite	*Goethite *Iron sulphates Hematite

* Invariably primary, secondary, or oxidized, according to column in which name of mineral appears.

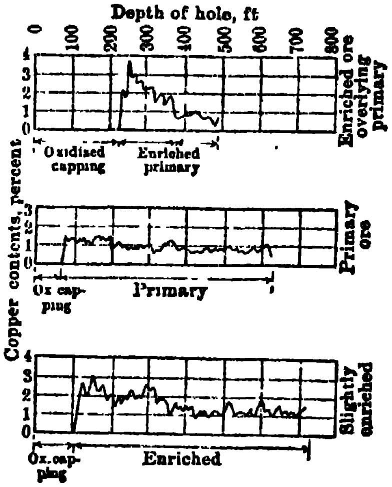

Fig 37

l. Metamorphism

Effect of metamorphism is two-fold; it produces commercial deposits and profoundly alters earlier ones. Those produced are non-metallics, formed by recombinations or recrystallization of rock minerals, and include asbestos, graphite, talc and soapstone, sillimanite and kyanite, emery and garnet. Metamorphism of earlier deposits produces physical rather than compositional changes; ores are made gneissic, particularly those containing galena, which flows readily under pressure; texture becomes streaked, banded, indiscriminate, and mineral content may be obscured.

Asbestos results from hydrothermal metamorphism of various rocks. The high-grade chrysotile varieties are the fibrous form of serpentine, altered from peridotite, serpentine (Quebec) or highly magnesian limestones (Sierra Ancha, Ariz). The commercial amphibole varieties, crocidolite and amosite, occur in banded ironstones in Africa; anthophyllite is mined in N America; asbestos occurs as cross, slip, and mass fiber, in narrow veinlets, separated from the rock mass after mining.

Graphite occurs disseminated in marbles, schists, gneisses, quartzites, and metamorphosed coal beds (a non-metamorphic occurrence is in pegmatite dikes). It is carbonaceous matter, formerly present, which has been recrystallized and segregated into pure carbon flakes. The rock mass is mined as a whole and the graphite extracted.

Talc and soapstone of commerce occur as masses associated with ultra-basic igneous rocks (peridotite, dunite), or as lenses in carbonate rocks. It is derived by hydrothermal alteration of highly magnesian rocks. Talc lenses are mined separately; soapstone masses, quarried, and commercial slabs sawn from large blocks.

Emery is a mixture of magnetite and corundum, with some hematite or spinel; occurs in pod-like lenses in schists or marbles, and results from metamorphism or contact-metamorphism.

Garnets for abrasives (chiefly almandite) occur disseminated in metamorphic rocks and result from metamorphism of aluminum silicates containing Fe, Ca, Mg, Mn, or Cu. Garnet rocks also yield placers of garnet. Adirondack deposits in gneiss contain 7–8% garnet.

Andalusite, sillimanite, kyanite, and dumortierite, used as refractories, also result from metamorphism of rocks.

4. PROSPECTING METHODS

Surface methods: tracing float, tracing by panning, trenching and test-pitting. Search for mineral that does not outcrop and lies at considerable depth is done by geophysical methods (Sec 10A), boring (Art 7), or shaft-sinking (Art 12; also Sec 7, 8, 9). Methods are varied and combined to suit local conditions or fancy of the prospector.

Tracing float (Cornish, " shoading "). Pieces of ore (float) are broken from outcrops by processes of erosion, and gradually work their way downhill into streams, where they may be carried long distances. The prospector finding float on a hillside, or in a gulch or stream, tries to follow it back to its source. A rough idea of the distance which float has traveled is gained from the size and abundance of pieces, and their roughness or water-worn condition.

Many outcrops which are the source of float are concealed by a covering of soil. In such cases, at some point below the outcrop the float disappears, or " goes down." Trenches or test pits are used to follow float farther. The distance between soil-covered outcrops and the point at which float goes down varies with depth of cover, topography, and climate. On flat slopes (6%) in desert regions of southwest U S, float has been found on the surface within a few feet of outcrops covered with 1 to 2 ft of soil. Two deposits of chromite in Md, in flat, unglaciated country, were found directly under strong surface showings of float. In Marysville district, Mont, at one point float went down on a hillside and was followed by pits for 500 ft before finding the outcrop; bedrock was 10 ft to 12 ft below surface. In the far north, where freezing and thawing have gone on a long time, the " creep " on the hillsides is great, and float may be found far from the outcrop. Practically no importance attaches to the sporadic occurrence of valuable mineral in glacial drift.

In general, tracing float is applicable only in searching for ores tough enough to escape disintegration by erosion. Gold-quartz, or pyritic ores with siliceous gangue, in particular, yield float which is resistant and easily recognized. The value of, and results from, the method depend largely on the personal equation of the prospector. Knowledge of ore, keen observation, physical strength, and unending patience are essentials. Most prospectors use the pan or horn spoon to estimate the content and value of float, largely because of expense and inconvenience of obtaining assays. The U S Geol Survey, the Bur of Mines, and mining bureaus of most western States will identify specimens by visual inspection free of charge. Some State bureaus make assays at reduced prices; free in Alaska, and to licensed prospectors in some Canadian Provinces. Oregon allows 2 free assays per mo to its own residents, but requires full disclosure (with privilege of publishing) as to source of each sample.

Tracing by panning (also called " tracing " in western U S, and " loaming " in Australia). This, like tracing float, is based on recognition of the results of erosion. Weathering releases small pieces of metal and minerals from outcrops, and these migrate downhill as do larger pieces of float.

Fig 38 shows an orebody outcropping under a soil cover, and the usual position of float metal or sulphides derived from it by erosion. In a new district, the prospector works along the bottom of hillsides at an elevation (*A*) sufficient to avoid the debris brought into the gulch from upstream points. Samples of the top 2 or 3 in of soil are panned. If specks of metal or sulphides are found, panning is continued uphill until the trace goes down at *B*; then trenches or test pits are dug. The placer miner's pan, or a frying pan 4 to 6 in diam, is used for panning. In practiced hands the latter gives accurate results, and is better where water is scanty. Float found in connection with this work should be crushed and panned as an aid in determining the source of " traces." This method was developed by "pocket hunters," and has been used chiefly in prospecting for gold, which is unaltered by weathering and easily recognized in the pan, even when present in minute particles ("colors"). It was used in Nevada, 1909, to find a concealed outcrop of a very soft vein of cinnabar, first trace found about 700 ft from outcrop. At Pamlico mine, near Hawthorne, Nev (485), gold colors were traced by panning at points along 10- or 20-ft contours. Limits of traces on each contour were marked with stakes. Resultant lines of stakes converged sharply to pockets; more gradually to ends of oreshoots. As in tracing float, correct interpretation of results requires geological knowledge. (See Art 5.)

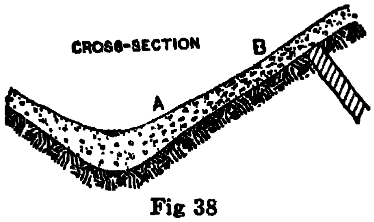

Fig 38

Trenches (Cornish, " costeaning " ditches), for prospecting and exploration, are confined to shallow soil; economic limit of depth, 6–7 ft, or about as far as a man can cast from a trench with a shovel. Best applied in drift or alluvium, not over 3–4 ft deep. Trenches are usually run at right angles to the formation or the supposed strike of orebody. Prospectors use trenches to follow float or traces under cover. Useless to carry trenches to bedrock, so long as float is found.

The results of tracing close to an orebody are often indefinite, giving no indications of the strike of the outcrop sought. In such cases, several trenches at right-angles to one another are better than a single trench or a series of parallel ones, which may parallel the outcrop and not uncover it. Surface prospecting on property adjacent to developed orebodies is done by a series of parallel trenches at right angles to the strike of the known deposits. This work will uncover outcrops of parallel orebodies if they exist (Art 4, 5, 6). In districts where orebodies have no general trend, such prospecting should be done with 2 sets of parallel trenches at right-angles to each other; their distance apart is from 50 ft to 500 ft, depending on size of known orebodies in the vicinity.

Cross-section of trenches should be as small as possible; it depends on their depth and purpose. In soil 1 to 1.5 ft deep, trenches can be 12 to 14 in wide at bottom and 18 to 21 in wide at top; for depths of 2 to 2.5 ft, the minimum bottom width is about 15 in, width at top about 20 in, varying with character of the soil. These dimensions are satisfactory in following float, but are too small if detailed examination of bedrock is necessary, or if any of the bedrock is to be shot out. In such cases, minimum bottom width is between 2 and 3 ft for trenches 3 ft deep, increasing with depth of soil. In trenches on SLOPING GROUND, work should begin at their lowest point and run uphill, so that they will be self-draining. This is important in frozen ground and tundra of the far north, where there is constant seepage into excavations, due to thawing on exposure to the air. (See Sec 3.) For systematic surface trenching and examples of cost, see Art 6.

Cost per cu yd for NARROW TRENCHES less than 6 ft deep is determined more by character of the soil than by any other factor. Duty of men picking and shoveling in trenching varies from 3 to 10 cu yd per 10-hr man-day; aver, 4 to 5 cu yd. The rate is lower in prospecting work, where much time is spent in examining float and bedrock. Where weathering has been intense, trenches often extend 2 to 3 ft into the decomposed surface rocks. As relative amounts of picking and blasting ground are very variable, no accurate estimates of speed and cost are possible. Wet ground retards progress and makes examination of bedrock difficult.

Test pits (small shafts) are used in alluvium too deep for trenches. Their field is in material free from large boulders and water, and requiring little or no timbering. They are applicable for depths to 100 ft; for over 30 to 50 ft, and, in general, in water-bearing ground, they may be less suitable than boring methods (Art 7; also Sec 9). In deep soil, a test pit is sunk above the point at which float or traces go down (*B*, Fig 38). If float is found, or if panning shows mineral, the outcrop lies higher; the pit is abandoned and a new one started above. This process is repeated until outcrops are found or the prospector is discouraged.

If character of soil permits, small drifts can be driven from the bottom of a test pit, and float be followed on bedrock. This cheapens the last stages of such work, especially in deep ground. Test pits are not so satisfactory as trenches; they expose only a small area of bedrock and may miss outcrops of narrow and irregular veins. This objection does not hold for large, flat orebodies; in prospecting for these, test pits are located with reference to known ore on adjacent property, or systematically, or at random. (For principles, see Locating drill holes, Art 7.)

Cross-section of test pits may be circular, elliptical, or rectangular. Diam of circular pits is 30 to 36 in; elliptical pits are 36 to 42 in long by about 28 in wide; rectangular pits are rarely smaller than 4 by 4 ft or 4 by 5 ft. In point of cost and speed, small circular pits are preferable to rectangular; the amount of material to be excavated and hoisted from a 36-in circular pit is about 0.35 of that from a 4 by 5-ft rectangular pit. Circular or elliptical pits are excavated with a short-handled pick and shovel; the workman straddles the handle. A windlass is used for hoisting. Galvanized-iron water pails make good buckets for small pits; ordinary windlass buckets are better for larger rectangular pits, 2 buckets or pails being provided for each windlass. A 0.25-in wire rope should be used instead of a hemp rope in small pits over 30 ft deep; at greater depths, the travel of a hemp rope across the windlass barrel is apt to throw the bucket against the walls and dislodge loose material. Objections to circular or elliptical pits, which frequently preclude their use: (*a*) require labor trained and willing to work in an awkward position; (*b*) no room for drilling and blasting, if boulders are met; (*c*) practically impossible to timber them, whereas in rectangular pits a soft stratum can be close cribbed cheaply with plank. Crew on either kind of pit consists of 2 men, one digging, the other on the windlass.

Examples of test-pitting. For brown hematite in Georgia and Alabama; round test pits, 30 to 36-in diam; depth, to 50 ft; in ordinary unconsolidated material, 2 men sank 10 ft per day (5). In Lehigh Valley, Penn, 2 men sank 30 to 36-in pits to depths of 50 ft at 20 to 30 ft per day (8). In Nevada, the author sank 40 by 29-in elliptical pits, with Chinese labor, in easy gravel, at 20 ft per 12-hr day for first 40 ft. Below 40 ft, gravel was hard and clayey. Aver speed for depth of 100 ft was about 5 ft per 12-hr shift (contract work). Under same conditions, white labor on day's pay averaged 2 to 3 ft per 12-hr shift in test pits of 4 by 5 ft cross-sec. In another locality, the author sank 11 rectangular test pits; aver cross-sec, 4.1 by 4.7 ft; aver depth, 7.5 ft; material, very hard clayey gravel overlain by 6 in loam; deepest pit, 10 ft; no windlasses used; labor, 161 man-hr; aver speed, 0.51 ft per hr.

E. D. Gardner and C. H. Johnson (18) quote following examples of test pitting in alluvial gravels: Near Skull Valley, Ariz, in 1932, Mexican laborers at \$3 per day sank 5 pits per man-shift, averaging 2 ft wide, 3 or 4 ft long, 3.5 ft deep, in fairly fine, loose gravel; cost about 65¢ per cu yd. On Bear Gulch, Mont, 3 men at \$3.50, in 1932, averaged 6 ft per day of 4 by 6-ft shaft, cribbed solid with 6-in round timber, through fine, loose gravel free from water; cost, \$3 per ft to 32-ft depth. On Sauerkraut Creek, Lincoln dist, Mont, one man sank a 4 by 5-ft, solidly cribbed shaft 30 ft through dry, loose, hillside wash and moderately firm gravel in 10 days. In Pioneer dist, Mont, in 1932, four men contracted to sink 1 000 ft of shafts, averaging 35 ft deep (range, 10–65 ft) for \$1 per ft. Gravel, moderately fine and free from boulders, stood unsupported except for a few ft through surface layer of hydraulic tailings, which was cribbed 4 by 4 ft; below this, shafts were circular, 4.5-ft diam. Working in pairs, and long shifts, men averaged \$3.50 per day. Under favorable conditions, 2 men could sink 10 ft per day. Groove sampling was done later. Shafts were spaced 400 ft, or one to 3.6 acres; cost per acre, about \$10 for sinking and \$4 for sampling. On Gold Gulch, near Bowie, Ariz, about 200 pits were sunk in 1932–33 through 3-30 ft of dry placer ground, consisting of surface layer up to 3 ft of clay soil, 1–6 ft of lime-cemented gravel, with bottom bed of tight, angular gravel, containing large percentage of coarse rock and boulders up to 3 ft diam. Surface pits, 4 or 5 ft wide and about 5 ft deep, were dug by gasolene shovel at 26.5¢ per vert ft. In bottom of each, a pit 2.5 by 4.5 ft was sunk by hand to bedrock at contract price of 75¢ per ft, to 9 ft below bottom of shovel cut, and \$1.50 per ft thereafter. No timbering, little blasting, no water. Some contractors earned \$6 per 8-hr shift. Groove sampling was done later. On Quartz Creek, near Rivulet, Mont, in 1932, two men sank 5 by 7-ft shaft, closely cribbed, through 12 ft of fine gravel with few boulders too large to handle, in 6 days. Strong flow of water at that depth was pumped by primitive means, and remaining 6 ft to bedrock required 9 days longer; total, 30 8-hr man-shifts to sink 18 ft. Subsequent 5 by 5-ft cribbed shafts were sunk under same conditions by same men to 18 ft at 2 ft per day.

For other details see Art 6; also Sec 3. For use of test pits in systematic surface exploration, see Art 5.

Hydraulic prospecting. Water, where available, is a great aid in stripping off soil for close prospecting of bedrock. Sometimes a small stream can be led by a ditch onto a hillside above the area to be prospected. By breaking into the ditch, water can be made to flow over any desired section of ground, and cuts a trench to bedrock. A series of trenches can thus be excavated.

Booming or hushing. Where water is scanty, small reservoirs are dug on a hillside. When reservoir is full, the water is released, and rushing down the hillside strips off surface soil. Process is repeated, if necessary, until bedrock is clean. Reservoirs may be provided with automatic gates. In other places, a small quantity of water is kept running down a hillside; the soil, loosened by picks, is washed away. Large duties per man-day are thus obtained.

Shallow surface cover is sometimes completely stripped from large areas by hydraulicking with a nozzle (Art 6). M. Sheppard in 1938 gives details of hydraulic stripping of a quarry site, where deeply channelled top of limestone was covered by tough clay to (max 10 ft) aver depth of 3 ft (9). Water was pumped by 4-stage centrifugal pump from a river 300 ft below, and discharged through 1-in and $3/4$-in nozzles. In 2 465 hr during 4 winter months, 8 300 cu yd was removed at $1.16 per yd (excluding supt and general), of which: power, 39¢; labor (17 240 man-hr) 64¢; supplies, repairs, 13¢.

Drivepipes have a limited use in soft soil free from stones (Sec 9). Pipes are 1 to 2 in diam. Fig 39 shows bottom length of pipe. The end is filed to a cutting edge, and has a slot *A*, about 0.25 in wide, in one side; this aids in gripping the soil and facilitates cleaning the pipe. Depending on depth and character of soil, the pipe may be churned down by hand, or driven with a maul, or a weight and tackle from a tripod. Upper end of pipe is protected by a cap while driving; a shoe is used on lower end in stony soil; short lengths of pipe are screwed on as the hole deepens. The pipe is pulled every 1 to 2 ft and contents examined. The method is cheap and gives a sample section of the ground passed through. If soil is underlain by soft or distinctively colored mineral, drivepipes can be used to outline its area. For small diam pipes, limit of depth is usually 15 to 20 ft.

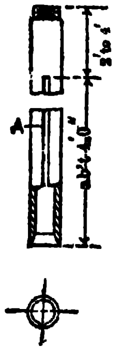

Fig 39. Lower End of Drivepipe

Piercing (or probing). Pointed steel rods are used in search for minerals lying at shallow depths in or under soil. The mineral sought is either much harder or softer than surrounding material, or possesses a characteristic color. Pointed bars are also used, as in Nor Quebec, merely to ascertain depth to bedrock, preparatory to trenching.

In southeastern Alaska, rods have been used to locate quartz veins covered by 2 or 3 ft of moss and humus. First quartz was found in the roots of an overturned tree. The "feel" and sharp clink of the rod against quartz distinguished it from the softer country rock. In Butler and Crenshaw counties, Ala, scattered lumps of brown iron ore, imbedded 3 or 4 ft deep in sandy soil, are located in same manner (15). Foster (10) gives following instances of the use of piercing: in France for buhrstones lying at depths of 10 to 18 ft in soft sand and clay; on the Isle of Man for shallow pockets of soft umber easily penetrated by the rod; in the Furness district, England, for hematite, under 6 to 8 ft of soil (detected by color); in South Carolina, for phosphate nodules, to depths of 15 ft in sand and clay. In Burma, bamboo rods are similarly used to ascertain the depth through clay to underlying gem-bearing gravels.

Sounding is the name given to a unique method of prospecting for phosphates on the Coosau River, S C. Phosphate rock occurs in irregular patches in the river bed, and is mined by dredging. Sounding is done from a boat by dragging a bottle filled with water along the bottom. A string is tied around the neck of the bottle, and a cardboard diaphragm attached to the free end is held against the ear, or the sounder holds the end of the string in his ear with his finger. On finding a deposit, floats are set to show its outline and guide the dredge (11).

Vegetation sometimes grows thickly along outcrops of one geological formation and sparsely on another, thus aiding in working out geological structure, or in limiting areas favorable or unfavorable to ore occurrence. At Cripple Creek, quaking aspens favor areas of tuff and breccia; fir trees grow on granite. In the Leucite Hills, Wyo, along outcrops of potash-bearing dikes, there is a noticeably rank growth of sage brush. In places in the southern Appalachians, the vegetation corresponds to underlying strata (12, 502). Recognition of geological structure from the air, even to very small details, is facilitated by habits of vegetation, particularly in semi-arid regions (647). Sec 17, Art 26.

Burrowing animals, as woodchucks, prairie dogs, gophers, badgers, also ants, sometimes aid the prospector by the debris they throw out when digging holes. Such material is examined for float, or panned for gold colors or specks of ore minerals (479).

Divining rod is still believed by credulous persons to be efficacious for finding water and mineral (13, 14).

Electroscope. Radio-active minerals have the power of discharging an electroscope; under suitable conditions the rate of discharge is proportional to amount of radio-active substance in the mineral. Electroscope is used by engineers and prospectors to detect radio-activity, and for quantitative tests. Radium is obtained solely from uranium ores, the amount of radium bearing a constant relation to amount of uranium present; normally

1 unit of uranium is accompanied by 3.3×10^{-7} units of radium. Thorium compounds and minerals also discharge an electroscope.

Fig 40 shows a simple electroscope suggested by B. B. Boltwood, which can be made in the field. It consists of a 5-cent piece, a quarter dollar, or an iron washer *A*; a drop of sealing wax or candle grease *C*; an upright *B* made from a piece of tin 0.2 in wide (or a 6d or 8d wire nail flattened at *E*); and the leaf *D*. The latter may be a piece of aluminum leaf, about 0.1 in wide, obtainable from any dealer in painter's supplies, or thin tissue paper, both sides of which have been coated with graphite by rubbing with a soft pencil. Leaf is attached to upright with mucilage or flour paste. Bottom of upright *B* must be insulated from base *A* by a layer of sealing wax; the wax must not be touched with the fingers after it is in place. A cover protects the apparatus from air currents; for the dimensions shown in Fig 40 an ordinary glass tumbler placed bottom upward will serve. Electroscope is charged by touching the upright with a piece of hard rubber (a fountain pen), or sealing wax, which has been electrified by rubbing on one's hair or sleeve. A protractor drawn on cardboard, so that its center point is at same height above base *A* as the point *E*, is placed behind the tumbler and the angle read between leaf and upright. Readings are repeated at regular intervals to determine rate at which electroscope will discharge itself by leakage. The mineral to be tested is placed inside the tumbler; radio-activity is proved by a rate of discharge faster than that due to natural loss of charge.

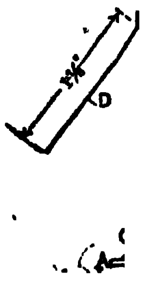

Fig 40. Electroscope

This crude electroscope gives surprisingly accurate quantitative results if handled carefully. Table 1 shows results of tests by H. G. Mead under author's direction, on a series of samples prepared by mixing pitchblende (35.7% U) with inert material in proper proportions to give samples containing 2, 5, 10, 15, and 25% U. Samples were crushed through 20 mesh and placed next to base of electroscope in a small pill box. Same size of box was used for all samples, each being filled level full, and placed in same position with respect to electroscope. Rate of discharge was determined as above, corrected for natural leakage, and net rate of discharge computed in degrees per min per % U. Max errors for paper and aluminum leaves were 0.7% and 1.9% U respectively. Aluminum leaf is much more sensitive than paper, and requires greater skill and patience in manipulation. Scrupulous care is necessary to avoid salting the containers used. For quantitative work a small sample of known uranium content is required to standardize the electroscope; unknown samples may then be tested.

Table 1. Tests for Radio-activity by Electroscope

Per cent U in sample	Paper leaf				Aluminum leaf			
	Rate of discharge				Rate of discharge			
	Deg per min	Leakage, deg per min	Net rate, deg per min	Deg per min per % U	Deg per min	Leakage, deg per min	Net rate, deg per min	Deg per min per % U

An outfit for testing ores for radio-activity is made by the Denver Fire Clay Co. Denver, Colo; price, in 1938, about $110.

Fluorescence. A few minerals, notably willemite, scheelite and fluorspar, become fluorescent when subjected to ultra-violet light, as is emitted by an arc of either high or low intensity between iron electrodes, or by mercury-vapor lamp; less vigorously by an argon lamp. Principle has been satisfactorily applied in exploration and development of scheelite mines in Nev and Calif, using portable apparatus which usually requires 110-v alternating current. Such equipment is supplied by: H. T. Strong, Chatham, N J ("Fluorospark" lamp, with quartz lenses for focusing the beam, $100); R & M Mfg Co, Pasadena, Calif (mercury-vapor lamp, adaptable to dry cells, $32.50); Stroblite Co, 35 W 52d St, N Y (a "black-bulb" lamp, illuminating a circle 6 ft diam at 3 ft distance, $15). Prices are as of 1938. Since each mineral responds most actively to wave lengths within a certain range, character of the light is more important than its intensity. For scientific principles and some practical applications, see Bib (88).

Geophysical prospecting methods include gravimetric, magnetic, electrical, seismic, temperature, radio-active, and micro-gas surveys. See Sec 10A for underlying principles, applicabilities and limitations, and interpretation of observations.

Methods have developed rapidly in recent years, and are used with success in many localities. They are not universally applicable or successful, and in considering their use the following observations should be borne in mind: (*a*) Methods (with possible exception of simple dip-needle survey) are too expensive to apply to " wildcatting"; better devoted to exploration for deposits whose presence has been indicated by other prospecting methods, or whose existence and probable form are reasonably suspected from geological evidence, such as extensions of known deposits, parallel orebodies in same formation, or deposits known to occur only in certain geological relations. (*b*) Any geophysical survey should be made under direction or cooperation of a geologist acquainted with formations, structures, and character of deposits in the locality. (*c*) Method must be appropriate to the particular deposit; no single method is applicable to all conditions, and where 2 or more methods might be applied to a given deposit, they may differ in reliability, speed, and cost. (*d*) Other conditions causing physical effects similar to those expected from the investigated deposit must be absent. Examples: graphitic zones or water-bearing selvages among metalliferous bodies explored by earth-resistance; disseminations of magnetite in wall rocks of chrome-ore lenses surveyed magnetically. (*e*) Most geophysical methods require expensive and delicate equipment, operated by trained personnel. Much work has been done for mining companies by contracting firms specializing in this business. Magnetic surveys, however, even with most refined instruments, can be conducted satisfactorily by usual mine engineering staff. (*f*) No method can do more than indicate existence of a deposit capable of affording the observed effects. Such a deposit may or may not contain profitable amounts of metal. Examples: copper or nickel in pyrite or pyrrhotite; gold with magnetite in a buried river channel. (*g*) Where 2 methods are applicable, both should be employed, since each may best disclose certain features. A magnetic survey for precise work should explore both vert and horiz components of the field. (*h*) Some deposits, as sphalerite and fluorite, not readily responsive to any geophysical method, have been found by tracing faults or porous areas of rock with which such deposits were known to be associated, such geological features being fairly easily indicated by appropriate electrical methods (334). For details see Sec 10A.

5. SYSTEMATIC SURFACE EXPLORATION

Value of thorough surface exploration is apt to be underestimated. It furnishes information which may either discourage further effort, or permit intelligent planning of subsequent work. Where feasible, it is an essential preliminary to underground exploration. It prevents overlooking important exposures, and secures a large amount of information with a smaller total footage of openings than haphazard work.

Factors involved are as follows (see also Art 12): Surface work can be done at much less COST and greater SPEED than underground work; from this standpoint its feasibility should always be considered because of the high RISK of opening unproved orebodies. TYPE OF OREBODY and DEPTH OF SURFACE SOIL are related factors. Cost of surface work increases rapidly with depth of cover. Trenching at close intervals, or complete stripping, is necessary to find and follow short, narrow, irregular veins on the surface. In general, these operations are not feasible where average depth of soil exceeds 2 to 3 ft (see Art 4 and Cobalt, Art 6). Outcrops of wide veins, beds, and masses are cheaply explored by trenching, where soil is not over 6 to 7 ft deep. Necessity for continuous openings, as trenches, decreases as the size and uniformity of the orebody increases; test pits give adequate data respecting size, shape, and value of large uniform orebodies, and in dry surface drift are feasible to depths of 30 to 50 ft or more. Deep wet alluvium precludes surface openings; when present, exploration must be by boring or underground work (Art 7). AMOUNT OF WEATHERING. Value of results from surface exploration depends on amount and reliability of information afforded by outcrops. Where rocks are fresh, or erosion has kept pace with weathering, an outcrop is a reliable section of an orebody; in such case, if surface results are negative, it is unwise to attempt underground exploration. Values have often been entirely or partly removed by leaching from the upper parts of an orebody (Art 3). Surface exploration may still determine its size, shape, irregularities, and location and size of shoots. These factors alone may decide whether further work is justified, and if so the best location for it. Leached outcrops generally indicate the character of mineralization in depth. Weathering in some cases has been so intense that it is practically impossible to trace outcrops on the surface, or to get any definite information from them; underground work is then the only alternative.

Methods vary with type of orebody; judgment determines extent and detail of the work. First essential is a map showing property lines, topography, geology, outcrops, dips and strikes, pits, trenches, underground work, assays, location of float or traces, and all obtainable details. MAP should be on a scale of not less than 100 ft to 1 in; for small areas, 40 or 50 ft to 1 in is better. Compass and hand level, plane table or transit are used in mapping, depending on accuracy desired; a small plane table is convenient and rapid. Numbered stakes may be set on corners of 100 or 200-ft squares, for locating subsequent work. If veins are exposed, their probable extensions are plotted on the map and staked on the ground (see Migration of outcrops). Probable course of faults, contacts, and sedimentary beds are similarly indicated. Such a map shows the relation between different outcrops, and between outcrops, geology, and topography; outlines drift-covered areas; shows where information is needed; aids in eliminating unfavorable areas and in planning exploration.

Geophysical methods (Sec 10A) exemplify systematic exploration preceding the details discussed here. Air-plane surveys (101, 102, 103, 505, and Sec 17, Art 28), with or without photography, are also used for preliminary systematic reconnaissance of large areas.

Tracing float. All pieces of float are labeled and their position noted on map (portions of each piece may be assayed or panned). By showing location of float with respect to topography, geology, and probable outcrop extensions, the amount of excavation necessary to uncover outcrops is often reduced.

Tracing by panning (Sec 31) may be used in a similar way. A level panful of dirt should be taken each time, so that results will be roughly quantitative. The mineral obtained is weighed and kept in numbered bottles, the number and wt of each trace being entered on the map. Blanks should be recorded as carefully as good showings. Having no exposures to guide the work, panning can be done systematically at corners of squares. Panning along exposed outcrops, or below probable location of drift-covered outcrops, is the cheapest way of finding oreshoots and determining their length.

Trenching. For a single orebody a series of trenches is usually dug at regular intervals, at right-angles to course of outcrop. Probable extension of outcrop should be staked on the ground as a preliminary. Distance between trenches is determined by type of orebody and depth of soil; they should be close enough to determine aver width and value of outcrops and to avoid missing oreshoots. Trenches over the latter are closer together than on barren areas.

The first trenches should be as far apart as possible; this generally reduces number, length, and cost of intermediate trenches. It is more satisfactory to follow narrow outcrops by trenching along them. In shallow soil not more than 2 men, in deep soil not more than 4 men, can be employed to advantage in trenching both ways from a single exposure (19). Fig 41 shows general arrangement of trenches on outrcops of large uniform orebodies, planned to avoid high cost of complete stripping. Where large drift-covered areas are explored for suspected mineral, trenches are usually dug along the sides of squares, 50 to 200 ft apart. First work consists of 1 or 2 long trenches, which give information as to geology, depth of soil, etc; this generally divides area into favorable and unfavorable sections. Good showings are explored first. If there are no surface indications, systematic work is started where the soil is shallowest; deep trenching is usually done last (see Cobalt, Art 6).

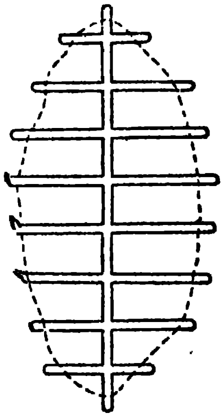

Fig 41

Test pits for systematic surface exploration are spaced on corners of squares. Principles involved in their location are same as for boreholes (Art 7).

Summary of results. All exposures in exploratory openings are measured and sampled; widths, assays, and any further geological data obtained should be entered on the map, and geological cross-sections made where necessary to interpret structure. Results of shallow exploration may often be summarized by computing from area of orebody exposed the tons of ore per ft of depth. Depth to which the known orebodies must continue to repay estimated cost of development and equipment and yield a profit can then be calculated. This figure, compared with local geology and type of orebody, furnishes a measure of the risk involved (20).

Migration of outcrops. With unwarped veins, beds, faults, and contacts, dipping 90°, the outcrop is in a straight line (the strike), regardless of topography (Fig 42, *A*). Outcrop of such a deposit on flat topography is also a straight line, regardless of its dip (Fig 42, *B*). On rough topography, the outcrop of a vein dipping less than 90° is curved or crooked; its deviation from the strike line increases as its dip decreases (Fig 42, *C*). Width of outcrop of veins of uniform thickness also varies on rough topography.

Many errors in planning mining work are made by assuming that geological surfaces are planes; they are always warped and twisted. Nevertheless, this assumption is useful in exploration work; by means of it an approx location of outcrop between or beyond known exposures can be laid out on the ground or on a contour map. Such approx locations vary in accuracy with depth of soil as well as with bends in the deposit itself; but they help to correlate observed data and reduce the excavation necessary to uncover outcrops. The following graphical methods are sufficiently accurate for this work, and apply to all the geological surfaces mentioned above.

Approx dip and strike of a vein can be measured with a compass at some point, or determined from 3 exposed points (Fig 43). Plot the 3 points *A*, *B* and *C* in plan in their correct relative positions, and note their elevations. Connect high and low points by line *BC*. Take point *D* on *BC* so that *CD* : *CB* = (elev *A* − elev *C*) : (elev *B* − elev *C*). *AD* is the strike line of plane *ABC*, and its bearing is measured with protractor from known bearing *AC*. Draw *BE* perpendicular to *AD*. Lay off *EF* to scale and equal to elev *B* − elev *A*. Angle *FBE* is dip of plane *ABC*. For accurate solution, see Sec 9.

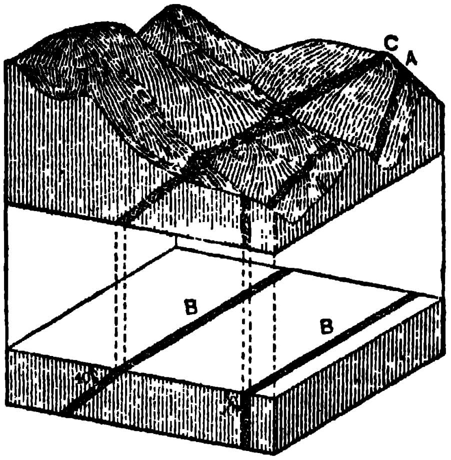

Fig 42

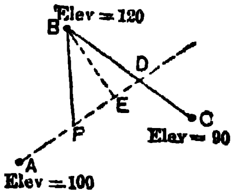

Fig 43

Plotting outcrop on a contour map from a single exposure (Fig 44).

Here the outcrop of a vein or bed is exposed at point *A*; its strike is line *AB*; dip 30°, as shown. The underground contours of the vein (considered as a plane) are a series of straight lines, *CD*, *EF*, etc, parallel to strike *AB*. The distance apart of these lines in horiz projection may be found by means of a right-angled triangle *xyz* (Fig 45), in which the angle *zxy* = dip of vein, *yz* = contour interval (the same as that for surface contours), and *xy* = *DF* (Fig 44) = required distance. Points of intersection of surface and underground contours of equal elevation mark points on the outcrop, and a line connecting such points represents its probable location. Same methods serve where a vein or bed is exposed by outcrops or work at several points. Fig 46 shows in horiz projection an underground (or structure) contour map of a vein, aver dip 45°, on which 4 shallow shafts have been sunk at points *A*, *B*, *C*, *D*. Assume that dip and strike are different at each of these points. Draw lines *AA′*, *BB′*, *CC′*, *DD′*, perpendicular to observed strike at *A*, *B*, *C*, and *D* and on them, by means of dip triangles (Fig 45), mark points at which they would be intersected by successive structure contours. Then draw these contours as shown.

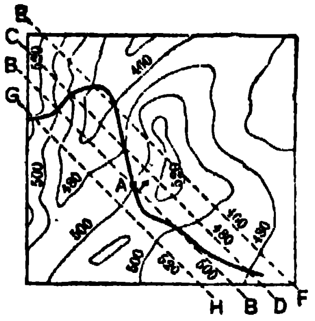

Fig 44

Fig 45

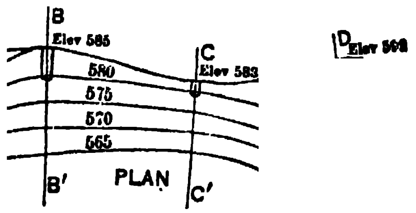

Fig 46

Beds and veins in general change their dip and strike gradually; hence, structure contours should show only gentle curves. If abrupt changes in direction are necessary to connect points of equal elevation, look for faults or other disturbances. Such contour maps are invaluable in planning underground exploration; when superposed on surface topography, they give close indications of the location of outcrops. For further detail of graphic methods, see Bib (21, 22).

Staking probable location of outcrop on the ground is done in different ways: (*a*) Plot probable outcrop on a contour map, and lay out this line on ground by ordinary surveying methods. (*b*)

Set up a transit over a known point on outcrop, and place stakes at regular intervals on strike line. Set transit on each stake, and cross-section to find outcrop, as for grade stakes in railroad work. This method involves much calculation, which can be reduced by using slope-stake diagrams. (*c*) Use transit with Shattuck solar attachment (23); set the attachment so that when it is revolved the deflected line of collimation will generate a plane at right angles to the telescope. Transit is set up over a point on outcrop, main telescope oriented in a line perpendicular to strike and the telescope turned down until line of sight is perpendicular to the dip (vert angle = complement of dip angle). Deflected line of collimation then revolves in a plane parallel to and slightly to one side of plane of vein. If the ground is sighted, each stake will be slightly off the correct line. Error is slight if the outcrop is traced from one set-up; where many stations are used, the error is cumulative. (*d*) Transit and top telescope. Loosen capstan screw, so that the top telescope will revolve in a plane parallel to main telescope. Set transit over point on outcrop, orient main telescope in a line at right angles to strike, and turn main telescope down until its line of sight is parallel to the dip (vert angle = dip angle). The top telescope then revolves in a plane parallel to plane of vein. A rod will give true points on outcrop, if sighted on at an elevation = height of instrument + (*c* + *cos* dip angle of vein); *c*, a constant for any instrument = distance between center lines of top and main telescopes. (*e*) Brunton compass, if set on a light tripod with a ball-and-socket mounting, is accurate enough for tracing outcrops short distances. The spindle of the instrument is tilted to a position at right angles to dip; then sights will rotate in plane of vein. See also "Geophysical Prospecting Methods," Sec 10A.

6. SURFACE PROSPECTING AND EXPLORATION EXAMPLES OF PRACTICE

Nova Scotia (24). Systematic prospecting is done here for gold-quartz veins in regions covered by deep glacial drift. Prospecting is confined to relatively small areas, in which rich float occurs. Surface is fairly level and ordinary conditions causing float to move downhill are absent. The general direction of glacial movement was a little east of south. Following methods apply generally to areas of glacial drift.

Prospecting methods are based on recognition of fact that while glacial drift contains rocks brought from a distance and entirely different from the underlying bedrock, it may be composed largely of material of local origin. Sequence of operations is as follows: Mapping. A contour map is made of the area on a scale of at least 40 ft to 1 in. On this are recorded details of geological structure, drainage lines, course of glacial transportation, distribution of gold-bearing float, position and depth of existing pits. A compass survey is usually sufficient. Panning. About 200 pans are taken from old dumps, surface soil, beds of brooks and sides of old trenches or pits. An exact record is kept, showing location of samples, number of pans taken, character and composition of drift (which may give clue to its source), and number and size of colors in each pan. Results are recorded on the map and summarized by drawing two lines, one enclosing the area in which float gold of any size occurs, and the other limiting the area containing shotty gold and large colors. This inner line incloses the center of gold distribution; within it and near its northern extremity most of the prospecting work will be done. Panning lessens the amount of heavy preliminary work. It usually confirms inferences drawn from the distribution of float and prevents work in barren areas. Two men, panner and helper, usually do this work in 4 or 5 days. Test pits are then sunk. A notebook is kept showing each pit in cross-sec on a large scale. Following details are noted: (*a*) depth, thickness, slope, mode of formation and composition of each layer in the drift. Each layer is given a number for future reference; (*b*) results from panning each layer; (*c*) absence or presence of float, quantity and estimated value per ton, number of pieces, size, degree of wear, and character of each variety and its associated minerals, as an aid to identification; (*d*) details of bedrock, dip, strike, cleavage, results and direction of glaciation; (*e*) depth and amount of water encountered; (*f*) size of pit and number of buckets hoisted; (*g*) labor, time, and material for sinking and timbering. Items *e*, *f*, *g* are useful for estimating future work. All pieces of gold quartz are kept for comparison with float from other shafts; they are numbered and put in boxes. Cross-sections show no orderly arrangement of strata; more beds occur in one pit than in another; 2 different layers may contain float from same lode. These irregularities are due to different periods of erosion; often transportation takes place in somewhat different directions at different times. But such correlation of various layers as is possible, and a comparison of their contents, give much information about origin and distribution of float gold. Location of pits. A test pit should always be sunk to bedrock near northern limit of area of richest pannings or float. Pits are put down in rows across direction of float movement. If all the gold is in upper layers of drift, its source is probably remote and pits can be placed at some distance apart; if all gold is confined to lower layers of deep drift, the vein is probably not far away. If gold shows only in upper layers, time and money can be saved by sinking only a few pits below the auriferous horizon. If pits on the right end of a row show no gold, the next row is shifted to the left and vice versa. Float gold is distributed from an oreshoot in a more or less fan-shaped form; hence the area to be prospected decreases as the source of the gold is approached. Often, post-glacial drainage has rearranged drift, rendering above methods fruitless unless old drainage and erosion processes can be interproted.

Cobalt, Ontario. Narrow veins of native Ag, associated with Co and Ni arsenides. Veins occur in diabase, conglomerate, and greenstone; some profitable deposits are 1 in or less in thickness. First discoveries were made by examination of rock outcrops; Co minerals oxidize to pink erythrite or " cobalt bloom." The pink color disappears under weathering, but is a good indicator when the rocks in the vicinity of a vein are freshly broken. All small crevices are examined; if ore is present, the crevice yields a soft black mud, CoO, containing nuggets of native Ag, or arsenates of Co and Ni are found a few inches below surface. Calcite veins are also considered favorable indications.

A large part of the district is covered by shallow glacial drift, in which prospecting is done by trenching. Rectangular coordinate lines are laid out on the surface at intervals of 50 to 100 ft and trenches are dug along these; in deep soil, trenches may be farther apart because of their higher cost. A few preliminary trenches are dug before thorough prospecting is attempted. On a contour map are recorded geology, rock outcrops, known veins, swamps, property lines, areas of deep drift, etc. Trenches are just wide enough for men to work to advantage; to allow cleaning the bedrock, they must be 2 to 3 ft wide at bottom; width at the top depends on depth and character of soil. When depth exceeds 6 ft, trenches are timbered by an occasional stull with uprights or head boards (19). In dry soil, bedrock in trenches is carefully cleaned with brushes; in clayey soil, by washing. Use of water is avoided where possible, as it conceals crevices by filling them with mud. Veins are difficult to recognize, especially in diabase; every likely place is blasted out. Each vein found is stripped as far as it can be followed, and shot out at close intervals.

R. B. Watson, Gen Mgr, Nipissing Mining Co, Cobalt, Ont, furnished following data on systematic prospecting by that company. In 1912 an HYDRAULIC PLANT was installed, to wash all the soil off the surface, for complete inspection of the rock. Water was pumped from Cobalt Lake. Details of installation: one-stage centrifugal pump, capacity 4 800 gal per min against 415 ft head; guaranteed effic, 78%; 650-hp motor, 2 200 volts, 1 180 r p m; spiral-riveted, 16-in pipe line, No 10 gage, with bolted joints to allow adjacent lengths of pipe to be turned through angles of 10° to 15°, without leakage. Some lengths of pipe had flanges on one end and bolted joints on other, giving a little stiffer pipe line. Size of nozzle was from 3 to 4 in, depending on whether a very strong stream was desired, or less force with larger volume For good results, pressure at nozzle of at least 100 lb per sq in was necessary. When all ground within reach of the nozzle was washed off, usually taking about a day, the pipe line was extended to the next set-up, which had been prepared in advance. After an area had been cleaned, it was examined, surveyed, and then served as a dump for spoil from adjacent areas. Dynamite was used to break rock and scatter heavy boulders. In 1914, the plant ran 79.08% of the time; 153 set-ups were made; aver time lost in setting up, 1 hr 32 min. Aver press at nozzle, 138 lb per sq in. 68 309 ft of pipe were shifted and 18 730 ft of roads were built. 95.55 acres were washed; aver depth of soil, 3.4 ft; 529 415 cu yd were moved.

Table 2. Trenching at Nipissing Mine

Year	No men	Miles of trench	Aver depth, ft
1909	87	33.1	3.4
1910	61	31.7	2.7
1911	25	13.7	2.7

In 1914, on La Rose property, the soil was shoveled off an area of several acres, in strips 20 ft wide; distance between strips was made as small as possible, determined by the height to which men could throw the dirt. Aver depth of soil was 1.9 ft.

Quebec copper-gold belt (Rouyn District); data from K. W. Fritsche and A. B. Parsons (504). Steep-dipping lenses of sulphides containing copper and gold occur usually in rhyolite and andesite, often associated with syenite-porphyry dikes.

Systematic prospecting is done over large areas, much of which is heavily wooded, making traveling without axemen difficult. Typical sequence of operations on a group of 40 claims (8 000 acres): (*a*) Parallel base lines at half-mile intervals are laid out by transit. (*b*) " Picket " lines, 200 ft apart, are run at right angles to base lines. (*c*) An experienced geologist makes observations along the picket lines and directs pick and shovel work or drilling and blasting on likely outcrops. (*d*) Dip-needle observations are made by young engineers every 50 ft along picket lines, to indicate presence of magnetite and pyrrhotite. Results plotted and maps studied by geologist, together with his own notes. Large areas can now generally be neglected as valueless. (*e*) On several groups of claims encouraging areas have been studied by electrical prospecting (Sec 10A). (*f*) If (*e*) is not done, favorable areas are studied in more detail. Dip needle may be replaced by a magnetometer (Sec 10A), and observations made at 10- or 25-ft intervals on lines 100 ft apart. (g) Promising areas are cleared of timber and brush and trenching begins; first trenches 50–200 ft apart, depending on depth of cover. Table 3 shows how duty of labor in trenching varies with depth, number of roots, amount of water and regularity of bedrock. Oxidized or enriched parts of outcrops (seldom over 2 ft deep) are blasted out before samples are taken. One man channel-samples 40–80 ft of trench per day in 5-ft sections. (h) Outcrops considered good enough are explored by diamond drill. (i) Shafts, crosscuts and drifts are made, and deposits explored further by underground diamond drilling.

Table 3. Duty of Labor in Trenching, Quebec Gold Belt (504), about 1924

Example No	Dimensions of trenches				Labor, man-days	Cu yd per man-day	Conditions
	Length, ft	Width, ft	Depth, ft	Cu yd			
1	16	3	4	31.9	6	5.31	Roots and gravel. No water. Bedrock smooth.
2	30	3	4.5				
3	13	2	2.5				
4	16	2.5	3				
5	20	2	2				
6	10	6	10	22.2	7	3.17	Gravel, large boulders and water.
7	54	3	3	18.0	7	2.57	Many roots. Bedrock rough.
8	20	3.5	5	12.9	5.5	2.34	Roots, gravel and some water.
9	10	4	7	10.4	5	2.08	
10	10	4	5	7.4	4.5	1.64	Sticky clay, much water.
11	40	3	4	17.8	12	1.98	(a)
12	30	2.5	2.5	6.9	6	1.15	(b)
13	65	....	....	....	3	....	(c)
14	110	....	....	....	4.5	....	
15	75	....	....	....	3	....	
16	72	....	....	....	3.5	....	

(a) 2 ft gravel underlain by 2 ft partly decomposed schist. (b) Partly decomposed schist, hand drilled and blasted; cost of powder not included. (c) Stripping moss, roots and some gravel; aver width of these openings, 2 ft; max depth, 2 ft.

Quebec gold vein. J. Y. Murdoch, in 1938, contributes following data on surface exploration of a group of 5 claims, 125 miles from RR in northern Quebec, performed during 4 summer months by 4 men with foreman and cook; wages \$4.50, less \$1.25 for board. Men and supplies transported by hydroplane. Previous work had exposed 120 ft length of vein, 6 ft wide. Area heavily wooded, but outcrops numerous; overburden, where trenched, 1–5 ft deep. Trenches perpendicular to outcrop, spaced 10–30 ft apart, were 5 ft wide; where rock blasting at bottom was desired, 6-ft width was better. In clay or sand, 1 man in 1 day dug about 10 ft of trench 5 ft wide and 4–5 ft deep (7–8 cu yd). Total trenching during 4 mos included 400 ft on the known vein, and 1 200 ft in search of parallel veins; rock blasting at bottom of trenches, for sampling below weathered zone, amounted to 200 ft. Double-hand drilling with $^7/_8$-in hex steel and 6 or 7-lb hammers made 12 ft of hole in 8 hr; holes 2–4 ft deep, loaded with 40% Forcite, 3 sticks for a 3-ft hole, and fired by fuse with No 6 or 8 caps. Channel samples were 1–1.5 in deep and 2–3 in wide; where mineralization was irregular, and free gold appeared, larger samples were taken. Two 10 by 12-ft tents and a 12 by 14-ft cook tent for 6 men. Floors of split poles; tents carefully screened. Staple food supply for the party for 4 mos weighed about 3 000 lb. Essential equipment of tools is listed in Art 13.

Witwatersrand, South Africa. Silicified conglomerates carry Au, and occur as members of a series of sedimentary rocks. The auriferous " banket " reefs dip at 16 to 90°. Faults complicate the work of locating outcrop extensions in places. " The surface is first examined to locate one or more beds of sandstone, with which the reefs are conformable " (25). Topography is closely related to the geology; hard beds form ridges and, in some cases, streams follow fault lines. In shallow soil, indications of the character of underlying rocks are obtained from ant hills; over banket these have generally a yellowish gray color, over basalt dikes they consist of red loam.

Trenches are dug at right angles to the strike of the formation at regular intervals. One trench near middle of property is continuous; the others are made only where the central trench shows that a reef is likely to cross. At each point where reef is found, a small shaft is sunk deep enough to provide samples from points unaffected by surface alteration. In deep soil a small shaft is sunk into solid formation, and a crosscut driven to give a section of the rocks; or 2 or 3 shafts are sunk and connected by crosscuts. Values are remarkably persistent and fairly uniform over large areas of reef; hence, surface exploration gives reliable indications of conditions at depth.

Suan Concession, Korea (480). An area of 15.5 by 10.5 miles was prospected and about 59 000 acres systematically explored in 1905–1916. Orebodies, generally lenticular, to 125 ft wide by 400 ft long, are contact metamorphic deposits around a granitic batholith 6 by 5 miles in area. Some deposits are distant from the contact. Valuable metals: Au, Ag, some Bi and W.

Some of the deposits were exploited by ancients; intensive study of old workings led to discovery of one important orebody and indicated marked surface impoverishment of ore which might have caused ancients seeking high-grade ore to overlook valuable deposits. Known gold placers in streams flowing from high ground at center of batholith furnished another aid to prospecting for ore in place.

A topographic and general geologic survey was made; all known data and all results of prospecting were mapped; maps were made for each square mile on scale of 1 in = 150 ft. Each square mile area was first explored by sinking test pits to bedrock at intervals of 300 ft along creeks and valleys. Systematic samples from each pit were panned and depth of pit, nature of bedrock and results of panning were recorded on map. On finding colors or favorable indications, intermediate pits were sunk 100 ft apart. Detailed study of surface conditions and local geology was made in vicinity of favorable showings. Such areas were then prospected intensively to locate source of mineral; traces were followed by test pits about 100 ft apart until approx line of mineralization was located, then a series of trenches at right angles to this line uncovered outcrops. Many outcrops were discovered, several containing profitable ore. Samples from test pits for panning were taken in 2-ft sections; composite samples, comprising the last 0.5 oz of concentrate in each pan from a given favorable area, were completely analyzed to determine the minerals present. The concentrates were also examined systematically with a microscope, which led to the discovery that small amounts of W were widely distributed around the contact. Native labor, in charge of a foreign miner or prospector, who had underground experience on the property, was used for prospecting; separate crews were employed for preliminary and intensive work. Native wages: 25¢ per 8-hr day for miners and 20¢ per 10-hr day for coolies. On intensive work a crew averaged about 4 square miles in 6 months; cost, about $2 000. Aver cost of test pits, about 5¢ per ft; cost of trenches varied widely, averaging about 7¢ per cu yd.

West Australia (506). Gold-bearing veins occur near porphyry dikes and jasper "bars," often in vicinity of contacts between granite and greenstone; such localities are sought as favorable for detailed prospecting.

Tracing float and "loaming" (tracing by panning, Art 4) are the principal prospecting methods. In arid areas, a "loam bag" of cotton cloth, 6 in diam by 6 ft long, with tapes sewed to it at 9-in intervals, is used for collecting and carrying samples to water for panning. The prospector having found float, colors, or favorable geology, digs parallel rows of holes, 4–6 in deep; holes in a row are about 12 ft apart; rows are about 30 ft apart and lie approx on contours. A sample from each hole is put in the loam bag; samples kept separate by tying the tapes between them. Holes showing colors are marked with stakes; stakes in lower rows indicate trend of traces to one side or other, and guide the prospector in locating the next higher row of holes. Work continues until colors cut out of surface soil, when values are followed in deeper ground by trenching. At times, samples are tested by "dry blowing," a winnowing process wherein the sample is repeatedly poured from a dish or pan (about 15 in diam), held at level of operator's head, into a similar dish on the ground. The wind blows fines aside, leaving coarser material and gold behind. Bib (506) describes dry-blowing machine for testing larger samples.

West Uganda, Africa. N. W. Wilson in 1938 described an exhaustive survey of a 155-sq mile area on SE flank of Ruwenzori Mt, E Africa (96). Region is a few miles N of Equator, at altitudes of 3 500–13 500 ft: lower elevations are generally open, bushy, or grassy; higher ones, densely wooded, cold and wet. Nearest RR at Kampola, 170 miles by air-line. Mapping and detailed prospecting were done concurrently. Three parallel main base-lines were laid out, one near N boundary, one on S boundary, and one midway. These were connected at right angles by grid of parallel traverse lines, 1 200 ft apart in open country, 2 400 ft apart in forest. On traverse lines, vegetation was cleared to width of 5–6 ft, and stakes set every 300 ft. It was considered that any orebody large enough to be valuable, if not actually intersected by a traverse, would be disclosed by neighboring float. Pits were sunk to bedrock at every second stake; also at every crossing of a gulch. Stream beds wider than 6 ft were traversed their full length; narrower ones by cuttings for 300 ft each side of intersection with a traverse line. Stream beds about $^1/_2$ mile wide were not pitted, because numerous large boulders prevented alluvial working. Black-sand residues from panning of pit material were collected into composite samples, representing 5 000 ft of traverse and critically examined at headquarters, together with specimens of outcrop and float Observations were mapped on scale of 1 : 10 000. Each prospecting party was under 2 Europeans; one with about 70 natives for clearing the lines; other with 10 natives for geological work. Alternate "strips," 6 lines wide, were worked by 2 parties. For close examination of likely spots, subsidiary lines 300–600 ft apart were cleared to width of 20 ft for inspection by engineer in charge.

Clinton hematites occur as stratified beds in the Clinton formation (Silurian age), all along the Appalachian Range, and also in New York, Kentucky, and Wisconsin. The beds vary in thickness from a few inches to 10 or 12 ft; they are subject to all the irregularities of sedimentary rock beds (Art 3; also Sec 2). Prospecting may start from discovery of float or outcrops, or by recognition of some member of the Clinton series with which these ores are associated. Above or below the ore bed there is usually some characteristic stratum which outcrops; measurements from this give an approx location of the ore-bed outcrop at different points along its strike. The outcrop is then uncovered by trenches or test pits. In the south, weathering extends to considerable depths, but on hillsides erosion has kept pace with it and unaltered ore is often within 5 ft of outcrop (5).

To determine thickness and grade of ore, dip, strike, etc, exploratory openings (inclined shafts or drifts) should be driven at regular intervals into unaltered ore. Since these orebodies are of sedimentary origin, they are apt to be uniform in size and tenor over large areas. Exploratory openings may be placed far apart and still give good basis for tonnage estimates (7). Geological structure should be carefully worked out. Diamond drills are used for deep exploration to check outcrop evidence, locate faults, etc (Art 7).

Brown iron ores (limonite) in the Appalachian valley. The two important types are residual deposits and replacement deposits.

Residual deposits consist of masses and boulders of limonite, embedded in clay and lying on an uneven surface of limestone or dolomite. Orebodies are very irregular and are covered by sand and soil. Discontinuous outcrops occur, especially in gullies, or limonite gravel is found (5). Mining is carried on in open cuts, and exploration must show area, aver depth, tonnage, and quality of ore, and depth and character of overburden. Usually a few test pits are put down to determine whether surface indications are connected with orebodies of any size; data on concentration and quality of ore are obtained by washing and analyzing the samples. Different methods are used for exploration if preliminary results are favorable. Alabama brown iron ores are often prospected by pits; first at corners of 200-ft squares, and then at closer intervals for more accurate delineation of boundaries (6). Pits, preferably circular and of 30- to 34-in diam, are sunk by hand, using short-handled (12–18 in) picks and shovels, hoisting by windlass and bucket. In soft material, sides can be supported by hoops of 1/2 by 2-in iron, with 24-in corrugated roofing in 5-ft lengths for lagging, recovered when finished. Unless water interferes, 2 men can sink a pit to 50 ft or more, at contract price (1937) of 25–50¢ per ft. Values may be estimated: (*a*) all material taken from ore bed, volume of which is calculated from thickness of bed and diam of hole, is quartered down, after breaking lumps, washed to remove sand, weighed, and sampled for analysis; (*b*) a vert groove, 2–3 in deep and wide, is cut down one side of finished pit, vol of sample measured, and ore contents weighed after washing; method (*b*) is faster and cheaper. Aver recovery of washed ore, 1 ton from 2.5–3 cu yd, exclusive of overburden. Elsewhere, augers or churn drills are used (26). Similar methods are used in prospecting for, and exploration of, Tenn and Texas brown ores.

Replacement deposits are from replacement of a particular bed (Art 3). They vary widely with dip and nature of rock replaced; methods of prospecting depend upon topography and geol (7).

Brown phosphate rock in Tenn (338). A few pits are sunk at selected points, to check results previously obtained by auger holes (Art 10-a) T V A (in 1936–1938) let contracts for this work, including digging, sampling, and refilling, at 60¢ for first ft, plus 50¢ per ft down to 10 ft; sliding scale for deeper pits made a 20-ft pit cost $16.35; still deeper, $16.35 plus $1.60 per ft. Contractors supplied all tools, and transported samples 40–50 miles to laboratory. Usual sampling practice was to cut a channel, 1 ft square, down one side of pit, recovering phosphate contents by washing. Dry wt of phosphate divided by depth of bed gave recoverable contents per cu ft.

Alluvial gravel. Initial prospecting is often done with test pits, especially in shallow ground free from water; (churn drills for deep or water-bearing gravel). First pits or holes may be located at random; later ones, on regular system or according to information gained. D. L. Sawyer contributes data in Table 4, on test pitting in exceptionally coarse gravel. Pits were 3.5 by 3.5 ft cross-sec; no water encountered; most pits were cribbed with 2 by 12-in planks on edge, notched at both ends; some were sunk on company account and some by contract; crew of 3 men at each pit under either arrangement. High cost of certain pits due to large boulders and fine, running sand.

Table 4. Labor Costs for Test Pitting in Coarse Gravel, Yavapai Co, Ariz

Pit depths, ft	Company account			Contract arrangement		
	Aver advance per shift, ft	Labor cost per ft	Earnings per man-shift	Aver advance per shift, ft	Price per ft	Earnings per man-shift
5	4.80	$2.50	$4.00	9.80	$1.75	$5.70
5–10	3.00	4.00	4.00	7.65	2.00	5.10
10–15	2.20	5.50	4.00	4 20	3.00	4.20

7. PROSPECTING AND EXPLORATION BY BORING (See also Sec 9)

Applications of boring in connection with prospecting and exploration are: location of minerals covered by soil, rock, swamp, or water; search for extensions on strike or dip of known orebodies; search for parallel orebodies; location of faults, faulted segments of orebodies, and water-bearing strata; detailed exploration of orebodies for estimating tonnage and value. LIMITATIONS. BOREHOLES *vs* OTHER OPENINGS. Boring is not always the cheapest method of prospecting or exploration, and may not furnish all the desired information. In such cases, use test pits, shafts, or drifts.

Choice of method in any particular case is based on consideration of following factors.

Type of orebody. Boring is not best adapted to exploring narrow, steeply dipping veins, small and irregular orebodies or high-grade, spotty deposits, although much of the diamond drilling actively and satisfactorily conducted in Canada is in such deposits. Boreholes, because of their small diam, may miss such orebodies entirely, or pierce them in pinches, swells, barren, or rich spots. Thus, diamond drilling cut a vein at a barren spot on City of Cobalt property, Canada, and failed to discover a rich vein system subsequently found by underground work (508). Boring from the surface is best suited to large deposits of fairly uniform grade, as masses or beds dipping less than 50°. Examples: Lake Superior iron ores, disseminated lead and zinc ores of Missouri, " porphyry copper " deposits, Clinton iron ores, and coal seams.

Cost. In surface drift, boring is done by augers, churn drills, or wash-boring; test pits are sometimes cheaper. Within its limited field an earth auger (Sec 9) will usually put down a 2-in hole for less than 0.2 of the cost of a test pit to same depth. To depths of 20 to 30 ft in surface drift, free from water and requiring no timbering, small test pits usually cost less per ft than churn-drill holes. Pits are better under such conditions for both prospecting and exploration, because of the more accurate information they afford. In soft rock, small shafts often cost less than either churn-drill or core-drill holes to shallow depths (20 to 50 ft). This is true only where no timbering is required and water is absent. In soft porphyry at Ajo, Ariz, 4 by 6-ft prospect shafts, 50 ft deep, cost less than diamond-drill holes to same depth (27). The cost of moving and setting up drills is largely responsible for the high cost per ft of shallow boreholes. For hard rock, and for greater depths in soft rock or alluvium, the cost of boring per ft is 0.2 to 0.5 that of small shafts.

Speed. Boring has little advantage over test pits for shallow work (20 to 30 ft) in dry surface drift requiring no timbering. In rock, and for greater depths in alluvium, speed of boring may be 3 to 10 times that of shafts or other underground openings. Presence of WATER increases cost and decreases speed of underground openings, but does not interfere with boring. Boring is therefore peculiarly applicable to prospecting and exploration in water-bearing formations.

Purpose of work. Many boreholes are made merely to locate strata or orebodies preliminary to sinking or driving to or through them. Thus, in the Clinton iron ores of Alabama, diamond-drill holes are bored at distances of 1 000 to 3 000 ft from the outcrops, to locate the ore bed and anticipate the effect of faults on location of shafts and workings. Similar cases occur in coal mines. On the Rand, also, the reefs under deep-level properties are located by diamond-drill holes before working shafts are begun.

Boring has a special field in prospecting for oil, gas, salines, and sulphur, where the borehole is used subsequently to conduct the mineral to the surface. For work under swamps, lakes, rivers, or deposits of quicksand, boreholes are most useful both for initial prospecting and for exploration based on indications given by geophysical methods (Sec 10A). Inclined holes are sunk from solid ground, or vertical holes from boats or through the ice in winter.

Speed *vs* cost. Where geological data are of chief interest, speed and cost are paramount factors, samples of the orebody are secondary objects, and boring has an advantage over shaft sinking which increases with depth of the deposit. At the other extreme is the work of detailed exploration to determine tonnage and aver values, in which cost and speed are subordinated to necessity for accurate samples; type of orebody then determines the choice.

Underground openings always give more accurate information and samples, but advantage can be taken of the speed and cheapness of boring in orebodies like the Mesabi iron ores and the " porphyry coppers," where values are uniform over large areas, or vary gradually from point to point. So much work has been done in some districts, as S E Missouri and in certain placer deposits, that empirical factors have been determined, to correct inaccuracies due to boring practice and to irregularities of the orebodies (Art 6).

Transport. In remote districts, cost of transporting boring apparatus may be prohibitive, except for shallow prospecting where hand drills can be used, although airplane

transport of heavy and bulky equipment is overcoming this difficulty (646). It should be noted that borehole results are susceptible of more accurate interpretation in districts where the details of geology and ore occurrence are well understood; shafts or other openings are therefore sometimes preferable for preliminary work in new districts.

or rough topography increases cost of boring, owing to expense of moving drills, and may compel the use of underground methods.

Boring from underground points by diamond drills, and occasionally by hammer drills, is done in many mines, in searching for orebodies, to locate the limits of wide orebodies, or to obtain geological information. Footage may often be saved over holes started from surface. Steep-dipping veins may be cut by holes nearly normal to their plane. Fig 47 shows a hypothetical case, where a crosscut on bottom level failed to cut a vein known on levels above; projection indicated that the vein would be cut at point *A*. Diamond-drill hole No 1 also failed to find the vein. Hole No 2 cut the vein as indicated; a raise was then started at *B* to reach bottom of ore.

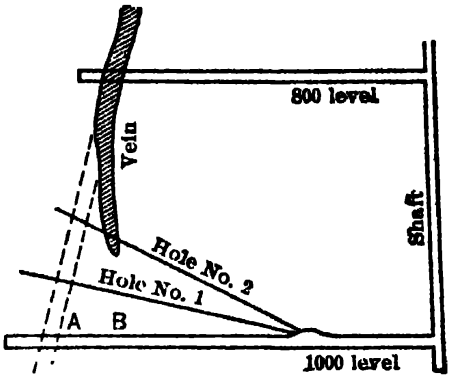

Fig 47. Locating Downward Extension of Vein

At Alaska Treadwell mine in 1913, 4 318 ft of holes were thus drilled to outline portions of the deposit (28). Rocks are hard diorite, quartz, and greenstone, and soft slate containing quartz stringers. A high core recovery was obtained; 90% in one horiz hole, 1 000 ft long. The information was therefore accurate. Drifting and tunneling would have taken 4 times as long, at a cost of $8 to $12 per ft. Cost of drilling was $1.62 to $1.74 per ft. Miami Copper Co did 2 714 ft of vertical diamond drilling from underground set-ups in 1912 and 1913 (29). Rock was silicified schist, broken into small pieces by fissures, the individual pieces being very hard. The holes caved frequently and were difficult to drill and sample; less than 10% of the core was recovered. Cost, $5.44 per ft; speed, about 5.5 ft per 8-hr shift. These examples show that the advantages of boring are lessened in very difficult formations. Fig 48, from M. G. Hansen (97) in 1933, shows diamond drilling on a level of United Verde mine, Ariz. Orebody is a pipe-like mass of sulphides, dipping about 60°; work was done to ascertain geology and locate walls and commercially mineralized areas. Most holes were nearly horiz, lying at angles between

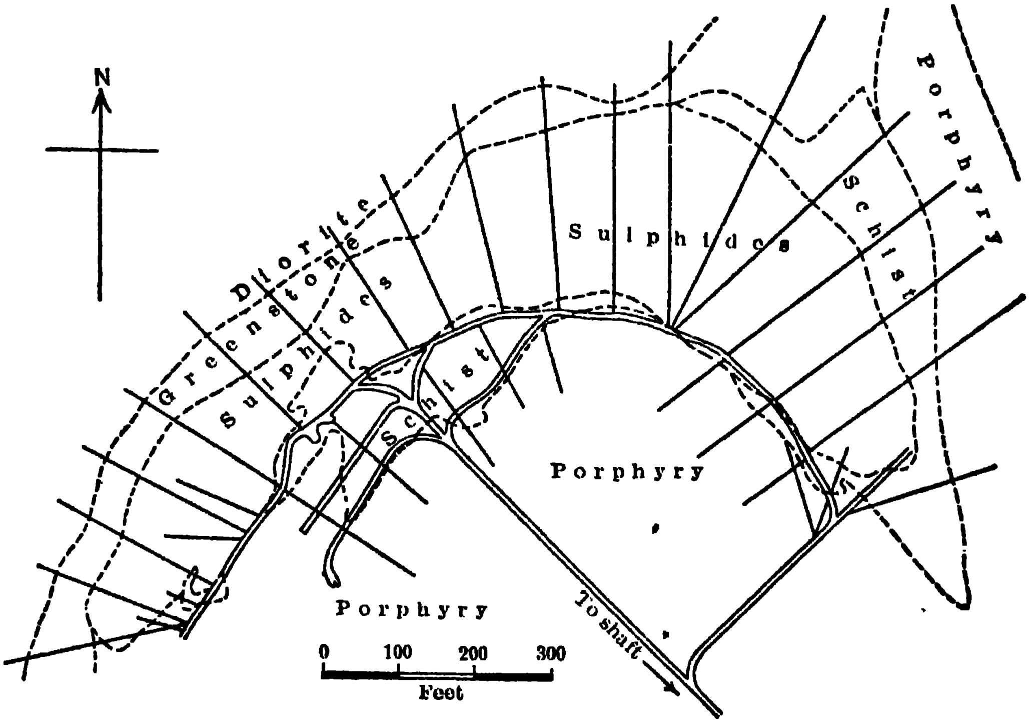

Fig 48. Diamond Drilling on One Level of United Verde Mine, Jerome, Ariz (97)

+12° and −5°, and 150–650 ft deep; deepest, 2 200 ft; several exceed 1 000 ft. For further details, see Art 10-c.

Choice of boring apparatus, from standpoint of depth of holes, speed of boring, first cost, operating cost, convenience of transport and character of formation: for these points, see Sec 9, also Art 10.

Locating boreholes. Choice of sites depends on nature of work to be done. In strictly prospecting operations, geological indications, or the position of ore on adjacent property are the only guides; in such work initial drilling is often done at random. Holes are placed systematically for detailed exploratory work.

Fig 49 shows in plan a mode of prospecting for FLAT MASSIVE OREBODIES. Coordinate lines are laid at intervals of 50 to 60 ft, depending on the type of orebody sought. If there is no adjacent work to indicate the probable location or course of ore, the first hole is sunk at the most convenient point, say at *A*. In the illustration, this hole would be barren. Assume that the second and third holes are drilled at *B* and *C*. They indicate that the trend of the orebody is not along either *AB* or *BC*, and subsequent drilling would be done in the directions *EF* or *GH*. Instead of drilling hole *C*, after ore is found at *B*, holes 3 to 10 might be drilled. An infinite number of variations occur; as a rule, before close drilling is attempted, it is cheaper to establish the general trend of an orebody.

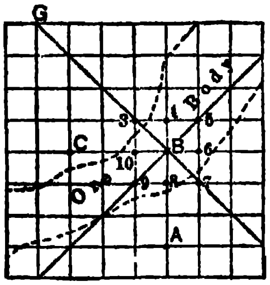

Fig 49

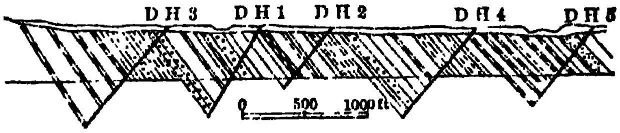

Fig 50. Diamond-drill Holes at Victoria Mine, Mich (after A. H. Meuche, *Ann Rep* 1909, Mich Geol Surv)

In the MICHIGAN COPPER REGION the orebodies occur in the amygdaloids and interbedded sediments of a series of tilted lava flows, truncated edges of which are covered by glacial drift. According to T. M. Broderick, overlapping diamond-drill holes, of which the spacing and inclination in a plane perpendicular to the strike are dependent upon the dips of the series, disclose the general succession and location of any mineralized horizons (Fig 50). These horizons are then drilled in greater detail, and if mineralization is persistent, trenching or underground investigation follows. Because of very erratic distribution of native copper in most deposits, the diamond drill is not expected to yield quantitative sampling information. Special conditions cause modifications of procedure. Where overburden is deep and difficult to penetrate, it may be more economical to drill holes steeper than at right-angles to the bedding, since the greater footage in rock necessary to cover a given stratigraphic interval may be more than compensated by the shorter distance in overburden. Occasionally, where beds and the fissures crossing them are both mineralized, it is desirable that diamond drilling give information on both types of ore occurrence. Certain combinations of dip and strike of beds and of fissures make it possible to do this by inclined holes oblique to the strike of both, which, while not cheapest for either, are most economical for simultaneous exploration of both ore structures.

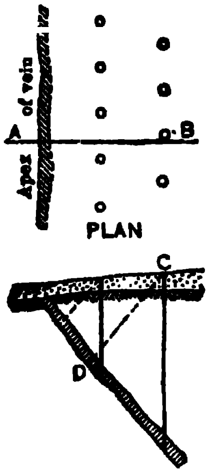

Fig 51

A plan similar to that in Fig 50 is applicable in prospecting coal formations. Fig 51 shows an amplification of this method, used for detailed exploration of veins, in the search for oreshoots in veins, and for exploring pitching coal seams. Closer information is usually obtained if holes in successive rows are staggered, as shown. Choice between vert and inclined holes (*CD*, Fig 51) depends on local conditions. Vert holes are cheaper where depth of surface drift is great. They are used in initial drilling where nothing is known of the dip of rocks or orebody, and in general where dip of formation is less than 20° to 30°. Inclined holes are preferred for steeper dips; they are shorter, there is less danger of misinterpreting the thickness of formations penetrated, and they generally cut the short dimensions of vugs and soft layers, which give trouble in both drilling and sampling.

For detailed exploration of flat massive deposits, drill holes are usually located on corners of squares. Some systematic arrangement is desirable to secure impartial samples at regular intervals and simplify subsequent calculations of tonnages and aver values.

Interval between holes is a matter of judgment based on type of orebody. Questions of cost urge that holes be spaced far apart, but accuracy demands that the interval be limited to a distance over which it is safe to expect the orebody to continue without marked irregularities in form or tenor. (See Art 10 for spacing used in different localities.)

Fig 52, from R. V. Norris, shows one method of locating diamond-drill holes used in the PENN ANTHRACITE FIELDS, for determining position and thickness of folded coal seams. Order in which holes were drilled is shown by their numbers. Hole 14 was required to interpret data from 12 and 13. Surface geology and outcrops are valuable aids in constructing such sections. In the Wyoming and Lackawanna valleys, Penn, coal seams often outcrop under present or old river valleys, filled with wash to depths of 50 to 175 ft. Wash borings are made on corners of squares to determine thickness of rock cover; size of squares varies from 100 to 500 ft, depending on this thickness and on irregularity of bedrock surface.

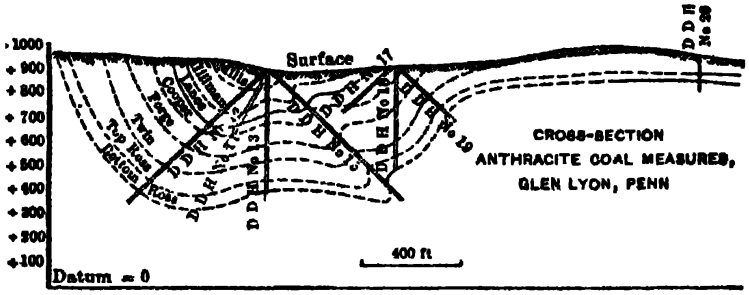

Fig 52

Prospecting for oil. Data on geology of oil deposits and location of boreholes are given in Sec 44; methods of boring, in Sec 9.

Drill roads are a serious item of expense in swampy districts, and where the topography is steep or rough. Standard rigs and diamond drills (except Missouri type) are moved on wagons requiring roads about 7 ft wide. For traction churn drills (Keystone No 5 and Star No 23), used in porphyry copper districts, hillside roads are made 9 ft wide in the solid. The fill is relied on only in case the machine skids. Max grade advisable is 15%, which is also about the limit for teams hauling fuel and water. Traction drills can climb 28% grades for short distances. Switch-backs are used when necessary; drills can not take so steep a grade while backing as when going ahead. In the Miami district, Ariz, with drill holes spaced 200 ft apart, a minimum of 300 ft of road was required per hole (33). At Miami, about 1 cu yd of material was moved per linear ft of road (34).

Organization of boring work. Good management is especially necessary where many drills are employed. Given suitable drills, economy in large-scale work may be secured by minimizing delays and labor required, and using common labor for roustabout work so that high-priced drillers spend maximum time in actual drilling. Scale of operations limits extent to which these economies are profitable. A map is essential to proper organization, and the points at which holes are to be drilled must be marked on the ground in advance.

Many DELAYS can be prevented by keeping at hand extra bits and small repair parts. Where tubs or barrels are used for samples, enough should be provided at each machine so that drilling can proceed while samples are settling or drying. Supply service for fuel and water should be carefully planned. Roads, if required, should be constructed before drill is ready to move; gasolene-driven diamond drills, mounted on skids and dragged by their own power, minimize expense for roads. FUEL. With coal, boxes or plats at the drill are necessary to prevent waste and give clean fires. Where wood is burned it should be cut to proper length before delivery; similar foresight is used in planning storage and delivery of liquid fuels, building power lines and handling cable for electric-driven drills.

Churn-drill work. The crew comprises a driller, helper, sampler, and sometimes a fireman (helper generally fires when coal fuel is used or when wood is delivered in proper lengths). If two drills are kept near each other, one sampler can look after both; hence, where several drills are in operation, they should be worked in pairs. Under favorable conditions one team can serve 3 or 4 drills within a radius of 0.5 or 0.75 mile. Keeping drills close together also allows easy supervision and use of fishing or other tools in common. A foreman for 3 or more drills will save his wages. Some engineers employ an extra driller or helper for every 2 or 3 drills, claiming that the saving in cost of moving, casing, and upkeep more than offsets the increased labor cost. For moving, setting up, casing, and pulling casing, 4 men (usually the crew of 2 shifts) are employed. For this reason, and in general, 2-shift work (either 8, 10 or 12 hr) is more economical than 3 8-hr shifts (34).

Diamond-drill work. The practice of keeping a number of drills near together has same advantages as for churn drills. Smallest possible crew for 1 drill consists of a drill runner and fireman for steam-driven drills (or a driller and helper for motor-driven drills), on day and night shifts, and a foreman on day shift. Foreman sets bits for both shifts and tends to sampling on day shift; drill runner does sampling on night shift. Except in remote places, it is now common practice to return worn bits for resetting at factory, maintaining a sufficient supply of fresh bits to permit uninterrupted operation. In some localities a drill runner and 2 helpers are used on each shift. In hard rocks giving good cores, where the sludge frequently is not saved, no special samplers are required; the foreman or drill runner can attend to the cores. Where accurate samples depend on saving the sludge, samplers are generally necessary. C. E. van Barneveld cites an illustration of large-scale organization on the western Mesabi range (35). For 30 drills working 1 shift, crew comprised 30 drill runners, 60 helpers, 5 pumpmen, 1 blacksmith, 3 diamond setters, 2 cooks, 4 waiters, 1 superintendent, 1 clerk, 2 foremen, and 3 samplers.

Contract work avoids outlay for drills and makes a considerable saving on small amounts of drilling. The practice is open to objection that the contractor may slight work of sampling to attain drilling speed. This objection is met by employing experienced men as samplers on company account, and by paying days' wages to the drill crew for reaming and casing (see Sec 9). Where there is steady work for drills, it generally pays to buy the machines and import trained drill runners, but practice varies. On the Lake Superior iron ranges most of the drilling is contracted, due to complete organization and equipment of local contracting firms and their reputation for careful work.

E. J. Longyear Co gives following data (1938) on 5 recent diamond-drilling contracts: (*A*) Iron exploration, Mich, 1930–31. Drilling from surface; overburden 50–150 ft deep, or approx 30% of total depth drilled. Carbon bits used exclusively. 4 drills worked two 8-hr shifts per day. Each crew included 1 runner and 2 helpers, while standpiping through overburden; 1 runner and 1 helper for drilling rock. Aver crew for the job: 1 foreman, occasionally assisting with diamond setting; 1 diamond setter; 8 drill runners; 12 helpers; 2 pump-station men; 1 team and teamster; intermittent truck service as required. (*B*) Test borings at a dam site, Tenn, 1934; about 60% of total boring in overburden. Carbon and bortz bits (set on the job) were used. 4 drills worked 3 8-hr shifts per day, with a crew of: 1 drill supt; 1 diamond setter; 1 asst foreman and setter; 1 clerk; 12 runners; 12 helpers; 3 laborers to prepare locations in advance and assist with moving; 2 pump-station operators; 1 pick-up truck (intermittent truck service as required). (*C*) Iron exploration, Mich, 1937. Drilling from surface, about 2% in overburden. Mechanically set bortz bits used almost exclusively. Of 2 drills, 1 worked 2 shifts, other 3 shifts, employing: 1 foreman and diamond setter; 5 drill runners; 5 helpers; 1 pump-station operator; part-time truck service. (*D*) Iron exploration, Mich. All underground core drilling, with 1 drill working 1, 2, or 3 shifts; carbon bits set on the job. Crew: 1 foreman and diamond setter; 1, 2, or 3 drill runners; 1, 2, or 3 helpers. (*E*) Gold exploration, So Dak. All underground core drilling with 1 drill; mechanically set bortz bits used. Crew: 1 head driller for day shift; 1 driller for afternoon shift; 2 helpers.

Cost of diamond-drill exploration, per ton of ore proved, may range from less than 1¢ in large, uniform orebodies, to over 10¢ in small, erratic deposits. C. K. Hitchcock reported in 1933 that Creighton mine proved 9 225 000 tons of ore with 28 803 ft of drilling at 1.4¢ per ton; Murray mine, 8 560 000 tons with 35 792 ft of hole, at 1.7¢ per ton; Beattie Gold mine, 5 330 050 tons with 8 822 ft, at cost of 0.9¢ per ton proved.

Borehole results are often misinterpreted. Fig 53 shows a case where 2 holes on the flanks of a folded coal seam indicate a thicker horiz seam *AB*. Careless use of data from the hole in Fig 54 would indicate 2 seams instead of the true conditions. Results should be interpreted in the light of collateral geological evidence.

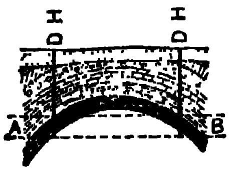

Fig 53

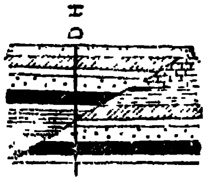

Fig 54

Single holes, while valuable for determining position of an orebody, give no information as to dip or strike, and often furnish erroneous values for thickness. The use of deflecting wedges (Sec 9) in deep diamond-drill holes, for getting a second section of the formation from the same hole, is a cheap means of securing additional data. For survey of deflected diamond-drill holes see Sec 9. A case of error from single holes has occurred in districts such as the Missouri and Wisconsin zinc fields, where churn-drill holes following rich vertical stringers were taken to prove the existence of thick, flat orebodies.

8. SAMPLING BOREHOLES (See also Sec 9)

Accuracy of sampling depends largely upon the character of the material drilled. Diamond drills give accurate samples in hard rocks where core recovery is complete. Accurate samples are also obtainable by churn drills in fine-grained, unconsolidated material, where casing pipe can be driven ahead of the drill bit or sand pump.

Soft, broken formations which cave in the hole are most difficult to sample. In these the efficiency of the diamond drill decreases both for drilling and sampling, and churn drills are commonly used. Vugs, crevices, and brittle sulphides make sampling difficult. Cores are more satisfactory than churn-drill sludge for determining geological details, but careful panning of churn-drill cuttings generally makes it possible to locate changes in formation or mineralization within 2 or 3 ft. A method of " structure " drilling employed on western Mesabi Range (Art 10-b) yields cuttings in coarse fragments, permitting better visual inspection. In coal, cores are necessary to get accurate widths, to locate partings and to secure correct analyses.

Length of samples taken from boreholes varies from 6 in to 10 ft; usual length, 5 ft. In soft, caving ground, or where mineralization is irregular, short lengths are advisable for accurate work. In firmer ground with uniform values, the longer lengths give adequate information and save expense for sampling and assaying. Calculations incident to large-scale boring are simplified by taking samples in 5- or 10-ft lengths and recording measurements in feet and tenths.

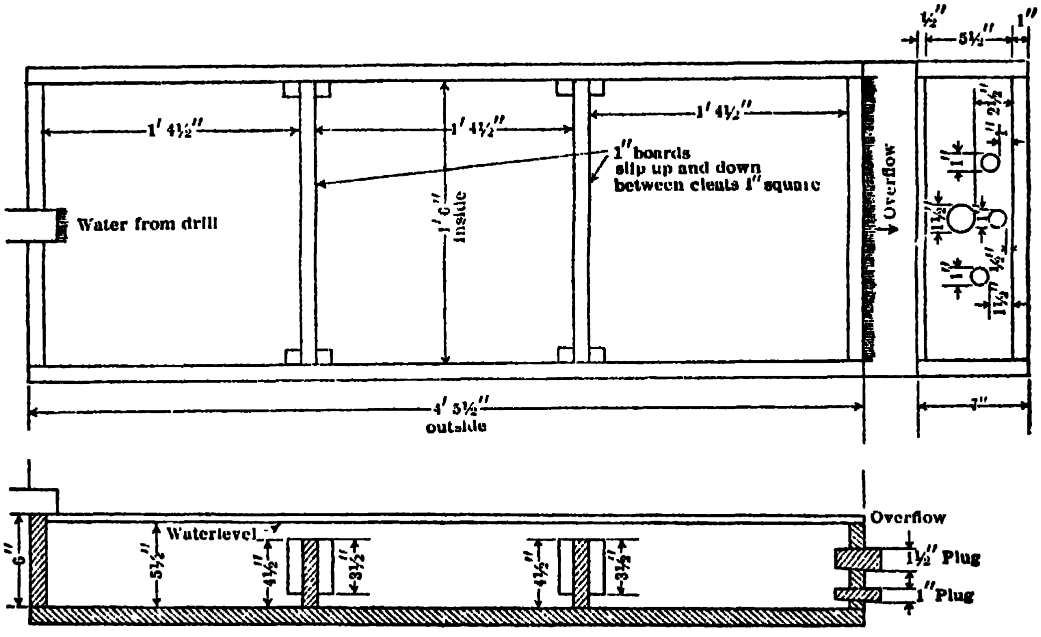

Fig 55. Wooden Sludge Box, Cleveland Cliffs Iron Co

Diamond-drill samples consist of core, or sludge, or both. Where complete cores are obtained they are assayed, or the values estimated. In soft, broken rock, where core recovery is low, the sludge must be saved and its assay combined with that of the core. Fine sludge is often difficult to catch, but all must be saved when drilling in ore which is near the merchantable limit of value.

Barrels or specially designed tanks are used for settling sludge in some districts (Art 10) and give accurate results provided enough of them are used, filled and emptied in rotation, to allow entire flow from the hole during a sample run to settle clear. SLUDGE BOXES are sometimes made on the ground. Fig 55 shows a type used many years by Cleveland Cliffs Iron Co; 2 such boxes are commonly connected in series, though frequently the second box collects but little sludge. Fig 56 shows another design (37); in this, the casing pipe projects through the bottom of the box, which allows it to be placed inside the drill shanty. Box is lined with No 26 galvanized iron. The baffles are of 0.25-in iron, hinged at top to $^3/_8$-in rods. Fig 57 shows a reinforced wooden box, with sheet-iron baffles, widely used on Mesabi Range. With all types of settling device, the sample is collected and transferred to drying pans after the clear water has been siphoned off, or drawn through plug holes. Lime or alum will accelerate settling. Care is necessary to avoid loss of fines; to prevent salting of succeeding samples, the box and drying pans must be thoroughly cleaned. Sludge containing sulphides must be dried cautiously to avoid oxidation and consequent errors in assays.

At Miami, sludge boxes were found inadequate to settle chalcocite slime, and samples were collected in heavy jute bags, which allowed the water to filter through. **Compressed air** was also used there at times, to force cuttings out of the hole and so avoid caves caused by flushing of water. Fig 58 shows method then used for catching samples. Air and cuttings were ejected through one branch of a cross placed in top of casing pipe, a small stream of water being forced into opposite branch. The sack used for collecting sludge allowed no dust or slime to pass, and indicated the air pressure in the hole (29).

Causes of errors in diamond-drill samples: (*a*) Caving ground (indicated by behavior of drill); corrected by casing or cementing. (*b*) Loss of sludge in crevices; detected by measurement of water fed to and discharged by hole (which should not differ by more than 1%); corrected by injection of sawdust or bran, by cementing, or (as at Roan Antelope) by plugging with lead wool. (*c*) Attrition by drill rods against upper wall of hole, which may either enrich or impoverish sludge sample or introduce extraneous matter; in a hole known to be free from crevices, attrition may be detected and roughly estimated by comparing wt of recovered sludge with that theoretically produced by the drill, allowing for wt of core not recovered in solid form. (*d*) Failure to retain all fine sludge in settling boxes or otherwise; in a sulphide ore, some of richest particles may tend to float. (*e*) Failure to collect all sludge at end of sample run, particularly coarser or heavier particles; corrected by inspection of overflow caught at intervals in a beaker until no trace of solids is visible; during this operation, pump should run at full speed, and direction of flow may be reversed by a temporary stuffing box around drill rod at top of casing; latter method gives higher rising veloc through rods, with smaller volume of wash water to be collected, but may not be feasible while drill is running. (*f*) Adhesion of sulphide mineral particles to greasy drill rods; in sulphide ores, oily rod-dopes should be replaced by soap if lubrication is needed.

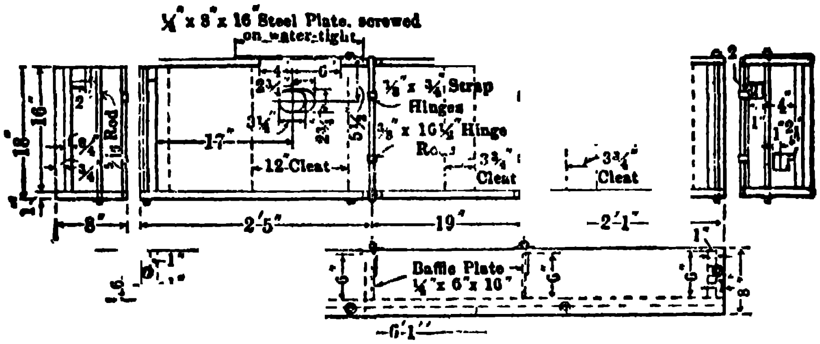

Fig 56. Sludge Box designed by G. S. Rollin (*E & M Jour*, Mch 28, 1914)

H. L. Botsford describes a case of attrition (38) as follows: A hole at a Lake Superior iron mine passed through following strata: soft slate and pyrite, 145 to 215 ft; banded ore and chert, 215 to 470 ft; soft iron ore, 470 to 545 ft; black slate, 545 to 602 ft. Cores from soft ore assayed 5 to 8% more in iron than corresponding sludge, and showed a trace of sulphur; the sludge ran 0.36% S. Cores from slate below 545 ft ran 5.1% Fe; sludge, 40 to 50% Fe. By suspending rods in the hole, and rotating them at normal speed for time necessary to drill 5 ft, nearly as much sludge was produced as when drilling ahead. This test shows that, even in ground not caving so badly as to interfere with drilling, the rods may dislodge enough material from walls of hole to salt the sludge.

G. W. Thomson (39), in drilling 4 holes in Porcupine district, Ontario, found the drag of values shown in Table 5. Orebody consisted of auriferous quartz stringers and lenses in schist, the latter carrying no values. Often the only core recovered from a 5-ft run consisted of short pieces of quartz of a combined length of not over 8 in. Values in the sludge did not correspond with the richer sections of the core, but appeared 5 to 10 ft below. Drag of values was roughly proportionate to depth at which ore was cut; little trouble was experienced from caving. Water supply was small, veloc of rising current being 6–8 in per sec. Theoretically, it takes about 75 min for a current of 8 in per sec to raise a quartz grain 0.08 in diam from a depth of 700 ft. These conditions would cause the larger and heavier particles of sludge to hang back and appear later than the corresponding core. Information as to amount of caving, contamination of sludge from walls, and loss of sludge in crevices can be obtained

by weighing or measuring sludge from a sample run, and comparing result with calculated wt or volume. This gives an index of reliability of the sample, and shows where casing is necessary; however, actual and theoretical sludge recovery may show close agreement, if losses and additions to sludge happen to compensate. Vol of sludge: cu in = 0.7854 ($LD^2 - CD_1^2$), where L = in drilled, C = core recovered, in; D = diam hole, in; D_1 = diam of core, in.

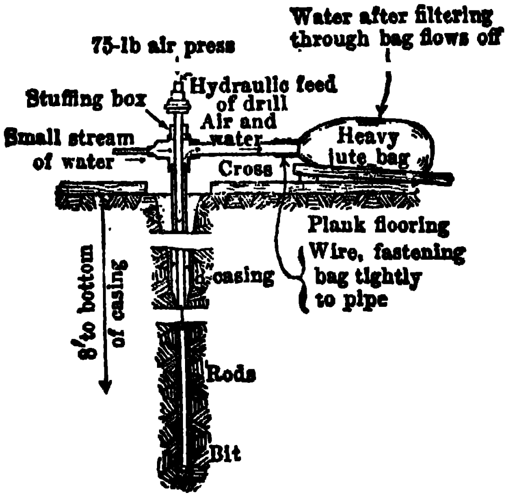

Fig 58 Catching Sludge at Miami, Ariz

Combining core and sludge analyses. Following methods are used for diamond-drill samples: (*a*) Core and sludge from a run are combined and assayed, giving correct results when the sludge is all from the sample run in question. (*b*) Core alone is assayed; correct only when complete core recovery is made, which is rare. Sometimes value of core is estimated from its appearance (Art 10-b, S E Missouri). On the Rand and elsewhere cores are split longitudinally; one half is assayed and the other filed for reference. (*c*) Sludge only is assayed; correct only when none or all of core enters sludge by being ground up in core barrel. (*d*) Core and sludge assayed separately, and an arithmetical aver is taken. This is incorrect, because volumes of core and sludge are unequal. (*e*) Core and sludge assayed separately and their values combined in proportion to their volumes. This gives correct results; also the cores may be split and one half kept for geological study. (Samples in Table 6, were taken in 5-ft lengths.)

Calculations for combining core and sludge analyses. Let D = diam hole, in, = diam of bit outside carbons + 1/32 in; D_1 = diam core, in, = diam bit inside carbons less 1/16 in; L = in drilled; C = core recovered, in; V_1 = cu in of core; V_2 = cu in of sludge; V = $V_1 + V_2$; A = aver assay of core and sludge; A_1 = assay of core; A_2 = assay of sludge. Then, A $A_1V_1 + A_2V_2$ $A_1\frac{V_1}{V} + A_2\frac{V_2}{V}$;

$$\frac{V_1}{V} \cdot \frac{C}{L} \times \frac{D_1^2}{D^2} \text{ and } \frac{V_2}{V} \quad 1 - C \times \frac{D_1^2}{D^2}; \text{ whence, } A = \frac{C}{L} \times \frac{D_1^2}{D^2}(A_1 - A_2) + A_2$$

H. L. Seward has constructed the diagram (Fig 59), from which values of $\frac{C}{L} \times \frac{D_1^2}{D^2}$ can be obtained for all cases where the sample run is 5 ft or less. When ratio between C and L is less than 0.1, effect of core assay may be neglected, and assay of sludge be taken as the aver.

Another diagram, Fig 60 from R. D. Longyear (123), indicates the weighting to be applied to coincident core and sludge assays, for varying percentage recovery of core and for 4 standard sizes of diamond drill; hole and core diams are estimated 1/32 in, respectively, larger and smaller than bit diams. For another or off-standard ratio of diams, the point corresponding to 100% core recovery can be calculated by dividing square of core diam by square of hole diam, and a straight diagonal to the 0% corner of diagram gives intermediate factors. This and similar diagrams or formulas assume that: (*a*) both hole and core have uniform and ascertainable diams throughout length of sample; (*b*) no attrition on upper wall of hole; (*c*) all sludge corresponding to the core has been recovered. Although none of these conditions may be perfectly satisfied, experience based on subsequent larger-scale sampling or actual production shows that sufficiently dependable results are attainable by careful attention to drilling and sampling technique. Where particular obstacles to accuracy are anticipated, the methods of calculation employed at Roan Antelope and described in Bib (124, 125) may become necessary, entailing determi-

A straight-edge from *C* to *L* intersects line *XY* at same point as a straight-edge from $D_1^2 \div D^2$ to $CD_1^2 \div LD^2$ Example: 21 in of core (*C*) were recovered in drilling 48 in (*L*) with a bit where $D_1^2 \div D^2 = 0.385$ With straight-edge connect 21 on scale *C* with 48 on scale *L*, mark intersection *O* on *XY* Hold straight-edge on *O* and 0.385 (scale $D_1^2 \div D^2$), and read 0 168 on scale for $CD_1^2 \div LD^2$ For solving this problem the 2 positions of the straight-edge are shown by lines passing through *O*.

Fig 59. Diagram for Combining Core and Sludge Assays

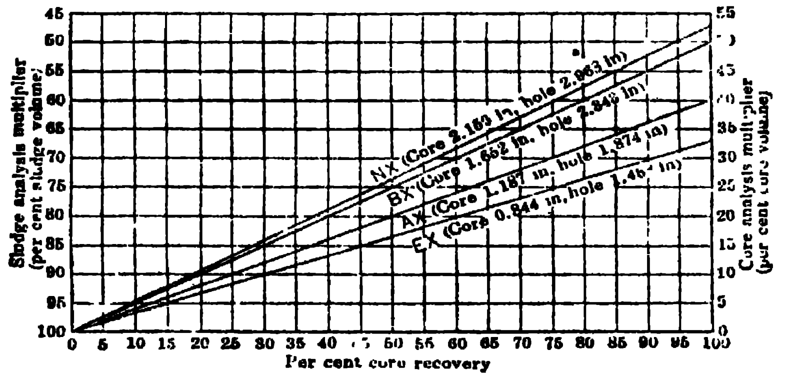

Fig 60. Weighting Factors for Calculating Average Assay of Core and Sludge

nations of sp gr of samples besides the above factors. Borehole estimates in 1930 gave an aver value of 3.44% Cu for easterly end of Roan Antelope deposit; subsequent production and systematic underground sampling in same area raised aver to 3.52%.

At Ajo, Morenci, and elsewhere in Southwest U S, assays are usually combined on basis of respective dry weights of core and sludge from a sample run, both being directly ascertainable (99, 100).

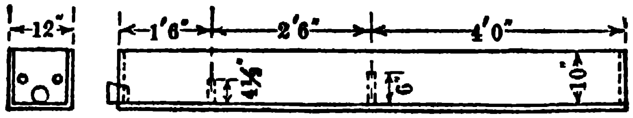

Fig 61

J. M. Weller describes (128) a method of calculation applied under difficult conditions at Round Mt, Nev; it involved length of run, length of core, dry wt of both core and sludge, and theoretical wt of core and sludge corresponding to 100% recovery of each, latter requiring determination of density.

Churn-drill samples (see also Sec 9). With hollow-rod drills, using water for flushing, samples are caught as for diamond-drill sludge. A sand pump is used with rope drills. The 6 to 10-in bits employed with these drills produce bulky samples. At Miami, in a 5-ft run, a 10-in bit cut about 450 lb of rock; 7.625-in bit, 260 lb; 6.25-in bit, 180 lb (41). Practice in handling these large amounts of material varies. Water and thin sludge are sometimes wasted, and larger and heavier cuttings saved for assay. This results in a total loss of slime and serious errors in assay, especially when drilling in brittle sulphides.

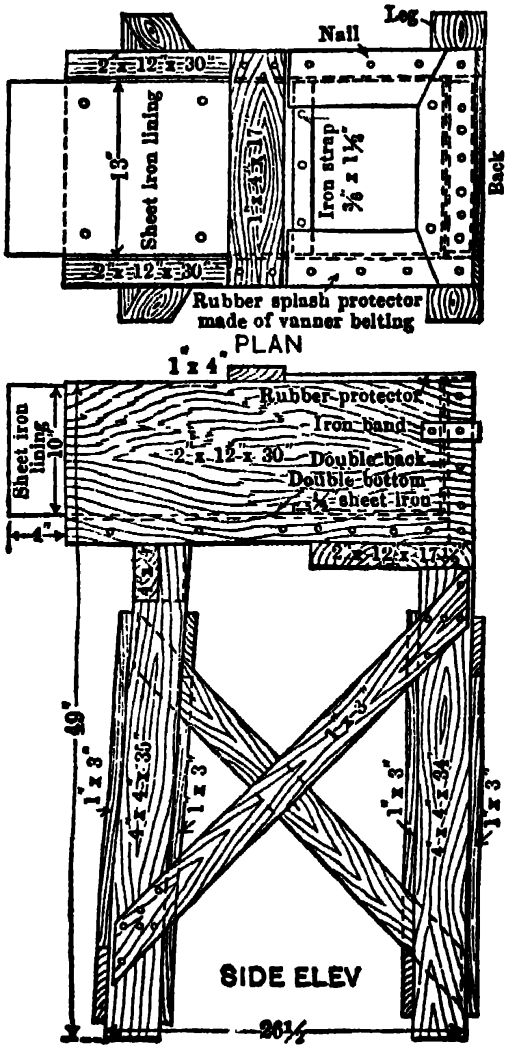

Fig 62

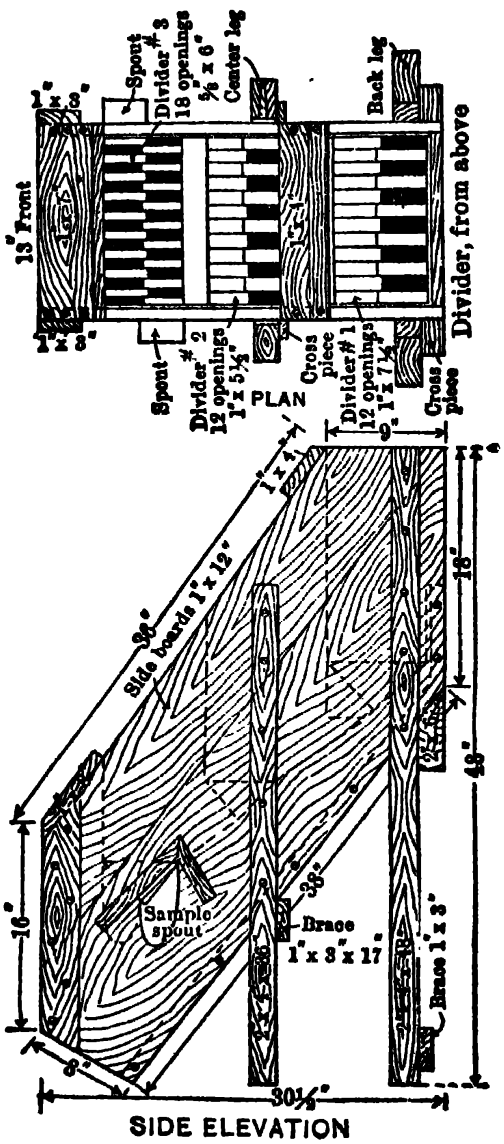

Fig 63

Sludge Splitter, Ray Consol Co

The sand pump may be discharged into a sluice box (Fig 61) built of 1-in surfaced lumber and set on low horses in front of drill. The partitions are set loosely between strips nailed to sides of box, for removal when cleaning up. Sludge is dumped into the 4-ft compt. After settling, water is drained off through plug holes in far end of box. Remaining sludge and water are swept out through large plug hole into a tub or pails, and dried for assay. Good sampling practice for churn-drill work has been developed in the porphyry copper districts, where the numerous samples taken and necessity for saving chalcocite slime make this work difficult.

At Nevada Consol mine, all sludge and water were poured directly into galvanized-iron wash tubs, and dried over a slow fire to avoid roasting the sulphides. A 5-ft sample required 4 tubs. In other districts, the sand pump is dumped into a launder containing split dividers, built like the Jones riffle sampler (Sec 30).

L. S. Cates furnishes drawings of a splitter used by Ray Consol Co. It consists of a launder (Fig 62), into which the pump is dumped and which in turn spills into the splitter (Fig 63). Fig 64, 65 are drawings of the riffles. At Ray, the last split (about 40 lb) was dried for assay. Five tubs were provided for each drill. Samples were taken in 5-ft sections. Sampler kept a record and panned sludge from upper portions of hole. When specks of mineral appeared, the 4 previous samples were dried, so that assays of ground 20 ft above first visible mineral were obtained and useless assaying and drying avoided (42). Similar devices are used in other districts, giving a final sample containing 0.25 to 0.0625 of the total cuttings in a sample run, depending on number of splitters used.

Fig 65. Riffles of Ray Consol Sludge Splitter

At the Utah Copper mine, churn-drill holes down to 1 500 ft are started as large as 26 in diam. Sampling is in charge of geological dept, one sampler per shift for each rig. Samples cover 5 ft of hole; suction bailer is preferred, and up to 12 bailings have been necessary to recover all sludge. Sludge from bailer goes into a launder, 2 ft sq cross-sec, usually 30–50 ft long and set on 6% grade, which leads to the split divider (Fig 66); this stands on the bench where the drill is working. The sludge is cut down to one-eighth of its original vol. Two samples are taken; one dried at the rig before going to mine assay office, where it is divided, and one portion sent to the mills for analysis, the other analyzed at the mine; the other sample is further cut at the rig for a 50-ft composite wet sample to be used in flotation tests. Wt of samples can be regulated by opening or closing the cutter openings. This system has proved satisfactory and is cheaper for installation than a type previously in use; it is also accurate for sampling low-grade copper ores.

Savannah Copper Co, Burro Mtn district, N M, dried samples in an assay office at a distance from drills. If sludge showed visible mineral, it was reduced in splitter to about

4 gal; if not, it was cut to 1 gal. Final samples were put into 1-gal milk cans, with tight-fitting covers, in which they could be transported in wagons without loss (43). One sampler did sampling for 2 drills, kept notes and checked drillers' measurements of depth.

At Mascot, Tenn, when churn-drilling in limestone carrying zinc blende, all bailings from each 3-ft advance are sampled and assayed; specimens of cuttings and their acid-insol residues are mounted on cards for compiling records. At Chino, N M, churn-drilling in disseminated copper ore, a similar permanent record is made by gluing specimens of cuttings to a strip of board, graduated to scale. Bottled specimens are also preserved.

In all sampling work, sluice boxes, splitters, and tubs must be scrupulously cleaned after each sample run, to avoid salting succeeding samples.

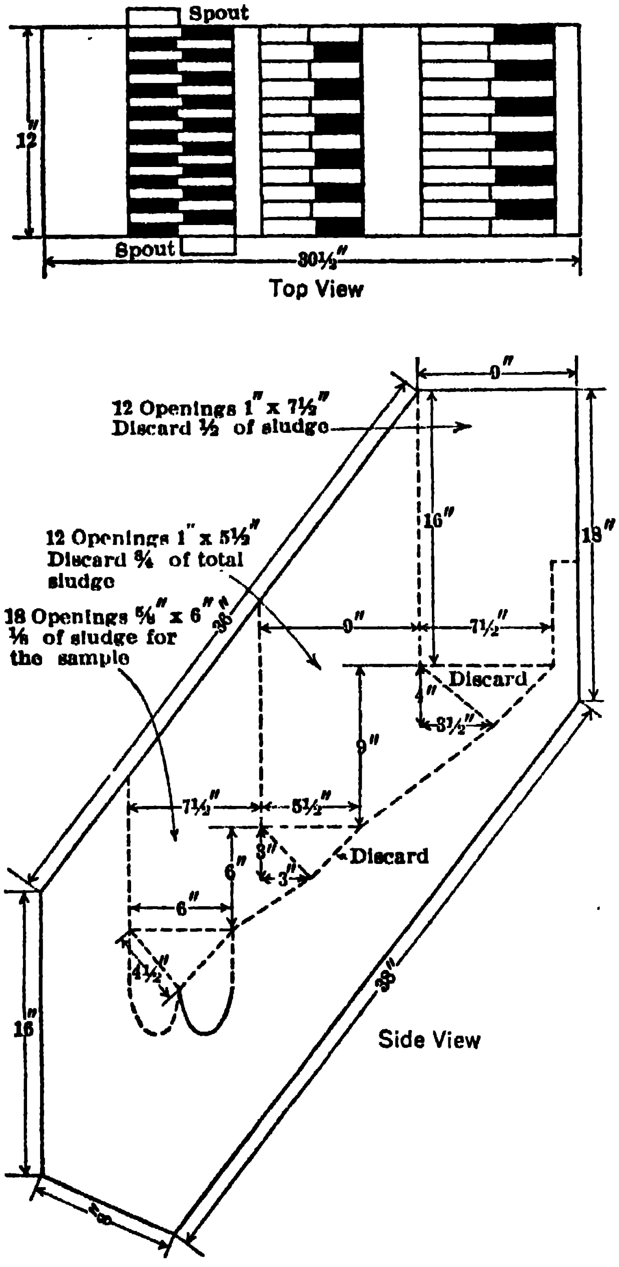

Fig 66. Splitting Device for Churn-drill Samples, Utah Copper Co

Errors in churn-drill samples, besides those due to careless handling of sludge on surface, may occur as follows: (*a*) Caving of walls of hole at some point above sample. This results in high or low assays, depending on whether cave takes place in rich or barren material. (*b*) Caving of walls of hole at point where sample is being taken. If cave is all from a rich streak, sample is false. In ore of uniform grade, effect of such caves on accuracy of sample is small. Hole should be cased before drilling ahead. (*c*) Inrushes of soft material from bottom of the hole, sometimes filling it for many feet, entirely destroy accuracy of samples. (*d*) Contamination of sludge by barren or rich material, rubbed off walls of upper part of hole by churning action of tools and rope, may cause serious error, especially in low-grade ores containing brittle sulphides or where a difference of 0.3% or 0.4% in assay decides between commercial ore and waste. (*e*) Loss of sludge in crevices or vugs. Sludge lost in this way is apt to consist of fine slime; seriousness of resulting error depends on character of mineralization. Cases are reported from Wisconsin zinc fields where entire sludge has been lost in this way and a hole in ore reported barren (44).

Above errors are often apparent through wide variations in assay of adjacent samples, and discrepancies between actual and calculated wts of sludge. Bad caving is, of course, indicated by drill itself. Remedy lies in proper use and handling of casing. In soft material, casing can be kept close to bottom of hole and sometimes be driven ahead of bit (Sec 9). In such holes a safe rule is to drive casing deeper before pumping. In harder rock, practically all sources of error would be eliminated if the drill hole were reamed after each sample run, and casing driven to bottom of hole before drilling ahead for next sample. This procedure is costly and offsets advantage of churn drill in both cheapness and speed. Also, for reaming and handling casing in deep holes, a calf wheel is required, which is not usually placed on portable churn drills. An approximation to above procedure is obtained more cheaply by starting hole with a large bit, casing as soon as sludge shows mineral, and continuing hole with a smaller bit. When caving is serious, another casing pipe is inserted inside the first and drilling is resumed with still smaller tools (Art 10-b, Porphyry coppers). In any given district, practice generally represents a compromise between cost and absolute accuracy. Pains are taken to get samples accurate enough for the purpose; beyond that, cost of reaming and casing is avoided.

Another error in churn-drill sampling occurs through failure of sludger to pick up all cuttings. Experiments have been made to determine loss from this source in placer testing. A piston (vacuum) pump in good order should be used. I. J. Stauber, while drilling in Burro Mtn district, N M, made it a rule to bail not less than 15 times after each sample run (43). Fixed rules based on experiment should prevent error from this source. Churning action of tools may produce a concentration of values in sludge in hole. At Ely, Nev, it was found that the first bailerful after drilling ahead assayed higher than succeeding ones (45). This causes no error if all bailings for any advance of hole are put into same sample. In churn-drill holes, values sometimes drag or appear in sludge obtained from points below ore horizon; caused by dislodgment of mineral from walls of uncased holes; or it may be due to incomplete recovery of sludge by pump. In latter case, serious errors may result in interpretation of both thickness and aver value of orebody.

Borehole results should be checked by shafts or raises, especially in new districts and where they are to be used as a basis for calculating tonnage and aver value (see Ajo, Art 10-b).

9. BORING RECORDS

Forms are needed for keeping drilling records and costs, and collating sampling and geological data for preparing estimates of tonnages and grades. The most suitable forms and amount of detail included depend upon the conditions of each case; following examples offer suggestions. Form in Fig 67 is a diamond-drill time record for one shift; that in Fig 68 covers 24 hr of drilling, with attention to details needed (jointly with assays) for compiling a record like that in Fig 73; the data on water recovery in Fig 68 are important as indicating degree of reliability of the sludge samples. Form in Fig 69, from Lake Superior iron district, facilitates calculation of aver grade from assays of core and sludge, combined in proportion to their wt. Form in Fig 70 applies only to churn drilling; that in Fig 71 applies to any kind of drilling. Fig 72 is a combined form for underground diamond drilling: entire form is filed at office, and each drill foreman receives duplicate of left-hand portion. Records in Fig 74, 74*a* are for exploratory hammer drilling (509).

Printed forms are preferable to notebooks, as they insure uniform data. In small-scale churn-drilling, the sampler's field notes are often recorded in an ordinary surveyor's transit book. The hole is drawn to scale on one page, and rock formation, changes in ground, depths, water-level, character of mineralization, and sample numbers are entered in proper position as they are obtained; the following page is used for explanations and other detail. These notes are transcribed into a similar loose-leaf book for office use, in which assays are also recorded. Complete detail is essential in interpreting results. Besides the above, records should include: date of starting and finishing hole; total depth; location of hole; elevation of collar; time for casing; names of drillers, samplers, and helpers (see also Sec 9).

Platting boreholes. Drawings of drill holes, showing formations and position and assay of ore, are often necessary for intelligent computation of aver values.

Fig 72. Report on Underground Diamond Drilling, Butte, Mont

Athona Mines (688) employed diamond drill at Lake Athabaska, Canada, in 1935, for systematic exploration of narrow quartz veins in sheared zones carrying erratic free gold; core recovery usually nearly complete. Vert trace of each hole was platted, at 1 in = 50 ft, on separate 11 by 16-in sheet of pure white, muslin-backed paper, using Japanese transparent water colors for tinting. Standardized system of over 200 symbols was adopted for these and related drawings. Plat included contacts, faults, intersections of dikes, interpretation of structures, and assays of core and sludge; also a legend stating: bearing, length, and dip of hole, coordinates and elev of its collar, and length of casing.

Cleveland-Cliffs Iron Co plats all boreholes on a loose-leaf form of tracing cloth, size 14 by 14 in, on a scale of 1 in = 50 ft (36). Fig 75 shows a scale plat of part of a diamond-drill hole near Scranton, Penn; col 1 is a classification of strata drilled; col 2 gives continuous measurements from the surface; col 3 shows thickness of each stratum. These drawings are generally made to scale of 1 in = 20 ft, smaller scales will not show details of coal seams (47). Fig 76 is a form used at Utah Copper mine, Bingham (119) for collating the geologic, mineralogic, and assay data secured at each hole, also indicating the lengths and positions of segments of casing not withdrawn. If boreholes are surveyed (Sec 9) deviations are shown on plats.

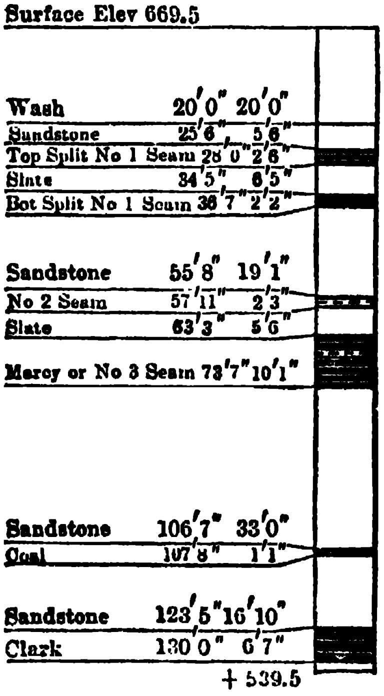

Fig 75

Core boxes for preserving diamond-drill cores are usually open trays, 5 to 6 ft long, 2 to 4 in deep, and wide enough to take 5 or 6 rows of core; longitudinal partitions divide the box into grooves $^1/_{16}$ or $^1/_8$ in wider than diam of core. Boxes have 1-in sides and bottom, with 0.5-in slats for partitions. A tray when filled should not be too heavy for one man to handle. Box shown in Fig 77, as used by E. J. Longyear Co, is made of 28-gage galv iron and holds 20 ft of EX ($^7/_8$-in) core; a sliding cover (not shown) permits box to be shipped without disarranging its contents.

Fig 76. Condensed Churn-drill Log

If much drilling is to be done, cases should be built into which core boxes slide like drawers. Fig 78 shows wooden core box for this purpose; corners are mortised, slats and bottom are nailed in place. It is advisable to mark by an arrow the direction in which core is laid in box; also depths at end of each row. Lost core may be represented by pieces of wood, on which length and character of missing material can be noted (36).

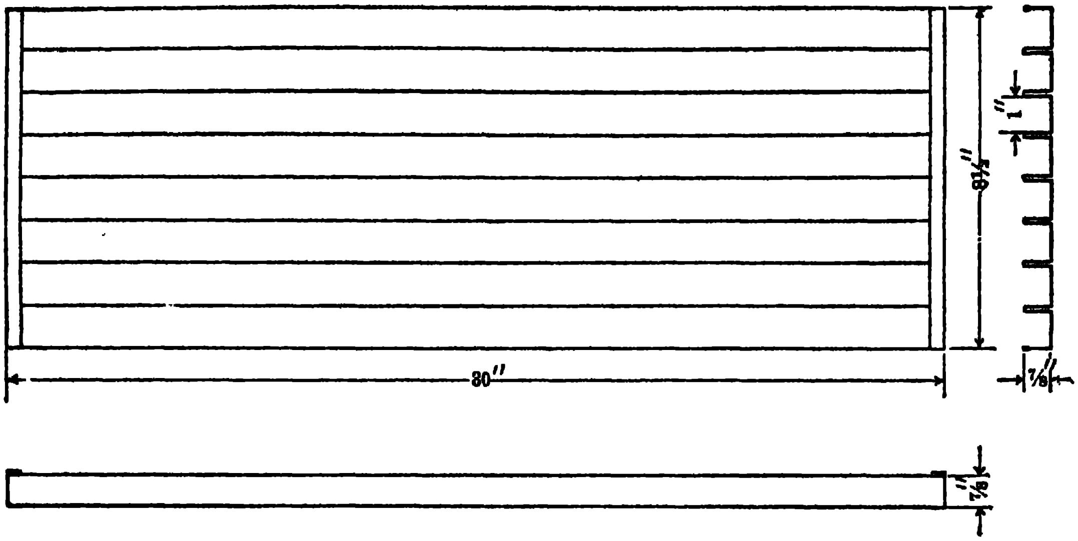

Fig 77. Galvanized-iron Core Box

For storing large amounts of core so that they will be easily accessible for observation, narrow shelves or trays may be supported at intervals of 1.5 in on the sides of A-shaped frames (48). A piece of corrugated sheet iron makes an excellent table on which to lay out core for inspection. A common form of core splitter, obtainable from diamond-drill makers, is shown in Fig 79.

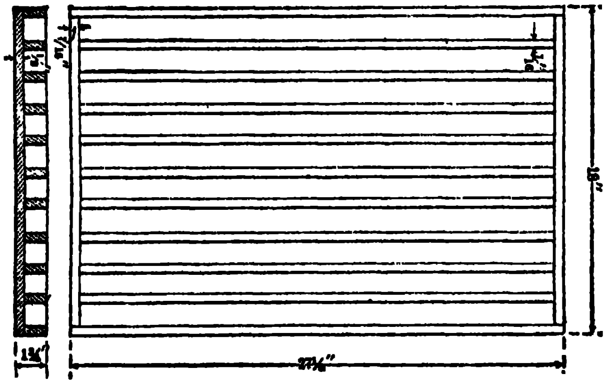

Fig 78. Wooden Core Box

10. EXAMPLES OF BORING AND SAMPLING PRACTICE

a. Shallow Work with Auger or Drivepipe

Mayarí and Moa districts, Cuba, contain residual brown iron ores, up to 80 ft thick; average 18 to 20 ft. The orebodies have enormous lateral area; in Moa, they are nearly continuous for more than 70 sq miles. There is no overburden, but surface is covered with a heavy growth of timber and underbrush. Ore is clayey and stands a long time in boreholes without caving. S. J. Cox (53) and D. E. Woodbridge (54) gave following data in 1911. Earth augers, used for exploration, were made from ordinary 2-in carpenter's augers with jointed rods (Sec 9). At Mayarí, first borings were on corners of 100-ft squares. Ore is remarkably homogeneous, and interval between holes was successively increased to 300, 500, and finally 1 000 ft. " Results were checked by borings 25 and 50 ft apart on 4 limited areas, widely separated and each representing several million tons."

Subsequent mining has confirmed the values calculated from boreholes. In the Moa district, 1 000 ft was the usual distance between holes, though some drilling was done at greater and smaller intervals. About 900 holes were drilled in an area of 8 100 hectares (1 hole per 22 acres) by the Spanish American Iron Co, 1906. Work was checked and confirmed in 1910 with a new set of borings made by an independent engineer. Two men on an auger put down 10 to 13 holes per day; aver depth, 20 ft. Drillers were paid 1.5 to 2¢ per ft of hole for the first 10 ft. A water boy and sampler were provided for each crew. Occasional test pits were made to allow close study of the ore. Where holes were sampled in sections, cuttings from a 5- or 6-ft length were saved as a sample. Where sectional samples were not taken, auger cuttings were piled on a cloth, coned and quartered down.

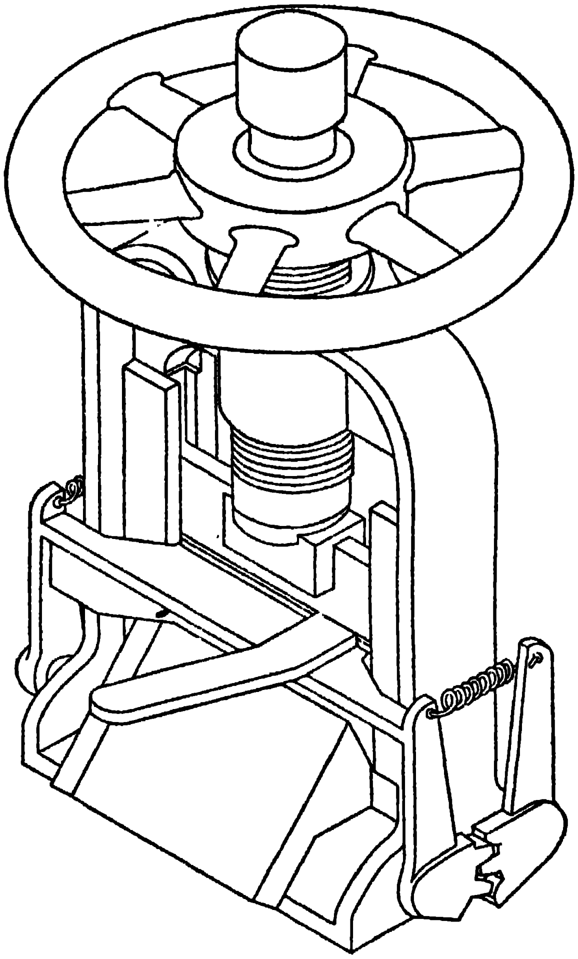

Fig 79. Core Splitter

Tennessee zinc and barite. Residual deposits of barite and calamine are overlain by clay and soil from a few feet to 100 ft deep (58).

In 1909, Newmarket Zinc Co explored a tract of about 11 acres containing a deposit of zinc carbonate and silicate in tough residual clay, 10 to 75 ft deep. Ore occurs near bed rock. Post-hole diggers (Sec 9) were used for holes at intervals of 50 to 100 ft. Dirt was washed and saved. Two men bored 20–40 ft per day. This simple method gives accurate samples in dry clay, which will stick on the digger and stand in hole without caving (59).

Yellow Aster mine, Randsburg, Cal, in 1934 sampled 2 300 000 tons impounded amalgamation-mill tailings, to ascertain suitability for cyanidation (31). Holes were at corners of 200-ft squares. Post-hole augers proved unsatisfactory. Drilling done by hand with 2-in ship augers, using $3/4$-in pipe in 5-, 20-, and 30-ft sections, for turning and lifting with aid of light tripod and tackle. Only casing used comprised short pieces at collars of holes, to support rod clamps while lifting and lowering. Total depth for 97 holes, 2 950 ft; aver, 30 ft; some, over 100 ft. Two crews, of 2 or 3 men each, took 45 days for the work. Each hole was sampled and assayed in 5-ft sections; composite sample representing each hole was required to check calculated aver to within 8¢ per ton.

Florida pebble phosphate fields. Phosphatic concretions rarely exceeding 0.5-in diam occur in sandy clay in horiz beds to 24 ft thick, overlain by 3.5–100 ft of barren sand and clay mixtures, with some thin seams of hardpan; muck and quicksand also occur. COMMERCIAL PRACTICE, described by C. A. Fulton (148) in 1935, usually calls for 16 holes on a 40-acre tract. Vert 4.5-in holes are sunk with hand augers to bottom of matrix bed, at about 5 ft per hr; cost, 30¢ per ft. All cuttings in matrix are recovered, weighed, and sampled. Complete record of each hole includes: (*a*) depth of overburden; (*b*) depth of matrix; (*c*) tonnage (long tons per acre, dry basis) of pebble coarser than 14-mesh; (*d*) corresponding tonnage of phosphate finer than 14-mesh (not considered in former years, but now recovered by flotation); (*e*) assay of each size of product for $Ca_3(PO_4)_2$, $Fe_2O_3 + Al_2O_3$, and insolubles. From above data, calculation gives cu yd of overburden and of matrix per ton of recoverable phosphate, and total tonnages, by grades, of phosphate in the tract. Work by U S Geol Surv in 1936, for purpose of CLASSIFICATION only, demanded fewer holes than commercial valuation, only 1 to 3 or 4 per 40 acres (149); these were drilled by hand with 4-in earth auger, inside a casing of extra-heavy 4.5-in steel pipe (4.25 in inside diam), with screwed joints flush outside. Bottom end of casing was notched, points of teeth being spread to excavate a section of 5-in diam. Casing was sunk by twisting under wt of 2 drillers operating auger from platform at top; bottom of casing was always (while in phosphate bed) ahead of auger. Depth of 110 ft was thus reached. All phosphatic material from a hole was collected, drained of its loose water, and weighed, still averaging 33% moisture. It was then washed in a box having a bottom of sheet steel punched with 0.5 by 1/32-in slots; all remaining on screen was called "pebble," weighed after drying, and calculated as a percentage of damp wt of original material, or "crude." Aver wt per cu ft of undried crude was also ascertained; usually about 125 lb. Pebble contents, long tons per acre, was computed from measured thickness of bed. Cost of such wide-spaced sampling estimated at $8–$10 per acre.

Tennessee brown phosphate (338). For geological occurrence, see Art 97. Earth augers and post-hole diggers are used. For preliminary examination, holes are at corners of 500-ft squares, but 50-ft spacing may be adopted for delimiting a deposit before mining begins. Phosphatic matrix can be recognized, and its value roughly estimated by visual inspection, but samples are taken systematically, washed free from clay, and analyzed. Aver matrix weighs 90 lb per cu ft in place. For prospecting a tract near Franklin, Tenn, the T V A let contracts for auger holes at base price of $1.15 each, for depths to 10 ft, plus 20¢ per ft to 20 ft, plus 35¢ per ft to 30 ft (30-ft hole thus costing $6.65), plus 50¢ per ft to greater depths. Contractors supplied all equipment except augers, and transported samples 40–50 miles to laboratory. From 1936 through 1938, cost to T V A for this prospecting, mainly by holes at corners of 200-ft squares, averaged $5 per acre.

Atolia-Rand gold-scheelite alluvial deposits, near Atolia, Cal, were systematically explored by boring in 1935. Large samples were taken and concentrated in a pilot mill on the property (32). Deposit, 15–65 ft deep, consisted almost wholly of angular gravel to 2-in diam, in which gold (partly free and partly included in quartz fragments) and scheelite were erratically distributed both vertically and laterally; present topography gave almost no indication as to bed-rock contours. Earliest holes were spaced 275 ft in rows 400 ft apart, but, as most promising areas came into view, holes were spaced 50 ft in rows 150 ft apart; holes in adjacent rows were staggered. Two " California cesspool diggers," a large pod auger, mounted on 3-ton truck and rotated by the truck motor, were employed, for latter half of the time on 2 8-hr shifts each, requiring per drill-shift: 1 driller, 1 helper, 1 laborer, 1 driver of truck conveying sample. No casing was necessary. Holes averaged 28-in diam, but dimensions corresponding to each sample were accurately measured; a level truckload (1.5-ton truck) was taken as standard sample, corresponding to about 0.5 cu yd of gravel per yd of depth. Cemented gravel, which could not be handled by the auger, was loosened with a 3 000-lb 24-in chopping bit, or a 2-in hole was drilled 2 ft deep at center of pit and fired with a light dynamite charge. Plow-steel cutting edges of auger were removable for sharpening; 2 sets usually needed per drill-shift. Performance over the whole period (1 drill 1 shift from June 14, 1 drill 2 shifts in July and Aug; 2 drills 2 shifts from Aug 28 to Nov 9) was as follows: total holes, 1 239; total depth, 16 705 ft; total samples, 2 495; total (place) vol of samples, 2 640 cu yd; payment to boring contractor, $0.986 per ft, not including surveying or testing samples. Aver performance during 2 mos, when both drills worked 2 shifts every day (61 days) was: holes per drill-shift, 1.95; depth of hole, ft, 19.4; depth per drill-shift, 37.95 ft; samples per drill-shift, 5.3; vol of sample, cu yd, 1.12; cu yd per drill-shift, 5.9; depth per sample, ft, 7.1; depth per cu yd, ft, 6.4; deepest hole, ft, 67. For details of concentrating samples, see Bib (32).

"Con-Tractor" drill, described by W. A. Van der Hoff (46), has been satisfactory in Sumatra for testing wet alluvials containing numerous 6–8-in pebbles, to depths of 28–30 ft. Drill comprises 24-in pipe or casing, turned by a clamped spur-ring actuated by worm at end of a universal-jointed shaft driven from a Fordson tractor, on which entire equipment is mounted. A toothed cutting shoe aids in displacing large pebbles. Total wt of outfit, about 6 tons; it consumes about 2 gal of kerosene per hr. Water remains in the hole. Gravel is excavated by 2 modified orange-peel buckets, one for coarse pebbles and bits of timber, and one for finer gravel; a third type is used for scraping bed-rock; all operated by winch and cable running over a pulley at top of a gin pole. Tests showed very high recovery of theoretical core.

Chip samples of buried outcrop suspected under as much as 100 ft of overburden have been obtained by a method described by J. Belknap (117). A 3-in pipe in 5-ft lengths was first sunk to bedrock by combined pile-driving and wash-boring, and seated firmly, using plaster paris for sealing, if necessary. Sampling bit (Fig 80) was a hollow cylinder *e*, 4.5 in long, 1 in outside diam, with 4 triangular teeth at bottom, diverging slightly, and surrounding a central hole *f* tapering upward, which acted as a trap to hold chips. Upper end of bit was screwed to bottom of a string of $^3/_8$-in pipe *c*, by which it was raised and lowered, and supplied with a gentle stream of water from hand pump. Impact was applied through another string of 1-in pipe *b* outside of the $^3/_8$-in, churned by hand from surface, and striking on washers *d* protecting top of bit; latter could be turned, but was not lifted off bottom until choked with sample.

Fig 80. Chip-sampling Bit

Drive pipes, without boring or pumping, were used for testing a 14-mile stretch of alluvium, averaging 200 ft wide, along Rock Creek, Atlantic City, Wyo, in 1932 (118). Gravel, under 3 ft of barren loam, was 9–12 ft (aver 10 ft) deep; it contained relatively few boulders, none over 18-in diam; of gravel later dug and washed, 65% was finer than 0.75-in. Decomposed bed rock was 2–5 ft deep and most of the gold (small and rounded) was within lower 6 in of gravel. First line of holes, spaced 150–300 ft, followed center line of channel. On other rows across channel, 0.5 mile apart, spacing was 20–60 ft, depending on surface indications. Holes averaged 14 ft deep and were driven through the decomposed bed rock. Pipe or casing, 4-in diam, with cutting shoe of slightly less inside diam to aid in holding core, was driven to refusal by 275-lb hammer operated by a winch driven by a Chevrolet engine on skids and dragged by its own power. Outfit cost \$300. Casing was pulled by tripod and tackle (4- and 5-sheave pulleys), assisted by jacks when necessary. Sample was removed (by special spoon) and panned in 6-in sections. Crew of 3 men sunk 140 holes in 2.5 mos at cost of \$2 000, or \$1.12 per ft; 4 holes were stopped by boulders, but were successfully redriven alongside. At 46 aver holes, 4 by 6-ft shafts were sunk, washing all the gravel in sluice-boxes. Aver values per cu yd (@ \$20.67 gold); 19¢ from holes; 21.8¢ from shafts; 25¢ from subsequent treatment of 740 000 cu yd along 2 miles of channel. When pipe-sampling, colors worth more than 1¢ each were not included in valuation.

b. Deep Boring in Rock

Porphyry coppers. These orebodies are large, low-grade deposits of copper minerals (usually chalcocite), disseminated in altered and shattered monzonite porphyry, granite, or schist. They have large horiz dimensions and are overlain by leached zones (capping) varying in thickness from 0 to 600 or 700 ft. Attention was first drawn to some of these deposits by favorable surface indications; others were discovered while working higher-grade deposits in their vicinity. Ores range from 0.6% to 3% Cu; lower limit is now a commercial one. BORING PRACTICE in different districts varies only in minor details. Holes are frequently bored on corners of 100 to 400-ft squares; most often, 200 ft; some work has been done with holes placed at corners of equal equilateral triangles; see Utah Copper mine, below. Drill-hole results are checked at intervals by test pits, raises or winzes, and by drifts run on coordinate lines to show variation in copper content between holes. Table 7 shows work done by some of the porphyry copper mines during early stages of their development, and the relative amounts of boring and underground work done before actual production began. An indeterminate part of the footages given for underground work at Miami, Ray, and Inspiration represents development work preparatory to mining; figures for Ajo cover exploration work alone. For details of churn-drilling practice on the porphyry coppers, see Sec 9. For churn-drill sampling practice, see Art 8.

Chile Exploration Co, Chuquicamata, Chile. P. Yeatman and E. S. Berry furnish following data on drilling from beginning of work, April, 1912, to Oct, 1914: High cost was

* Sep 1, 1910. In Jan, 1910, about 700 ft of raising had been done alongside of drill holes (62).
† Instead of barren capping, this deposit was overlain by low-grade carbonate ores, 20 to 150 ft thick.

due to extraordinary expenses and troubles incident to starting work in a remote region. At first there were numerous small difficulties in getting fuel to drills; water had to be hauled 2 miles by mule team to an elevation of 1 000 ft, while pumps and pipe lines were being installed. Delays during first 6 months' operation, due to late delivery of repair parts from U S, caused shutting down of some drills for weeks at a time, while wages of drillers and helpers continued. 11 holes were over 1 000 ft deep; many were between 600 and 1 000 ft. 8 churn drills were purchased, costing, with necessary repair parts, delivered on property, about $67 000, or $1.47 per ft of hole drilled.

New Cornelia mine, Phelps Dodge Corp, Ajo, Ariz. Diamond drills exclusively were used for initial exploration by Ajo Copper Co in 1911–1913. Greenway and Joralemon furnish following (27): When work was started, it was decided to drill 1 500 ft of hole on most favorable showings. Diamond drilling could be contracted at $4.75 per ft; no churn-drill contractors were available. The limited time required operation of 2 drills. Cost of buying 2 churn drills was $8 000; cost of churn drilling was estimated as $3 per ft. Assuming sampling costs equal for both drills, and allowing nothing for 2 churn-drill outfits at expiration of work, diamond drilling would save $5 375 on 1 500 ft of hole. These factors led to choice of diamond drills. They gave accurate samples, and the results warranted further exploration. To secure uniform sampling data, work was continued with diamond drills at contract price of $6 per ft. Extremely rough topography and consequent difficult construction of drill roads, also influenced choice of drills.

Holes were drilled on corners of 200-ft squares; company men did the sampling. A low percentage of core was recovered, because of fractured nature of rock. Drill holes were sampled in 5-ft sections. All sludge was caught in barrels (4 or 5 at each hole) and settled, water decanted, and sludge dried and quartered to 3 or 4 lb. Small samples of core and sludge from each 5-ft section were kept for reference. Sludge and core assays were combined on basis of respective dry wts of material recovered. Shafts, 4 by 6 ft, aver depth 50 ft, were sunk to check drill-hole results. Sinking was done by hand drilling, hoisting by windlass, with Mex and Indian labor, usually under contract; to 50-ft depth, a shaft could be sunk more cheaply than a diamond-drill hole. Muck was sampled as shafts were sunk; later, groove samples were cut on all 4 sides of each shaft. A little drifting was done on coordinate lines, to show variation in copper content between adjacent holes, and some raises were put up on drill holes from drifts. Two years were spent in doing the following work: 84 diamond-drill holes, 200 to 1 000 ft deep, total, 23 176.6 ft; 1 059 ft of shafts for checking drill holes in carbonate ore; 175 ft shafts for checking drill holes in sulphide ores; 2 721 ft shafts in advance of drilling; 1 513 ft drifting in sulphide ores; 142 ft raises. Calculations based on this work showed about 40 000 000 tons ore. Shaft samples in carbonate ore averaged 0.005% lower than corresponding drill-hole samples; shaft and raise samples in sulphide ore averaged 0.05% lower than drill-hole samples, and drifts in sulphide ore averaged 0.26% higher than values indicated by drill holes at corners of blocks. Table 8 gives cost of drilling, based on 17 310 ft of hole, and cost of sinking 4 000 ft of shaft; superintendence, office and engineering expense are not included. For further details of diamond drilling prior to 1932, see Bib (100).

Recent work at Ajo has not varied greatly from that in the early development. No diamond drilling has been done since Sep, 1937, to which time 270 holes totalling 141 300 ft had been drilled. Aver depth, 523 ft; deepest, 2 200 ft. Aver core recovery from 231 holes was 49.8%; max from any hole, 78.4%; min, 8.3%. In 1937, cost of 10 562 ft of drilling was: contract price, $3.42; supplies, $0.07; sampling and eng'g, $0.80; total,

Table 8. Cost of Early Work at Ajo Copper Mine, Ariz
(Now the New Cornelia Mine, Phelps Dodge Corp)

		Total	$10.1159*

* Aver depth, 50; max, 125 ft. Last few ft of shafts, 125 ft deep, cost over $30 per ft.

$4.29 per ft. Recently a few holes were drilled with one of the CHURN DRILLS regularly used for blast-hole drilling, but equipped to handle 1 200 ft of cable. These drills are electric powered, mounted on caterpillars, and self-propelled. Total wt of tools, including 500-lb bit, 2 535 lb. Bits are 9-in diam, drilling a 10-in hole. Holes are cased only at the collar, with one 24-ft length of 10-in casing. In 5 holes averaging 649 ft in depth (max, 775 ft), an aver of 21.6 ft was drilled per 8 hr, or 5.6 ft for each bit change. Excluding supervision and overhead, cost of churn drilling has averaged $1.33 per ft as follows: operating labor (*a*) $0.46; bits (*b*) $0.43; power, water, casing, $0.21; transportation (*c*) $0.04; maintenance, $0.10; sampling, $0.09. Total, $1.33. (*a*) Driller and 1 helper. (*b*) Bits sharpened mechanically; aver cost per sharpening, $2.41, incl steel loss. (*c*) Drill serviced once each shift by a truck having power hoist for handling bits, with driver and 2 helpers.

Chino mines, Santa Rita, N M. Data from H. A. Thorne (63) in 1931. Orebody is roughly elliptical, about 13 500 ft in perimeter and at least 600 ft deep at center. A core of porphyry is surrounded by sedimentaries, both greatly altered and containing disseminated sulphide and oxidized copper minerals; aver grade of open-cut orebody was estimated in 1930 at 1.27% Cu. Leached capping varies from nothing to 150 ft thick. Earliest holes were bored with steam-driven churn drills, at corners of 100-ft squares, later increased to 200 ft; subsequent holes, averaging 900 ft deep, by gasolene-powered drills, starting usually at 13 in; casing used whenever caving occurs, but always upon entering or leaving an ore zone; bits sometimes as small as 3-in. Sludge is bailed at 5-ft intervals and split on riffles into 4 samples for mine, mill, engineers, and reserve. Table 9 gives records of 2 holes, one drilled by steam and one by gasolene power; for each, total labor cost about $23 per shift.

Utah Copper mine, Bingham, Utah. For geological data, see Art 96. Prior to acquisition of the property by Utah Copper Co and its exploitation by open-cut methods, the margins and upper parts of orebody had been explored by many miles of underground work (Fig 81) (119). The Co continued exploration by boring, mainly with churn drills. A few diamond-drill holes were found unsatisfactory, due to wide discrepancies between core and sludge assays in this ground. Earlier churn-drilling to over 2 000-ft depth was done with oil-well rigs with 75- to 80-ft frame derrick. For recent work, a modified Star rig with 80-ft steel derrick is used, operated electrically. Most holes are drilled from benches in the open cut, starting in ground loosened by blasting. Because of this and the depth, holes are begun at 26 in, with stove-pipe casing to 80 or 100 ft; 23-in casing follows, with smaller sizes, even down to 4-in, as required. A max of 50 ft of uncased hole is allowed. Holes are roughly at corners of equilateral triangles, and spaced at about 400 ft, except on nearing limits of orebody, where spacing is 200 ft. For sampling, in charge of a sampler at each rig, see Art 8. Cost of earlier holes was about $20 per ft. Recent (1938) work is done on contract at 50¢ per ft, the company furnishing all equipment and casing. Aver cost of five 1 000-ft holes, $12.43 per ft, incl sampling. Early drilling rate, 4 ft per day; present rate, 12.7 ft from spudding-in to completion.

Northern Rhodesia. Data from Matson and Wallis (125). The bedded, disseminated copper sulphide ores were first explored by churn drilling, which failed to give adequate information as to geological structure and was replaced by core drilling (diamond and shot). Spacings up to 1 000 or even 2 000 ft were considered satisfactory in the early work, due to persistence of the ore strata. Close attention was given to insuring complete return of water, as this was believed to determine reliability of sludge assays better than calculations of theoretical volume of sludge recoverable; if measured flows of descending and rising water failed to agree within 1%, the hole was cased or cemented before proceeding. At end of a run, not exceeding 4 ft, drill was stopped, pump run at full speed, and washing continued (sometimes 45 min or more) until overflow carried no sediment; flow was sometimes reversed for quicker return of sludge. Entire overflow was led by 20-ft swinging launder consecutively to one of 10 or more semi-cylindrical, galvanized-iron tubs, 9 ft long by 3 ft wide, each supported in a wooden frame, and standing in a semicircular row (Fig 82). Tanks had inside rocker pipes (Fig 83) for decanting water after sludge had settled; sludge was discharged into a smaller tub by unscrewing the pipe inside, dried, weighed, crushed through 30-mesh, and quartered to two 4-lb samples. Fig 82. Catching Drill Sludge, Nor Rhodesia. (Sump used only when insufficient fall for natural drainage)

sludge, including that from the calyx, was crushed until nearly all material except iron would pass 60-mesh; coarse iron was extracted by magnet, and weighed; that in the fines was determined by analysis, and deducted by calculation. Core was weighed dry and in water, for its sp gr; also measured as to length and diam for calculating sludge recovery; finally split, and one half crushed for sample. For detailed method of calculating aver value for a hole and for orebody, see Bib (125); in discussion, the method was criticized as unduly elaborate.

Lake Superior iron ranges. Ores are masses of soft or hard hematite, in metamorphic rocks. Orebodies were formed by leaching and concentration in troughs caused by folds, faults, and intersections with dikes. Mesabi ores lie horiz and present ideal conditions for exploration by boring. Elsewhere, the iron formation dips steeply, and orebodies, where exposed, show their edges only. Region is drift-covered, but, in Marquette, Eastern Menominee, Gogebic, and parts of Vermilion ranges, there are numerous hard-rock outcrops, to which early exploration was confined.

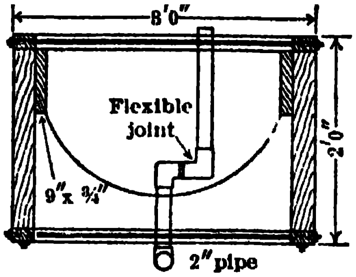

Fig 83. End Elevation of Sludge Box

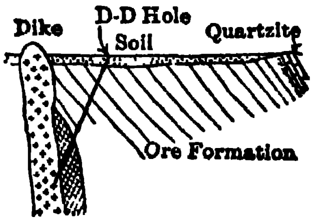

Fig 84

Surface showings have been taken up and exploration is now limited to diamond drilling for orebodies at depth. Much successful drilling has been done at random, but geological conditions are now so well known that the usual hazard of exploratory work is reduced. C. K. Leith states that with intelligent supervision 2–8% of exploratory drilling should be in ore, depending on the district (50) Maps, published by state and national geol surveys, show location of areas covered by iron formation (51). Within these areas, outcrops, petrology, stratigraphy, and geol structure are studied in detail and magnetic surveys made before drilling is begun. This information tends to eliminate worthless areas. Highly silicated and strongly magnetic areas, and those in which the rocks of the iron formation are " lean and tight," are nearly barren of commercial orebodies. Prospecting is probably most difficult on Menominee and Gogebic ranges, because of their complicated structure. Usually holes are drilled perpendicular to dip of iron formation. Following examples from P. B. MacDonald (52) are typical.

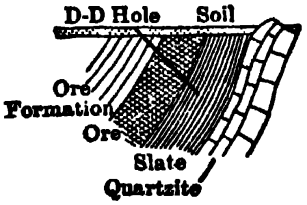

Fig 85

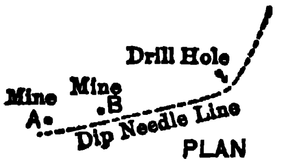

Fig 86

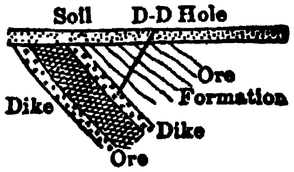

Fig. 87

Fig 84, Marquette range. Diamond-drill hole, 600 ft deep, located between 2 outcrops, a diorite dike and a low hill of Goodrich quartzite known to overlie iron formation in this district. Hanging wall of dike offered a favorable place for concentration. Fig 85, Marquette range. "Only outcrop is a ridge of Ajibik quartzite, a rock known to underlie Siamo slate usually forming the footwall of ore formation." Dip of formation was determined from the quartzite, and hole started far enough back to allow for thickness of Siamo slate. Fig 86, Amasa district. Good orebodies were known in mines at *A* and *B*. No outcrops; surface drift, 100 ft deep. Magnetic survey showed a line of max dip, which indicated a bend in formation about a mile away. Since such angles are favorable places for ore concentrations, a diamond-drill hole was put down at about same distance from max dip line as mines *A* and *B*. Fig 87, Crystal Falls district, shows a diamond-drill hole which was abandoned in a fine-grained gray dike thought to be footwall slate. Later microscopic examination revealed its true character and drilling through the dike disclosed 100 ft of ore. For details of practice and costs of diamond drilling in Lake Superior iron districts, see Sec 9. SAMPLING PRACTICE is illustrated by following rules of procedure

(1938) by the Cleveland Cliffs Iron Co, according to E. L. Derby, geologist for the Co. Set SLUDGE BOX (Fig 55) just below floor of drill shanty, in such position that there is room to siphon off water and take out sample without moving box. (Frequently 2 boxes are used in tandem, sludge water flowing from box to box, to insure an accurate sample.) Connect a tee to top of standpipe or casing, and lead a pipe from it to nearer end of sludge box, at such height that it will be level or slant towards sludge box and just rest upon its top, and of such length that it will not project more than 1 in beyond edge of box. The pipe must not exceed 2 ft long; if longer than 1 ft, it must be split on top for 1 ft nearest sludge box, so that sludge collecting in pipe may be seen. Set box level, so that water will overflow evenly across whole width at far end, and wedge partitions firmly in close contact with bottom of box. Top of partitions should be 1 in below water level. Box is now ready to receive sample. While drilling, care must be taken that no water from drill hole escapes around or over the tee, except through pipe leading to sludge box. There must be no leak from box and the plug at the end must be tight. Sludge samples are taken for every 5 ft drilled, or less, preferably from even 5-ft intervals; that is, from 460 to 465, 465 to 470, etc. Whenever a sample is to be taken, drilling must be stopped and hole washed out clean. Pipe leading to sludge box must be cleaned out into the box and pump must then be stopped or tee turned so that water will not discharge into box Carefully remove partitions in box, so as not to stir up sludge. When sludge is settled siphon off surplus water, keeping end of siphon near surface of water, and not disturbing or drawing off any fine sludge from the bottom. Siphon may be allowed to flow until sludge begins to go off with water. Take out hose and thoroughly mix sludge in box to a mud, which is then placed in a pan on a boiler to dry. Pan must be at least 8 by 12 in by 1 in deep, with flat bottom, and is thoroughly cleaned each time before a sample is put into it. If enough water cannot be drawn off, without disturbing sludge, so that sample can be contained in this pan, use a larger pan. When sludge has been cleaned out, remove plug at end of box, wash out with a pail or two of water, then replace plug and partitions, and drilling may be started again. Sludge must be labeled, giving depths between which the sample was taken, and must all be saved and turned over to inspector when drilling in iron formation, or in other ferruginous or red material. While drilling in material from which a sample should be taken, if water is lost, or if sludge does not come up with water, or if it is contaminated with material caving from upper part of hole, drilling must be stopped until hole is put in such condition that good sludge can again be obtained, or until inspector permits drilling to proceed. Whenever drill runs into or out of ore, 1 ft or more thick, drilling must be stopped, and sludge box cleaned out, without waiting to complete the 5-ft run. When drill runs out of ore, continue taking and saving sludge samples for at least 20 ft, no matter what the material, to ascertain whether ore is caving. Keep CORE separate from sludge; each time core is pulled, label it with depths between which it was recovered. Each run of core is kept separate, and all core saved and turned over to inspector. When core is pulled, if it is found that more is saved than in proportion of 1 ft of core to 10 ft of drilling, sludge box must be cleaned without waiting to complete the 5-ft run, and the sludge labeled and saved separately. If sludge from a shorter distance than 5 ft is in box at end of shift's work, and if less than above proportion of core is saved, sludge may be left in box, provided shanty is locked and box is inaccessible from outside. If anybody can get at the box, and if there is no watchman, sludge must be removed from box, dried, labeled, and placed with other samples.

Mesabi Range, Minn. Ores are massive, flat deposits of hematite, of great horiz extent as compared with their depth. Orebodies are generally less than 200 ft thick, and may extend laterally for a mile or more. They are overlain by soil and glacial drift averaging 65 ft deep. Fig 97 (Art 11) shows a typical section. There are few surface indications of ore. Early practice was to sink test pits through the drift, and as far into ore as permitted by facilities and cost for handling water, hoisting, and ventilation. Exploration was continued from bottom of these pits by boring. At present, both prospecting and exploration are done entirely by boring from surface, which is cheaper, quicker, and avoids dangers from numerous open test pits. Following data on BORING PRACTICE were contributed by J. V. Claypool, Oliver Iron Mining Co, in 1938. Churn drills, with both straight chopping bit and perforated bit and hollow rods, and diamond drills are used, with water under press for flushing cuttings to the surface. Cyclone and Keystone drills are also used in drilling from surface and in open-pit areas; samples recovered with a sludge bucket Holes are churn-drilled through surface drift to ore or hard rock and cased with heavy 3-in pipe. If iron ore is found, drilling is continued with 2-in casing through the ore to hard rock; diamond drilling then starts, whether the rock had appeared directly under the surface drift or under an orebody. Should the diamond drilling go through the taconite and into more than 5 ft of ore, the hole through the taconite is enlarged by blasting and the 2-in casing is churned down through the blasted rock and the underlying orebody to rock, keeping the casing close to bottom of hole to insure accurate samples. Diamond drilling then continues to a certain depth into taconite, depending on engineer's judgment. One hole in each 40-acre tract may be drilled into quartzite, underlying all iron formation in district.

Land is held in 40-acre tracts, and for preliminary prospecting, 5 holes are put down on each tract. Spacing of the holes varies; common arrangement is to put 1 hole in center and others 250 ft from each corner towards the center. Many companies space their holes about 500 ft apart. Fig 88*A* shows a spacing used when adjacent tracts are being drilled for same parties. If ore is not found by these 5 holes, tract is temporarily abandoned, although 5 holes are not final proof; should a more thorough examination be desired, other holes (usually 4) are drilled, the 9 holes being spaced as in Fig 88*B*. If ore is found, a topographic map is made, coordinate lines are laid out at 100-ft intervals, and detailed exploration is done by drilling holes 100, 200 or 300 ft apart, usually 200 ft. Drilling is done largely by contract; local contractors have established reputation for care and integrity. Crew of 1 drill runner and 2 helpers on each outfit (combined diamond and churn drill).

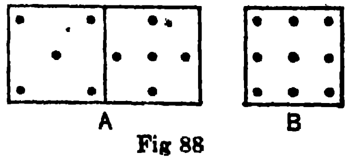

Fig 88

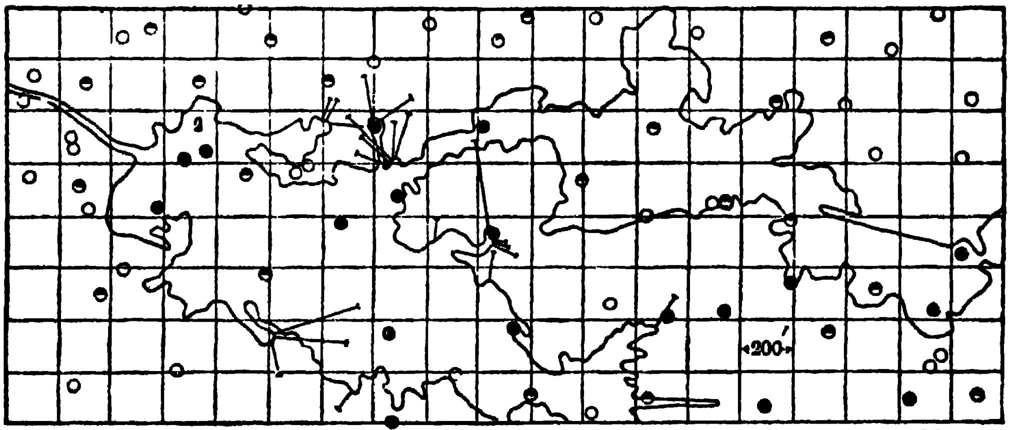
Sampling. C. E. van Barneveld gives following data in 1912 (35). Surface soil is not sampled. Cuttings from both churn and diamond drills are discharged with flushing water through a T in top of casing, and settled in barrels, tubs or a series of settling tanks. Drilling practice favors accurate sampling; churn drill, used in all soft formations, allows casing to be kept close to bottom of hole. In passing from sandy drift into ore, casing is driven into ore ahead of drill bit. Some difficult ground is drilled "dry"; pump is stopped, hole drilled 5 ft with just enough water to form a sludge, casing is driven to bottom, and sludge re-drilled if necessary, and flushed out. Drill holes are sampled in 3, 5, or 10-ft sections, usually 5-ft. Each drill is supplied with 4 to 7 barrels. A hole bored in the side of barrel, 8 in from bottom and fitted with a wooden plug, allows most of the water to be drawn off when sludge has settled; remainder stands 2 or 3 hr and is decanted. Sludge is dried, mixed, and cut into samples for analysis. Core samples are taken in hard formations; 2 to 3 ft of core is recovered per 5 ft drilled in hard ore, slate, and quartzite. Some companies do not sample diamond-drill sludge, if core recovery is more than 30%. Others combine core and sludge analyses. With care, very good samples are obtained; in a clean orebody, drill samples and subsequent mine samples check surprisingly closely. Streaky ores, having alternate layers of hard material and small streaks of soft ore, show much variation; sometimes 6 or 8 points. Very soft fine ore often stays in suspension, and the water comes up muddy.

Structure drilling. For testing the "wash" ores on the western Mesabi Range, consisting of narrow alternate layers of Fe_2O_3 and waste (largely sand) which must be separated to yield marketable ore, a method devised by J. S. Schultz (130) is widely employed. Churn drilling is done with a hollow cylindrical chopping bit, 2 3/8 in outside, 1.5 in inside diam, with 6 chisel-edged notches on its end. Bit is attached by screw joint to 2-in rods; a 3-in casing is used, down which water is pumped and rises inside the rod. This is called "structure" churn drilling; it delivers cuttings in larger fragments than is possible with standard tools, and hence is more informative as to physical character.

Magnetic iron ore, Mineville, N Y. Orebodies are large pitching lenses in gneissic rocks. Diamond drill exclusively is used to explore lenses indicated by outcrops, to determine extent of partly developed orebodies, and to explore in advance of proposed shafts. Orebodies are fairly regular and conform to gneissic structure of the rocks. Formal spacing of holes is of secondary importance; dip, strike and pitch of lens are controlling factors in locating holes. Importance of core recovery is stressed even in rock; complete recoveries are usual in the ore horizon. Cores in ore are classified by eye, into rich, lean, and very lean; each section is split and per cent Fe and P determined. To provide against possible loss of core, sludge samples are taken; experience shows that sludge assays about 5 units Fe in excess of core. All core, including split halves in ore, is stored in racks in a core house. Method of estimating tonnage from drilling is simple. For example, the horiz working face in one lens, at right angles to axis, is 1 850 ft. Three holes were drilled an aver of 738 ft in advance of working faces. Aver thickness of ore at working face and in drill holes was taken as the aver thickness of deposit and multiplied by horiz area to give cu ft of ore. Dip is disregarded purposely, to give conservative estimates. Tonnage is computed by applying weight factors (which vary with Fe content) to total cu ft. Data from E. C. Henry (518).

Southeastern Missouri. The disseminated lead ore occurs in flat masses in dolomite, at depths of 200 to 600 ft. Thickness of orebodies, up to 70 ft; they cover considerable lateral area. Overlying rocks are limestone and shale conglomerates, and dolomite, free from chert. There are no outcrops; prospecting and exploration are done by diamond-drilling from surface. Churn drills are used as auxiliaries to put holes down to bed rock through deep surface soil. Geologic features indicate probable orebearing areas in a broad way. H. A. Guess, V-pres Am Sm & Ref Co, furnished following data in 1915

(Fig 89) (see also Bib 55). "In extending the limits of known orebodies, the only way to do is to feel along with the diamond drill until the full limits of orebody are defined. For this work, holes are close-spaced, usually 200 ft, sometimes 100 ft. For general prospecting for new orebodies, holes are spaced 400 or 600 ft or even farther, either in checkerboard fashion or in lines transverse with supposed strike of ore run. When ore is cut, detailed drilling is begun with spacing of 200 ft or less." Procedure varies with different companies. A solid bit is used until near expected ore horizon; then a core bit with a 5 or 10-ft core barrel, until the hole bottoms in sandstone known to underlie the orebodies. About 25% of total footage is cored. Lead content of cores is estimated from their appearance; one estimator is employed for 10 or 12 drills. Cores are assayed occasionally as a check. Throughout the mineral zone, all sludge is caught and assayed, to check estimations and core assays. Sludge serves as a further record when a considerable part of a soft lead layer is ground up in trying to core it. Combined solid and core-bit drilling has been done by Federal Lead Co. Aver speed of drilling per 10-hr shift: for solid bit, 60 ft; for core bit, 30 ft. Fig 89 shows outline of workings on one orebody, and location of holes for preliminary and final exploration. Short horiz holes are also drilled from different headings, to supplement indications given by holes from surface. Drilling results are used for laying out work and estimating tonnage and value (Art 11). C. F. Jackson (155) states that minimum limits of orebodies considered workable are 7 ft thick, with 15 ft-% lead. Where thickness exceeds 7 ft, if entire section averages less than 2% lead, the workable thickness and its grade are calculated by trial.



●=Pay hole; ◉=Indicative hole; ○=Blank, unfinished or abandoned hole

Fig 89. Boring near Flat River, Mo (H. A. Guess)

Tri-State District. Irregular orebodies of sphalerite and galena in breccia of chert and limestone lie at depths of 75 to 300 ft. Ore occurs in large or small pockets, long narrow stringers, or in horiz sheets 10 to 20 ft thick, of considerable area. Portable churn drills exclusively are used for prospecting; preferred to diamond drills because of fissured ground and brecciated chert. Drilling is mostly contracted; usual prices, 90¢ to $1.25 per ft. In many parts of district, upper extensions of orebodies often occur directly under and 40–50 ft below basins in upper surface of chert formation, which is overlain normally by 30–40 ft of shale, offering no topographical indications. In such areas, "shale" holes are first drilled, at 40–60¢ per ft, until shale of abnormal depth, 90–100 ft, is discovered; deeper drilling is then confined to that portion of the area (156).

J. R. Reigart (161) supplies the data in Table 10 on 8 properties in Tri-State district, covering exploratory drilling before active development. Records of several companies in Cherokee Co, Kan, during 12 yr prior to 1932, show that $4 473 300 was spent in drilling 16 281 holes ($274.75 per hole) of which 9 591 holes were on properties which later became producers. C. W. Nicolson (191) in 1938 states that practice favors Keystone No 5 drill, mounted on truck which supplies power; it has a 6.25-in bit and $^7/_8$-in steel rope instead of the 2 $^1/_8$-in

Table 10. Exploratory Churn Drilling, Tri-State District

Acres	Holes drilled	Holes in ore	Aver depth, ft	Total cost	Cost per ft
80	129	35	250	$35 000	$1.08
104	129	52	279	53 980	1.50
320	162	49	326	66 015	1.25
105	120	43	305	37 482	1.02
160	219	84	330	79 497	1.10
60	90	.....	300	27 256	1.01
80	138	55	235	40 834	1.26
40	78	47	300	26 450	1.13

manila cable formerly used. Steel rope requires springs under sheaves. Drilling speed, 4 ft per hr, cost about $1 per ft. Cuttings bailed every 5 ft in overlying rocks, and every 2.5 ft in ore horizons. Holes are usually at 200-400-ft intervals until ore is found; thereafter at 50-ft or more. W. F. Netzeband (192) states that bore-hole samples are usually high in zinc and low in lead, as compared with ultimate mill recovery.

Southwestern Wisconsin. Following information was contributed in 1938 by J. G. Trewartha, Gen Supt, Vinegar Hill Zinc Co. Very irregular bodies of blende and galena occur at depths of 20–270 ft in limestones and dolomites. They are usually found over basins of broken, oily shale, which apparently permitted a slumping of the limestone, resulting in " pitches," " flats," crevices, and vugs. Ore-bearing solutions have followed these openings, depositing the minerals therein. Churn drills are used to locate and outline the orebodies. CHURN-DRILL PROSPECTING is done in areas where galena was formerly mined to shallow depths, on lands adjacent to and along the trend of known orebodies. The possibility of an orebody is also sometimes suggested by discovery of traces of ore by farmers drilling wells, or by finding crevices on the surface. If ore is struck in churn-drilling, several holes are drilled around the discovery hole and 20–25 ft from it, to determine trend of orebody. Holes are then drilled along this trend with larger spacing; usually started at $6^1/_2$-in diam; if a hole drills well it may be finished at this diam. In bad ground, casing is set and the hole finished with smaller tools. If casing is used, and the company decides it may later need the hole for mine ventilation, the casing is left in the hole. Blank holes are usually plugged; driller pulls casing, sets a large boulder about 6 ft below collar of hole, which is filled to the surface. Drilling is usually by contract; prices 60¢ to $1 per ft. CUTTINGS are removed from hole at 5-ft intervals, until ore horizon is reached. Thereafter hole is carefully cleaned out every 2 ft. Cuttings are caught in a tub, and an analysis is made for each 2-ft run, if sample carries enough mineral to warrant it. In doubtful cases, the engineer pans a small part of the sample for examination under a microscope; an experienced engineer can thus estimate closely the value in the cuttings. A record is kept of each hole, including: depth where water was first struck, depth at which water stands after hole is completed; and occurrence of open ground. Experience has shown that ore estimates based on drilling records are satisfactory.

Witwatersrand. Data from R. S. G. Stokes (195). In 2 yr ending 1935, about 200 000 ft of prospect boring (chiefly by diamond drill) was done, of which about half was to prove western extensions of the Rand. Steam rigs were most common, but oil or gasolene engines were cheaper to operate, more portable, and required less water. Derricks for deep holes, 60–67 ft high. Direct or reduction-gear drives and hydraulic feed were usual. In uniform ground, So African bortz could replace imported carbons. Final core size was usually $1^3/_8$ in; occasionally $^7/_8$ in. Chief difficulties in West Rand were: chert boulders in subsoil, alternating strata of chert and dolomite, and fissures in the latter. Aver advances of 500–600 ft per month were frequent in good ground, with continuous drilling; in 1 case, 982 ft per mo at 2 000 ft depth. Aver cost for deep holes in good ground, 30–40s per ft, including administration and deprec; in bad dolomite, cost might be doubled. Under favorable conditions of Far East Rand, 5 holes totaling 10 382 ft cost £16 000 ($7.50 per ft). Most drilling was on straight contract; when especial trouble was foreseen, on basis of rental, and cost plus 10%.

N E Washington. Walter Sack, in 1938, gives estimated and actual costs for diamond-drilling of closely-spaced holes to 800-ft max, totaling 50 000 ft, for exploring a large, much faulted lead-zinc deposit (206). Lowest contract bid, $3 per ft, plus drilling expenses for Co account, brought estimated cost to $3.85, besides cost of clearing heavily timbered sites and providing drill water. On rental basis for 2 rigs, each averaging 875 ft per mo of 75 shifts, estimated cost per ft was: rental, $0.39; upkeep, $0.06; diamonds, $0.50; operation, $1.10; total, $2.05. Company then purchased 2 complete rigs for $12 000, charging entire price against 50 000 ft of hole, or $0.24 per ft; other items, same as above, gave total cost of $1.90.

c. Diamond Drilling Underground

Josie mine, B. C. Roughly parallel veins of pyrrhotite, carrying chalcopyrite accompanied by Au and some Ag, occur in hard augite porphyrite and diorite. Veins dip 50–80°; oreshoots are related to contacts and intersections of veins with a complex system of steep-dipping dikes. Some dikes are parallel to, others cut veins with or without faulting. When a drift on a vein cuts a dike and ore is not found beyond, a diamond drill may be used to seek faulted segment of vein; or, if there is no fault, to seek ore in a parallel vein. On finding such ore, drifting is transferred to the parallel vein and, later, holes are drilled back to explore extension of first vein. This plan minimizes length of nonproductive drifts and speeds exploration work. Approx limits of shoots are found by " fanning " holes vert and horiz from one set-up, but about 96% of holes are flat. Country rock gives good cores; dikes are broken and boring in them is avoided where possible.

All drills had double-tube (" Stone ") core barrels. Sullivan " E " drill was used for flat holes; outside diam bit, 1 $^7/_{16}$ in; core, $^7/_8$ in. This drill has a rated capac of 450 ft, but was used for holes 600–1 000 ft deep. Down holes were drilled of the same diam with Sullivan " S " drills. Chip bits often used, especially in short holes, but were unsuitable in broken ground. Normally, 2 ft of drilling per ft of development (510).

El Potosí mine, Santa Eulalia, Mex. Data from H. A. Walker (503) in 1922 and 1934. Silver-lead ores occur as irregular replacements in limestone; frequently in form of chimneys 60–300 ft diam, related to a system of vert fissures; also in horiz "mantos" (see Art 37). Diamond drill is used extensively to explore new ground, secure geol data, and determine limits of orebodies; also occasionally to bore holes for drainage or elec conduits. Work done by especial foreman and crew. LOCATION OF HOLES. If stopes or other convenient openings are not available for setting up drill, special drill bases are excavated about 15 ft wide by 25 ft long by 9 ft high, so located as to avoid known bad drilling ground or interference with mining and tramming, to allow thorough exploration, and to cover max possible area from one set-up. Usually a series of horiz holes, 15° apart in azimuth, and a corresponding series of holes pointing downward 15°, are drilled from each set-up. The general direction of the "fan" of holes so drilled in new ground is usually at right angles to the strike of a known fissure system, but the fan frequently extends through 180°. As close drilling is required to avoid missing orebodies, sets of holes are drilled into the same areas from different levels. Holes from different set-ups are then staggered to reduce unexplored distance between adjacent holes to 100 ft max; this requires careful pointing of holes in each set. A transit is used to point the first hole; the others are pointed by means of wooden templates held against rods projecting from the first hole. A spirit level on the feed screw is used to start horiz holes, the rods being carefully centered in the chuck. Location and elevation of the collar of each hole are determined by survey; its direction is computed from the location of two points, as far apart as possible, on the drill rods projecting from the hole. Dips are measured with a Brunton compass. The holes themselves need not be surveyed, as they are comparatively shallow and show only slight deflection from their course. When completed, each hole is plugged and marked with a numbered copper tag for future identification. If ore is found, further drilling to determine size of the orebody, etc, is guided by local conditions. For example: the horiz and dipping holes in one set found an orebody and determined its horiz section. A 30° down hole drilled from same set-up was barren; a 20° down hole was then drilled and located the bottom of the deposit. Development openings were next driven to, and in the ore, and raises put up to determine its upper limits. Ventilation became difficult in the raises, and top of the deposit was located by drilling from a higher level. As these orebodies are mined by underhand stoping, the top of the ore must be found before stopes can be planned. EQUIPMENT in 1934 included following types of drill: (*a*) EX, air-driven, 2-man, for 700-ft max, 500-ft aver, holes; 10-ft rods, single or double core barrels, $^7/_8$-in core, bit set with black diamonds, $^3/_4$-2 carats per stone; costs in col I, Table 11. Same machines with 5-ft rods may be run by 1 man to max 350 ft, sometimes substituting borts or small natural carbons; costs in col II, Table 11. (*b*) EX, electric-driven by 7.5-hp, 440-volt, a-c motor, with gear transmission and clutch for speed control; pump is direct-connected to 5-hp motor; costs in col III, Table 11. (*c*) Same type of 2-man drill, but driven by 5-hp, adjustable-speed, induction motor; pump has 3-hp motor. This and preceding type both use 10-ft rods, and bits set with borts, scrap, or small carbons. (*d*) Air-driven, hydraulic-feed C drill with A rods. 3-man crew, for geol work to 2 500 ft max depth. (*e*) Light-weight, air-driven, 1-man, for 200 ft max, 150-ft aver, depth; 5-ft rods, double-tube core barrels, giving 0.75-in core; bits set with small carbons; costs in col IV, Table 11. (*f*) Prospector EX, for max 250 ft, 1-man, elec, with 3-hp motor and multi-speed drive; pump, duplex, double-acting, with 1.5-hp motor. This drill is expected to displace (*e*) type. For all of 2-man types, except (*d*), max effic drilling depth is 400–450 ft. The 1-man drills with 5-ft rods require less excavation for sites. Type (*c*) is more effic than (*b*); and both (*b*) and (*c*) are more economical of power than air-driven drill (*a*). At this mine, drilling largely in fissured limestone, small natural carbons have proved cheaper than borts or scrap, except as the latter may be salvaged from work requiring large stones.

Aver carbonate ore is soft and gives little core; rods are pulled every 2 or 3 ft and the sludge used for assay. Core recovery in sulphide ore reaches 95% and rods are pulled every 5 or 10 ft. Manganese stains and broken ground in limestone often indicate proximity of ore and aid the driller. Drilling speed in usual limestone is 50–100 ft per 8-hr shift. Diamond loss in 1922 was 5.91 carats in drilling 12 480 ft in limestone and 170 ft in hard galena ore; loss greatest in hard sulphide ores.

United Verde mine, Jerome, Ariz, employed underground diamond drilling extensively (25 000–30 000 ft per year, 33 376 ft in 1930) for preliminary exploration of its irregular, lenticular, steeply dipping, sulphide replacement orebodies lying within a zone averaging 300 ft wide (97, 227); see also Fig 48, Art 7. Cores were $^{7}/_{8}$–2 in diam, the latter in special cases for taking a large sample. Some holes, to 3 in, have been bored for drainage, conduits, ventilation, or running slime into fire areas. Of all holes to 1933, 64% were between 200 and 600 ft (7% over 1 000 ft), and 79% inclined between +12° and −5°. Core recovery in all rock averaged 91.3%, from 79.2% in greenstone to 95.3% in massive sulphide. Cementing was almost invariably used in dealing with caving, broken, or sandy ground. Core pulled every 5 ft, except when a sharp contact was encountered at a shorter interval; all core was crushed for sample, retaining a few pieces for record. Sludge was collected and sampled only while boring in mineral, and its assay combined with that of core on theoretical vol basis depending on core recovery and size of bit.

Following data on PRESENT PRACTICE were contributed in 1939 by C. E. Mills, Chief Engr. Most diamond drilling is now short-hole work, 100–500 ft, to delimit known ore areas, prospect stope walls, determine structure or general geol formation, and to aid locating development headings. Occasional long holes, 1 000–2 200 ft, are drilled to prospect outlying areas. The ground drilled varies from comparatively soft chlorite schist and metamorphosed quartz porphyry to relatively hard rhyolite porphyry, diorite, and hard, massive pyrite carrying quartz and jasper. Most footage is within massive sulphide areas. Representative sections of core from long holes or holes of especial interest are kept for record; otherwise, entire core is sent to the assay office. Part of the pulps is saved for composites and future analysis. EQUIPMENT. A Boyle B B U drill with M-size bits is used for short-hole work; Longyear U G drill is used in harder ground for 200–1 000-ft holes, and Sullivan C hydraulic drill for deep holes. The E bit, giving a $1^{9}/_{16}$-in hole is used where depth requires surveying, and an AX bit ($1^{27}/_{32}$-in) for long holes that may need grouting or casing. A Wright bore-hole surveying instrument is used for depths over 500 ft, to observe deviation. BITS. Bortz is used almost exclusively in all ground; carbon occasionally, for gage stones in broken quartz or siliceous sulphide. Bortz loss is 0.02–0.1 carat per ft, depending on kind of ground. Cutting edges of bits are rounded and set with bortz averaging 20 stones per carat. M bit, a special size for short-hole drilling, has 100 stones and requires about 6 hr for setting; its outside diam is EX or $1^{7}/_{16}$ in, and inside diam of $^{15}/_{16}$ in gives the largest core possible with this size of bit. The $1\,^{17}/_{32}$-in E bit averages about 120 stones and requires 7 hr for setting; the $1\,^{27}/_{32}$-in AX requires approx 150 stones and 9 hr for setting. Recovery of stones from used bits averages 50%. All-metal CORE BOXES, with corrugated removable trays, are used to handle core from working place to diamond-drill shop. SPEED AND COST OF DRILLING. In short-hole drilling (aver 250 ft), footage per shift is from 40 ft in aver schist or porphyry to 25 ft in hard sulphide. For long holes, set-ups are provided to permit 20-ft changes of rods, and footage per shift is from 30 ft for short holes to 10 ft for 1 500-ft holes. Direct cost per ft during 1937 and 1938 is shown in Table 12. Carbon loss averaged 0.031 carat per ft of hole in 1937, 0.030 carat in 1938; max loss in one month was 0.098 carat per ft. In 1938, footage per drill-shift averaged 25.3 ft; footage per bit, 60.3 ft; loss of carbon per

bit, 1.81 carats. Besides the footage drilled on Co acct, 2 059 ft were drilled by 1 crew on outside contract.

Edwards zinc mine, N Y. Underground diamond drilling has been found well adapted to discovery and exploration; orebodies are lenticular, roughly parallel, sulphide replacements in limestone, dipping about 40° (253). Drill stations are cut by company, but drilling is on contract, power and water supplied. Small, air-driven drills take 7/8-in core. Lateral holes are pointed within 5° above or below horiz; down holes usually at about 45°, to cut ore at right angles. Core recovery is high; no sludge saved, core assayed only when expert visual inspection is in doubt. During 1930, 10 holes totaling 3 386 ft cost $2.05 per ft.

Cold Springs ferberite mine, Nederland, Colo. Narrow, steeply dipping oreshoots in granite Conventional boring methods are used for exploration, but instead of a diamond bit, "firthite" (tungsten carbide in cobalt matrix) is brazed, with Tobin bronze and oxy-acetylene flame, directly on lower edge of core barrel. This increases diam of core obtainable with drill employed from 15/16 (with diamond bit) to 1 5/16 in; loss of bit in fissured rock at this mine is also avoided. Complete firthite crown costs about $75, and the cutting material can be used repeatedly, with care to avoid excessive brazing temp. Max depth drilled in this hard rock during 1931 was 18 ft for 1 setting of firthite. Total drilled in 1931, 1 932 ft; aver depth, 75 ft; aver cost, $2.16 per ft; aver core recovery, 80% (290).

Table 12. Cost of Underground Diamond Drilling at the United Verde Mine

	1937	1938
Labor (*a*)	$0.82	$0.76
Carbon	0.31	0.16
Operating supplies	0.02	0.10
Comp air and water	0.02	....
Miscellaneous	0.02	...
Total	$1.19	$1.02
Number of holes	58	34
Total footage	6 922	4 585
Aver length of hole, ft	119	134
Max depth of hole	507	526
Percentage of holes in:		
Hard siliceous sulphide	6.3	....
Aver sulphide	31.9	....
Schist	27.5	....
Porphyry & diorite	34.3	..

(*a*) Aver wages: drill runner, $6.88 in 1937, $6.40 in 1938; helper, $5.60 in 1937, $5.16 in 1938.

Hollinger mine, Ont, has used underground diamond drilling extensively (309.2 miles of hole to end of 1934) for exploring intricate and frequently discontinuous quartz veins, dipping about 75°, in a wide shear zone in or adjacent to porphyry. In 1935, equipment included 8 drills using E S rods (7/8-in core) and 6 E P rods (5/8-in core), all operated by air. Most core barrels are double-tube; bits set mainly with bortz, usually 9 or 10 per carat, 45–60 stones per bit. Drilling (2-man crew) is on morning shift only. E S drills average 45.8 ft per shift. All drilling is contracted at rate per ft which, with E S machines, is based mainly on percentage of core recovery, 87¢ for 90%, 72¢ for 55% or less; for E P holes, price is 75¢ flat. Recovery is lower in porphyry than in other rocks. Contractor pays wages plus a bonus for footage, per 8 hr, above 32 ft with E S, or 35 ft with E P machines. Most holes are horiz or slightly inclined, aiming to cut vein system normal to strike. Owing to numerous parallel drifts, where drills can be set up, it is seldom necessary to bore a hole more than 200 ft to gain all information expected at that point (306).

Other examples of cost. Walter Sack, in 1938, gives estimated costs for underground diamond drilling at 2 places (206). (*A*) To prove tonnage and value of known, large, low-grade body of gold ore in WESTERN MONT, already considerably developed. Total necessary footage not predictable, but estimates were based on four 500-ft holes. Lowest contract bid ($2.60) plus freight both ways, compressed-air power (from rented compressor), and installing air and water lines, all for Co account, raised estimate to $3.96. Drill rental for 3 mo ($675), and operating by Co, was estimated to cost per ft (on 2 000 ft): rental and upkeep, $0.36; freight, $0.13; compressor (rent, hauling, and piping), $0.16; fuel and maintenance, $1.03; drilling labor, $1.21; diamonds, $0.30; total, $3.19. Actually, 9 000 ft were drilled in 9 mo, at $2.43 per ft; machine-set bits used. (*B*) To cut and sample a vein at 250 and 500 ft below present sump of a silver-lead mine in COEUR D'ALENE DISTRICT, Idaho. Length of 2 short and 2 longer holes totalled 1 700 ft; diamond drilling not regularly required at this mine; drilling possible on only 1 shift. Rental for 5 mos ($1 250), $0.74 per ft; frt and upkeep, $0.13; labor (125 shifts), $0.89; comp air (from mine), $0.02; diamonds, $0.50; estimated total, $2.28. This job was contracted at $2.25 per ft, including everything but comp air.

d. Exploratory Hammer Drilling

Exploration and sampling by SHORT HOLES, drilled with ordinary steel and equipment, as drifters, stopers, or mounted jackhammers, and to max depth of 22 ft, has long been routine practice at many mines for following purposes: (*a*) Sampling at face of heading or stope; in a massive and fairly uniform ore (as at Miami), drill cuttings may be as accurate as a channel sample, but in a vein with banded structure a drilled sample is likely to be salted with softer (and often richer) vein material, to about same degree as a channel sample; sample holes in such a deposit are obviously unreliable unless drilled to cut the laminations at 45° or over. (*b*) Exploring from walls of a drift to be advanced in some fixed relative position with respect to walls of orebody; also to ascertain width of latter. (*c*) Exploring for nearly parallel or branching veins, or offsets behind waste inclusions. (*d*) Check sampling of a block of ore exposed when square-setting; also, in other stoping methods, to determine grade and location of ore to be broken. Shallow holes for above purpose are usually drilled horiz or slightly upward, and without water. If dependable assay is required, cuttings may be caught in a sack held closely around drill hole, the steel passing through a hole near bottom of sack; if visual inspection suffices, cuttings can be caught in pan or powder box.

Hammer drilling of DEEPER HOLES, often to 150 ft, occasionally to 250 ft (one of 272 ft is on record), is a fairly recent practice made possible by design of a satisfactory coupling for sectionalized drill steel and mechanism for the positive rotation of a long and heavy rod. Within this range of depth and in rock not too hard, hammer drilling compares favorably with diamond drilling as to speed and cost, especially in ground tending to cause loss of diamonds or bits. Chief drawbacks of deep hammer drilling for exploration (its principal use) are: (*a*) results depend wholly upon return of sludge, loss of which, in fissured ground, is less easily prevented than in diamond drilling; (*b*) where rock carries narrow stringers of soft ore minerals outside of the main orebody sought, contamination of cuttings by abrasion from wall of hole is more serious than in diamond drilling; in such circumstances, data from a hammer-drill hole may have negative value only. Principal factor limiting depth of a hammer-drill hole is hardness of rock, causing rapid loss of gage; corrected by reaming with sharp bit of same gage before changing to next smaller size, or by applying Stellite to wings of bit. Any positively rotated standard drill can be used, but extra-heavy drifter machines, specially designed for deep drilling, are available; preferred mounting is on a cross-arm supported by 2 columns for extra rigidity. Commonest inclinations lie between 5° and 30° above horiz, insuring rapid return of sludge (assuming ample water supply) without throwing excessive wt on drill; with up-holes of 45° or more, a counterweight must usually be arranged to carry wt of drill steel, commonly 1.25-in hollow round. Down-holes can be drilled, but with more difficulty in recovering sludge; a water swivel to admit compressed air at short, regular intervals aids in lifting sludge. Collection of sludge, when required for assay, is somewhat inconvenient; a good method for up-holes involves drilling a short hole, collaring just below and pointing upward to intersect the deep hole about 1 ft inside of its collar; a short piece of pipe is then wedged into the lower hole, delivering sludge to tubs or settlers (468).

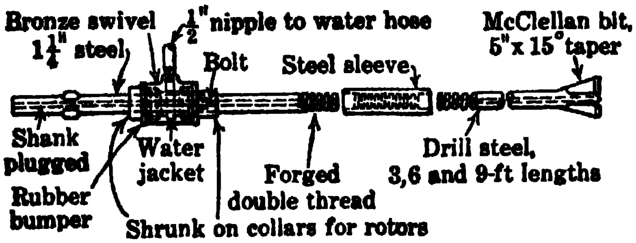
(B) Irregular beds and chimneys of sulphides in limestone. (C) Thick beds of sulphides in limestone, assoc with quartzite and shale, often fractured and unconsolidated. (D) Narrow, ramifying stringers of cinnabar in medium-hard sandstone and shale. (E) Large lenticular masses of Fe-Cu sulphides, between schist and graywacke walls. (F) Fine stringers and disseminations of sulphide in quartz-sericite schist. (G) Sulphides with quartz gangue in hard limestone and brecciated porphyry. (H) Pb-Zn sulphide and quartz vein in sheared or sheeted quartzite. (I) Massive sulphides in quartz-sericite schist, with quartzite layers.

Chief Consol mines, Tintic, Utah. Silver-lead ore occurs as lenses on bedding planes in limestone and in connecting pipes. Occurrence is irregular. Regular systems of exploratory workings will not find all orebodies, hence proportion of non-productive exploratory and development work is high. Exploration costs have been reduced by boring from underground points. Diamond drills were discarded after 6–8 months' trial, because of high costs due largely to diamond loss. A small churn drill also proved inapplicable. Hammer drills of independently rotated type proved successful. A heavy tunnel machine with 1.25-in steel was used for contract drilling of holes 100–200 ft or more in depth. A lighter, mounted sinker with 1-in steel was used by leasers for holes to 150 ft deep. Double-column mounting was required to preserve alinement of deep holes; a single-column and arm could be used for shallow holes.

Fig 90 shows joint between drill rods and water swivel. Usual water inlet through shank is plugged, and water under good press, supplied by small pump if necessary, is admitted through a forged-steel swivel between shank and bit. For down-holes, swivel can be arranged to take air at $^1/_4$ or $^1/_6$ of a revolution; resulting air lift aids in recovering cuttings. McClellan cross bit was used; starting bit, 2.5-in for 1-in steel, 3.125-in for 1.25-in steel. These sizes permit 8 gage drops of $^1/_8$ in each before hole becomes too small for the joint. If loss of gage is too rapid, hole is reamed with a new bit of same gage as the previous one. In some cases 6–8 reaming bits are used before putting in next size. Sludge for each 3 ft of hole is collected in a powder box placed at mouth of hole, and sacked for assay and physical examination. Methods described in Art 8 for careful collection of diamond- and churn-drill samples were considered too complicated for ordinary miners. It was recognized that the sampling practice was liable to error, but character of ore occurrence was such that subsequent channel samples checked hammer-drill samples.



Bronze swivel
$1\frac{1}{4}$" steel
$\frac{1}{2}$" nipple to water hose
Bolt

Forged double thread
Drill steel, 3,6 and 9-ft lengths

Fig 90. Swivel and Steel Assembly for Deep-hole Hammer Drilling

During 19 mo (Oct. 1923, to Apl, 1925) holes totalling 36 232 ft and averaging 80.5 ft deep were drilled in 1 538 drill-shifts (2 men per drill), or 23.5 ft per drill-shift. Deepest hole, 272 ft; 150 ft and over was frequently attained. Labor cost ($5.25 and $4.75 per shift) averaged 60¢ per ft; total cost about $1, compared with $4.94 for diamond drilling under same conditions (509). Fig 74, 74*a* (Art 9), show record forms used.

Empire Zinc Co, Gilman, Colo. Deep-hole drilling is used for prospecting and planning development. Orebodies are thick, gently dipping, sulphide replacements in limestone, quartzite and shale. In some places, ore and adjacent rocks occur in fractured zones of loose, uncemented, large and small fragments (319). Ore is such that accurate sampling of cuttings is unnecessary. Drills are Gardner-Denver No 34 Turbo drifters, mounted on 2 columns. The 1.25-in drill steel is upset to 1.5 in at both ends, and is oil-tempered after each 600 ft of drilling. Bits: (*a*) crossbit with center hole for hard or coarse-breaking rock, (*b*) crossbit with forward-pointing side hole for soft ground, (*c*) Carr bit for loose and caving ground, in which crossbits are harder to pull. Outer faces of all bits are stellited to retard loss of gage; cutting distance per bit is thereby increased 6–8 times over plain steel; a 125-ft hole can often be bottomed with the starting bit. A bit can be made and stellited in 40 min, at cost of 28.5¢ (1 lb Stellite for 14 bits) and can be used about 12 times before reshaping. Standard sizes: 3 $^1/_8$, 3, 2 $^3/_4$ in; the former 8 sizes of all-steel bits are not now required. One 228-ft hole, starting at +45°, was drilled by 2 men without aid of counterweight. Hole surveys show no fixed rule as to vert deviation, but in hard ground a hole will usually start dropping at start, and fall 12–15 ft in 150 ft; in soft ground, hole usually climbs during first 50 ft, is about on grade at 150 ft, and then drops rapidly. Table 14 gives data on continuous operation of 3 drills during 1 yr ending May, 1931; most of the time was occupied with experimentation; satis-

Table 14. Deep-hole Hammer Drilling at Gilman, Colo

(Year ending May 31, 1931)

Total footage	15,187
Aver ft per drill-shift	17.5
Percent time drilling	78.2%
" " moving	8.3
" " in trouble (*a*)	13.5
Cost per ft:	
All underground labor (*b*)	$0.608
Maintenance labor (*c*)	.193
Supplies (*d*)	.164
Total (*e*)	$0.965

(*a*) Fishing, stuck rods, repairs, air, and water lines. (*b*) Drilling, timbering, preparing drill stations, pipe work, and clean-up. (*c*) Outside labor on maintenance and repairs of machines, stelliting, fabricating new equipment. (*d*) Supplies and new equipment for deep-drill maintenance. (*e*) Not including 5.2¢ for assaying; 2.4¢ office exp; 9.3¢ for engineers and geologists.

factory operation not attained until last 2 mo, when cost per ft declined quickly to 50.5¢, or about half of what it was 4 mo previously, with corresponding doubling of footage per shift to 33.1 ft.

New Idria quicksilver mine. Seamy and minutely fractured sandstone, erratically impregnated with cinnabar, was prospected by deep-hole drilling at large saving over other methods (320). Accurate sampling not attempted; cuttings from each 3-ft advance were panned. Heavy drifter was mounted usually on cross-arm between 2 columns; in tight places, on horiz bar only. Most holes were 8°–50° above horiz; one, of 147 ft, was 78° below horiz. Aver depth of 87 holes, 99.3 ft; deepest, 228 ft. Starting bit, 3.25-in, reducing by $^1/_8$ in to smallest at 1.75-in. Water at 100-lb press obtained by tapping the pump column. Aver advance per 2-man drill-shift, 30 ft in medium shale and sandstone. Total cost (1931), 75¢ per ft, including purchase of one complete outfit for $1 800.

Tri-State district has used deep-hole drilling, usually to advantage, in proving or disproving occurrences of ore in suspected areas without expensive drifting; cuttings seldom assayed (569). In low headings, drill is mounted on 2 columns; in high headings, on heavy tripods. Holes are usually pointed upward at 10° or over; several were drilled 50 ft at 60° above, and a few to 100 ft or more at 5° below horiz; latter were cleaned by injecting water and air through pipes. To April, 1930, deepest hammer-drill holes were about 150 ft (probably not the limiting depth). A few cost data follow: Federal Mining & Smelting, 2 675 ft, at $1.75 plus estimated 15¢ for deprec. Canam Metals Corp, over 1 000 ft, at $1.70, excluding deprec. Mo-Kas Zinc Corp, several thousand ft, mainly in solid limestone, at 60–70¢, including deprec. Eagle Picher Lead Co, 3 477 ft, at $1.69, including deprec; at same Co's Lucky Jew mine, 1 072 ft largely in solid limestone, at $1.14. Costs usually averaged about $1.70 per ft to 1930, but reductions were expected with added experience.

Roseberry mine, Tasmania. Pb-Zn-Fe sulphide orebody, surrounded by fine-textured quartz-sericite schist with bands of quartzite and quartz veins (321). Exploration is done with Gardner-Denver, 225-lb hammer drills. Holes start at 15° above horiz; deepest, 138 ft. Air consumption (85-lb press), 110 cu ft per min for first 50 ft, to 225 cu ft at 100 ft. Water, 70-lb press, 4 gal per min. To mid-1930, 15 holes totaling 893 ft were drilled in 83 2-man drilling shifts, plus 12 shifts moving and setting up; aver, 10.7 ft per drill-shift, or 9.4 ft per elapsed shift. Max for 1 shift, 30 ft. Diamond drilling (1-in core) in same ground averaged 9 ft per shift. While drilling, changes from rock to sulphides are recognized by color of cuttings; assays showed enrichment of Zn and Pb in slimes from a massive pyrite ore, demanding care in recovery of sludge.

11. ESTIMATES, FROM BOREHOLES, OF ORE TONNAGE AND VALUE

(For survey of boreholes, see Sec 9; for platting boreholes, see Art 9)

Average value of ore in one hole. Let $V_1, V_2, \ldots V_n$ = assays of successive samples; $L_1, L_2, \cdots L_n$ = their respective lengths; V = aver assay of ore. Then

$$V = \frac{V_1L_1 + V_2L_2 + \cdots + V_nL_n}{L_1 + L_2 + \cdots + L_n} \tag{1}$$

If sample lengths are equal, aver assay is arithmetical aver of assays of samples. For methods of averaging assays of diamond-drill core and sludge, see Art 8 and Bib (123, 124, 125, 128).

Average value and tonnage of an orebody are calculated from borehole averages in different ways, depending on ore occurrence and information desired.

Examples. Iron-ore deposits at Moa and Mayarí, Cuba, and placer dredging properties, are examples of surface orebodies with no overburden, and fairly regular bedrock. For such orebodies, estimates may be made thus: Let $V_1, V_2, \cdots V_n$ = aver value or assay of drill holes 1, 2, 3, $\cdots n$; $A_1, A_2, \cdots A_n$ = respective areas of influence of these holes, sq ft; $D_1, D_2, \cdots D_n$ = respective depths of holes, ft; A = total area of deposit; V = aver value of deposit; D = aver depth, T = total tonnage; C = cu ft per ton in place; n = number of holes. Then,

For holes spaced irregularly:		For holes spaced at regular intervals:
$V = \frac{A_1V_1D_1 + A_2V_2D_2 + \cdots + A_nV_nD_n}{A_1D_1 + A_2D_2 + \cdots A_nD_n}$	(2)	$V = \frac{V_1D_1 + V_2D_2 + \cdots V_nD_n}{nD}$
$D = \frac{A_1D_1 + A_2D_2 + \cdots + A_nD_n}{A}$	(3)	$D = \frac{D_1 + D_2 + \cdots + D_n}{n}$
$T = \frac{(A_1 + A_2 + \cdots + A_n)D}{C}$	(4)	$T = \frac{AD}{C}$

Where ore is overlain by barren material, or occurs in bodies overlying each other and separated by barren or low-grade material, the same methods apply, but only the *V*, *D*, and *C* relating to workable areas penetrated by each hole are considered.

Area of influence of a borehole is the area within which the values shown by that hole are assumed to persist. Theory of averaging samples in general is based on assumption that values vary at a uniform rate between sample points. This assumption is met by so taking the area of influence of a hole that every point within it is nearer to that hole than to any other.

Fig 91 shows general case for holes spaced irregularly. Area of influence for hole No 1 is found by drawing lines 1–2, 1–3, etc, connecting hole No 1 with all those around it. Lines *ab*, *bc*, *cd*, *de*, and *ea* are perpendicular bisectors of lines 1–5, 1–4, 1–3, 1–2, and 1–6, respectively. They enclose polygon *abcde*, which is area of influence of hole No 1, which area may be measured with planimeter, or calculated from scaled bases and altitudes of its component right triangles. A different method for defining areas of influence of irregularly spaced holes has been used in S E Mo (322). Triangles are first constructed by joining each hole with those nearest to it (Fig 93). Lines are then drawn from each apex to center of opposite side (intersecting at center of gravity of triangle); polygon thus constructed around hole No 1 of Fig 93 has twice as many sides as that of Fig 91. Fig 92 shows construction applied to holes spaced on corners of squares. In this case, area of influence of each hole is a square (*abcd* for hole No 1), the side of which is the distance between holes. For discussion of these principles, and application to prisms of varying scalenity and to cases where check holes have been drilled in centers of regular blocks, see Bib (512). Another common method for irregularly spaced holes, for which aver values were computed by formula 1, at beginning of Art, is to consider 3 holes in closest proximity as edges of a triangular prism, the depth and value of which are averaged from those of the 3 bounding holes. In Tri-State field, the unweighted, arithmetical aver is employed for depth of prism, and values are weighted only in proportion to depths of ore in the 3 holes (323). This method is less accurate than that by formulas 2 and 3, wherein data of an individual hole are additionally weighted in proportion to the portion of the triangle nearest that hole; that is, to the area of the quadrilateral bounded by 2 sides of triangle and their perpendicular bisectors (Fig 94). To avoid necessity for measuring or computing these quadrilaterals, C. E. Temperley (324) gives a diagram (Fig 95) for thus weighting each of 3 holes involved, requiring only a protractor measurement of angles. (Areas, however, must be ascertained for calculation of tonnage). Having measured the angles of the triangle, to find wt applicable to, say, *A*, enter bottom of diagram at point corresponding to larger of the 2 other angles, say, *B*; follow vertically to intersection with curve corresponding to smaller angle, *C*, and thence horizontally to read wt on *A* in percentage.

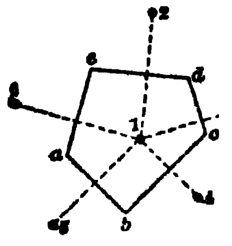

Fig 91

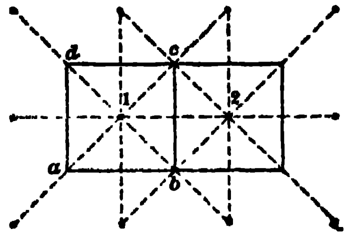

Fig 92

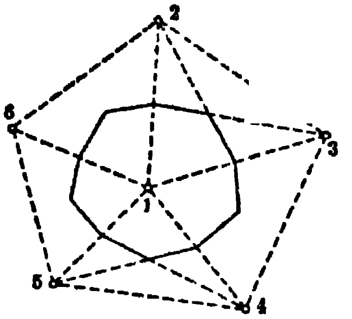

Fig 93

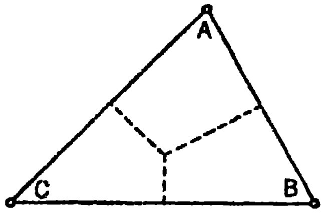

Fig 94

Specific gravity of ore, or cu ft per ton in place, must be accurately determined, since any error will affect computed tonnage. This can be done by: (*a*) A single, good-sized chunk, suspended by fine wire from a spring balance, may be weighed, first in air, and then submerged in water; wt, lb per cu ft, is then 62.5 × wt in air ÷ (wt in air − wt in water). (*b*) Apparatus simulating picnometer flask of the physicist can be improvised with water pail and platform scale, and by using a 20–50 lb wt of coarse ore, representing aver grade, results are likely to be more accurate than those obtained on much smaller fragments (see Sec 1); wt in lb per cu ft = 62.5 × dry wt of ore ÷ wt of water displaced; latter obtained by direct measurement or by difference. (*c*) Using a 500- or 1 000-cc graduated glass cylinder, a known dry wt of fragments to 1-in diam is dropped into a previously noted vol of water in the cylinder, and expansion of vol is observed; wt in lb per cu ft is then 62.5 × wt of ore in gm ÷ expansion of vol in cc. (Sec 1.)

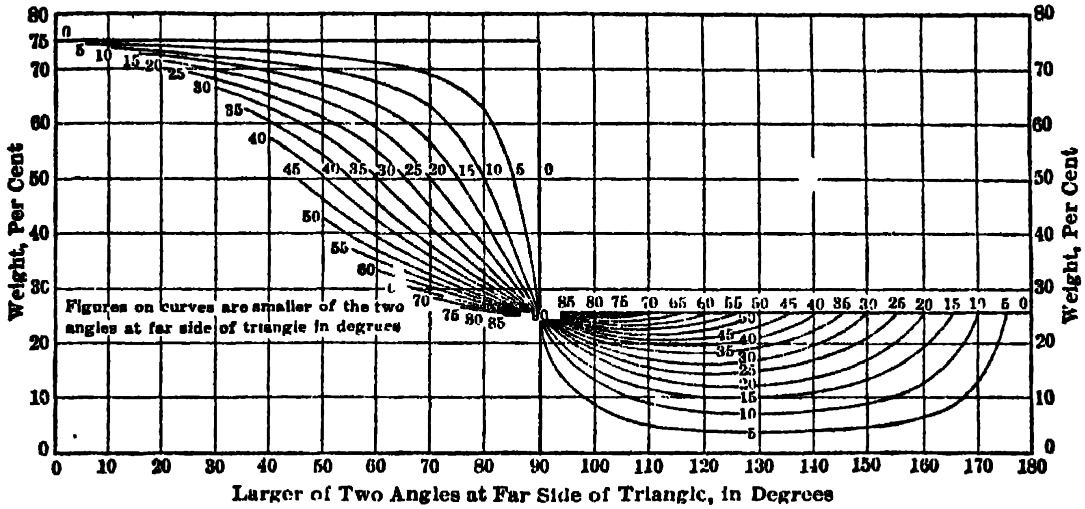

Fig 95. Weighting Factor for Any One of Three Adjacent Boreholes

Mesabi estimates. (Data and drawings from J. F. Wolff. *Mines & Min*, Feb, 1909.) Boreholes, topography, property lines, etc, are first located with respect to a system of

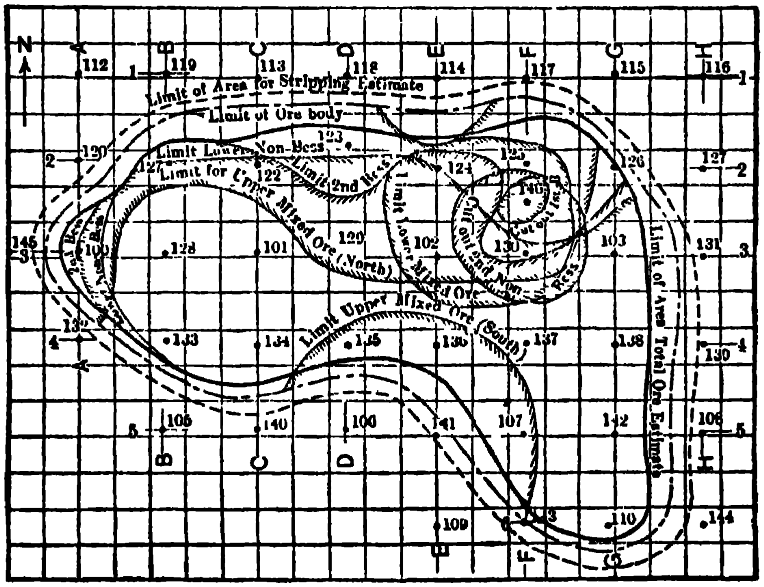

Fig 96. Typical Mesabi Orebody

coordinate lines at 100-ft intervals. From boring data 2 sets of vertical cross-sections, at right angles to each other, are constructed on a scale of 40 ft to 1 in. Analyses of samples placed on sections alongside holes make it possible to outline the layers of different grades of ore. Fig 96 shows in plan a typical orebody, on which 5 E-W sections and 7 N-S sections are laid out. Fig 97 shows section *FF* of this orebody (sample analyses are omitted). From sections, a plan is made, showing superposed contours of surface and top and bottom of orebody. Usually, extension of ore beyond last hole in any section is arbitrarily set at a distance equal to depth of ore in that hole, and bottom of ore is assumed to be a line joining this point with bottom of hole. The 2 sets of sections are checked against each other, and from them, limits of orebody are outlined in plan (Fig 96). Three preliminary estimates are then made as follows:

(*a*) **Total tonnage** is computed from area of orebody and its aver depth. To allow for wedge shape of edges of orebody, the line marked " limit of area for total ore estimate " (Fig 96) is drawn half-way up the slopes on margins of the orebody. Area enclosed by this line × aver depth of ore ÷ cu ft per ton gives total tonnage. Areas are measured with a planimeter, aver depth of ore is computed from borehole data, and cu ft per ton are estimated from tests and experience.

(*b*) **Stripping estimate.** Proper BERM distance is laid out between edge of orebody and toe of the bank of overburden; slopes of 1 : 1 or 0.75 : 1 are selected (depending on character of surface drift), and intersection of this slope with surface contour is platted. Aver area to be stripped (limit of area, stripping estimate, Fig 96) is taken as a line half-way up this slope. This aver area × aver depth of stripping ÷ 27 = cu yd of stripping.

(*c*) **Possible power-shovel tonnage.** With the aid of sections and combined contour map, a system of tracks is laid out for operating shovels and ore trains. This gives shape and size of deepest possible shovel excavation. Elevation at which each borehole would be cut by this excavation is noted, and aver depth of ore taken out thus determined. This aver depth × area previously determined (total tonnage estimate) ÷ vol per ton gives the tonnage used for preliminary estimates. Final or detailed estimates are made as follows:

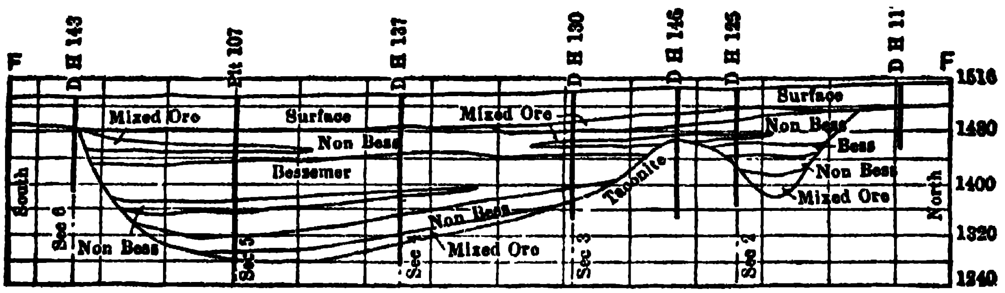

Fig 97. Section *FF* on Fig 96

(*d*) **Graded-tonnage estimates** for securing relative tonnages of Bessemer, non-Bessemer and mixed ore. Two methods are used. In COMPOSITE-HOLE METHOD, aver depth of ore of, say, Bessemer grade is first computed as arithmetical aver of depths of Bessemer ore cut in all holes within area of orebody. If a hole shows no Bessemer ore, it is included in the aver as zero. This aver depth × area (total tonnage estimate) ÷ cu ft per ton gives total tonnage of Bessemer ore. Same calculation is made for other grades. Second and PREFERABLE METHOD is shown by Fig 96. From cross-sections, the outlines of different grades of ore are worked out and plotted in plan, and planimeter measurements are made of the area of each grade at each horizon. From these areas and their respective aver depths, volume of ore in each grade is computed. Plotting the areas of different grades is intricate work. In the example, the taconite horse, shown in section *FF* (Fig 97), cuts out roughly circular areas from 2 ore layers. Such areas are measured and subtracted from total area of the respective grades in which they occur.

(*e*) **Graded-tonnage estimates and aver analysis.** Tonnage estimates are made by the second method under (*d*). Aver analysis of ore in a grade is obtained by averaging drill-hole samples in proportion to their length (Eq 1 above). Products of sample length × per cent are locally called FOOT UNITS, which are computed for Fe, P, SiO_2, Al, Mn, CaO, and S, or for such of these elements as are desired. "If for each ore-bearing hole, foot units are computed for each grade and these results added together, the sums are respective total foot units for the grades in the orebody. Such sums are divided by respective total feet of samples to give average analysis for each grade of the orebody." TON UNITS is the name given to the products obtained by multiplying tons of any grade by its aver analysis (in Fe, P, etc). Aver analysis of all grades in the deposit is the sum of ton units for each grade ÷ total tonnage of deposit (Eq 2 above). Complete summary (514).

Porphyry coppers. Holes commonly spaced on corners of 200-ft squares. From borehole data, two sets of vert cross-sections are constructed at right angles to each other, and orebody is outlined on each. Usually there is some underground work to aid in this. A. J. Sale (60) recommends that sections be passed through diagonals of squares (*AG*, *BF*, *DJ*, *EI*, etc, Fig 98), instead of on the sides (*AJ*, *BI* . . . *AD*, *LE*, etc), thereby increasing distance apart of holes in any section, but bringing sections closer together. Diagonal sections are adjusted to agree at their points of intersection *P*. This method would tend to greater accuracy in orebodies with irregular outlines. In any case, some cross-sections made through orebody at an angle to regular section lines are desirable, to detect errors and secure correct interpretation of borehole data. Where underground mining is to be done, sections do not show all irregularities, but are adjusted to outline an orebody of mineable shape. For orebodies of simple shape, estimates of aver value and tonnage can then be made by Eq 1, 2, 4, above, taking depths D_1, D_2 . . . , etc, as depths of ore in holes. It is usually better to make planimeter measurements of area of ore in each cross-sec, and use the prismoidal formula (Sec 36, Art 11) for calculating tonnage, taking alternate sections as middle areas. Aver value of deposit is found as follows: Aver value of ore in each hole is first found by Eq 1 (see beginning Art 11). Where holes are equidistant, the aver value of ore in a section is obtained by combining aver values of holes in proportion to their depths. Where holes are spaced unevenly, their aver values should be combined in proportion to area of influence of each hole in plane of the section. For equidistant sections, Σ (section areas × their respective aver values) ÷ Σ (section areas) = aver value of whole deposit. Where sections are spaced at unequal distances, they should be combined in proportion to their vol of influence. Estimates made for both sets of sections should check each other closely. Usually no allowance is made in estimates for extension of ore beyond last hole in any section.

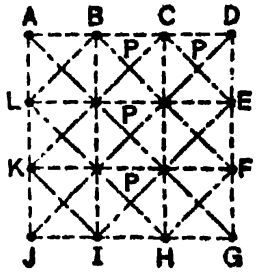

Fig 98

At Ray Consol Copper Co's property, holes were on corners of 200-ft squares. Tonnage and aver value of each 200-ft block were calculated separately, using data from 4 corner holes. L. A. Blackner (61) gives following example of calculation for a block having holes 251, 249, 267, 263 at the 4 corners, the area of rectangle formed by these holes being 84 404 sq ft: Sum of tons in each block gave total tonnage, which was checked by prismoidal calculations from cross-sections. Aver assay of entire tonnage was obtained by combining aver block assays in proportion to their tonnage (see Table). In disseminated copper deposits, values usually grade out gradually into rock on sides and bottom of orebody. In such cases, outlines shown by cross-sections merely represent limits of profitable ore; minimum assay varies with copper prices and with methods of mining and milling. Total tonnage in orebody increases as lower-grade ore is included in it. A. J. Sale (60) gives a convenient method of analyzing these variables. Before averages are made, assays of drill samples are corrected for mill recovery, corrected values being called net per cents. Sets of sections are then constructed to include on margins of orebody ore having minimum net assays of, say, 1, 1.5, 2, 2.5, and 3% Cu. (This range of minima is for illustration only; min marginal grades of less than 1% are included in estimates at several porphyry coppers.) Estimates of tonnage and aver value (net mean grade) are made for each minimum net % used, and results plotted as shown in Fig 99. Curve of net production, in lb of copper, is computed from known points on curves of tonnage and net mean grade. Interpolations made on these curves show at once the effect of including ore of any minimum net grade between 1 and 3%. This device is of course limited to the special conditions outlined above. See also Bib (513).

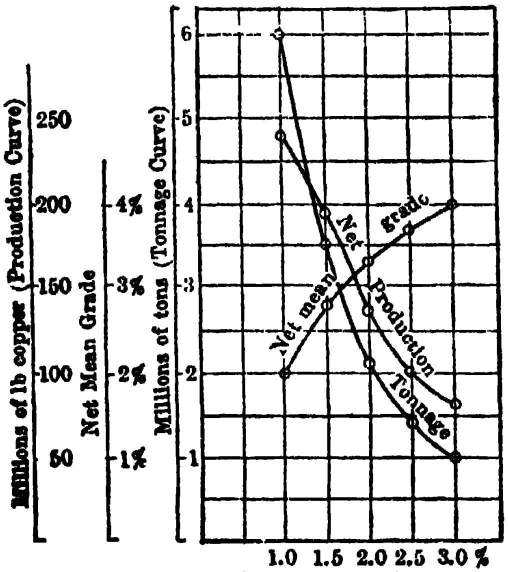

Fig 99

Block Calculation, Ray Cons Mine

Hole No	Thickness of ore, ft	Aver % Cu assay	Ft × %
251	90	1.77	159.30
249	345	1 86	641.70
267	100	2 65	265.00
263	80	2 62	209 60
Total and aver	615	2 07	1 275.60

Av thickness ore in block = 615+ 4 = 153.75 ft.
84 404 × 153.75 + 12.5 (cu ft per ton) = 1 038 169 tons   Av value = 1 275.6 + 615 = 2 07% Cu.

In recent work at Utah Copper mine (Art 10-b) holes were drilled as nearly as practicable at corners of equilateral triangles with 400-ft sides; near margins of orebody, 200-ft spacing. Whole area was divided into 100-ft squares and each block, corresponding in depth to proposed height of bench on that level, was estimated. Where a 100-ft block contained a drill hole, its aver value was taken as that of the hole between elevations of top and bottom of bench; value of a block containing no drill hole was averaged on basis of its distance from nearest adjacent holes. For modes of ascertaining boundaries of profitable ore, especially as to depth of capping, see Bib (119).

12. EXPLORATION BY SHAFTS, TUNNELS, AND DRIFTS

Underground exploration is undertaken where conditions prevent surface work, or where surface exploration gives no information as to underlying orebodies. Art 3 contains suggestions as to location of openings with respect to geology. General rules: (*a*) keep workings in the orebody; (*b*) do first work on best showings, to see whether or not they are superficial; (*c*) cost must be low, due to high risk involved. For selection of equipment, see Bib (515) and Art 13.

Narrow veins are explored as in Fig 100. On each oreshoot, a small shaft has been sunk, following sinuosities of vein (see cross-sec *AB*), and drifts are run on each shoot.

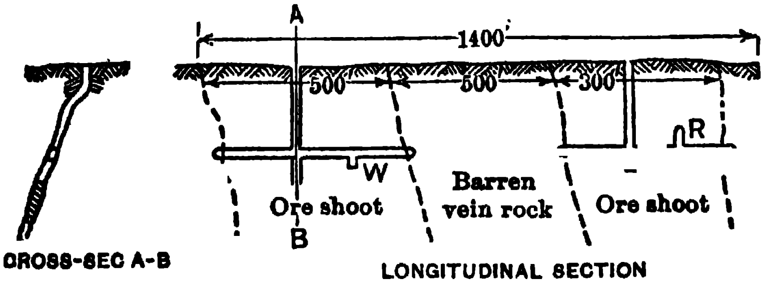

Fig 100. Typical Exploratory Work

Depth at which drifting starts in such work is from 50 to 100 ft. It depends largely on depth of surface alteration and level of ground water, but is influenced by so many local factors that only general statements can be made. Good showings in the drift may be explored with raises *R* or winzes *W*. In long oreshoots, raises may be put up at regular intervals. Workings are sampled and estimates made of tonnage and value of ore exposed (Sec 25) as work progresses. At different times these figures, together with geol conditions, form a basis for judgment as to whether: (*a*) prospect should be abandoned; (*b*) further exploration is warranted, and, if so, its amount and character; (*c*) net value and amount of ore proved and whether probabilities for extensions are sufficient to warrant systematic development and equipment for the property. Further exploration would consist of deepening shafts and driving other drifts at intervals of 60 to 100 ft. Wide veins are explored by same general methods, but crosscuts are driven from wall to wall at regular intervals to determine width, character, and value of ore.

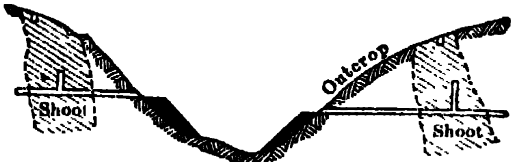

Fig 101. Longit Sec in Plane of Vein

Veins outcropping across a ravine may be explored with drift tunnels and raises (Fig 101). Tunneling in general is cheaper than shaft sinking; the workings drain themselves, and hoisting is avoided. With steep topography there is great temptation to drive crosscut tunnels to intersect an orebody in depth (Fig 5, Art 1), lateral exploration being done by drifts, raises, and winzes as before. This involves a higher risk than where workings follow the orebody; the latter may be cut in a pinch and not be recognized; faults, and changes in dip or strike may cause the tunnel to miss the orebody. Large amounts of water occurring near surface may justify use of crosscut tunnels for early exploration. Difficulties of such work should be recognized; tunnels should not be far apart and there should be money enough to continue work, if orebody is not cut at point calculated from its surface dip.

Beds which outcrop are explored by drift tunnels, slopes, or crosscuts. Vert shafts are sunk to reach beds, flat deposits, and masses which do not outcrop. Where overburden is alluvium, test pits are located on corners of squares (Art 4, 5, 6). If such orebodies lie under a rock cover, exploration usually consists of one or more vert shafts, from which a series of drifts and crosscuts are driven to outline the orebody at different levels; raises extending to the capping above determine vert extent of ore.

Exploration vs systematic development. There is no sharp separation between the two activities. Drifts and other openings for exploratory work are of small cross-section. Drilling is usually done by hand, and windlass or whim is used for hoisting. Power hoists improvised from automobile engines are economical when shafts go deeper than 50–75 ft. Portable gasolene-powered compressors are useful. Expenditure for more elaborate plant is not made until justified by results of work. For cost and speed of driving small drifts, tunnels, and raises, see Art 20, 21; for cost of shafts, see Sec 7. Factors governing choice of different openings are as given in Art 15, 16. It is desirable to plan and locate exploratory openings with reference to possible future development, but this should be subordinated to the primary object of exploration, as defined in Art 1.

Résumé. (*a*) Main objects of exploration are to reduce mining risk, lessen cost of development, and increase profits of mining by obtaining information upon which intelligent plans of work may be based. (*b*) Cheapest and quickest methods of obtaining this information are by surface exploration and by boreholes. But, in many cases, underground exploration is necessary and cannot be neglected. (*c*) Underground work at first should be so conducted as to obtain information even at expense of making special excavations of no value for mining purposes. Underground exploration should extend far enough in depth to prove character of the unaltered deposit below the zone of surface action, or to prove existence of a sufficiently large body of altered mineral for mining operations. (*d*) Exploration, surface and underground, should be pushed far enough to determine the character and extent of irregularities in thickness and in richness, and to obtain some idea of location and distribution of workable areas and their relations to areas of barren and unworkable ground. (*e*) Number of openings made in the deposit, as shafts and drifts, will depend on local conditions. In deposits of irregular and uncertain character, openings should not be so far apart as to permit large areas of barren or unworkable ground to escape detection. (*f*) If necessary, crosscuts or boreholes should be driven at intervals, to search for and prove parallel beds or fissures, or to prove the deposit itself if wide or thick. (*g*) Assays should be made from time to time on carefully taken aver samples, and these, if required, may be supplemented by working tests on lots of representative ore. (*h*) Exploration and development should be pushed far enough to make sure that there is sufficient mineral to warrant erection of a permanent plant, and far enough to determine all questions affecting profitableness of the enterprise. On the other hand, unnecessary exploration or over-development must be avoided. H. S. Munroe (64).

13. EQUIPMENT AND FOOD SUPPLY FOR PROSPECTING AND EXPLORATION

Surface work. Following is a list of tools and supplies for 4 men doing surface exploration in Nova Scotia (Art 6) (24):

12 picks
6 long-handled, round-point shovels
2 short-handled, round-point shovels
1 stone hammer
1 striking hammer
1 blacksmith's hammer
1 crowbar
1 prospecting pick
1 handsaw
1 blacksmith's file
2 saw files
1 cold chisel
1 pr tongs
1–$1^{1}/_{2}$-in auger
1 brace
1 framing chisel
1 water barrel
1 portable forge
5 short drill steels
1 single jack (hammer)
1 cleaning spoon
2 axes
3 pails
2 gold pans
1 tub
1 pocket lens
1 compass (surveyor's or geologist's)
100 lb mixed $5^{1}/_{2}$-in and 7-in nails
25 lb $3^{1}/_{2}$-in nails
1 claw hammer
50 ft 1-in hemp rope
1 hoisting bucket
1 windlass
1 diaphragm pump, $2^{1}/_{2}$-in suction
1 combined anvil and vise

In addition: repair parts for pump, 1-in lumber for general purposes; $1^{1}/_{2}$-in lumber for cribbing test pits; enough dynamite, fuse and caps for, say, 20 shots; $^{3}/_{8}$-in round iron; hoop iron; camping and cooking outfit for 4 men; 1 month's provisions.

Prospecting, Quebec gold belt. Following supplies were suggested by Frische in 1925 (504), for each man prospecting in Quebec gold belt: *Clothing*—1 complete outfit, including topboots, waterproof pants and coat, 1 suit underwear, 1 duck shirt, 3 pr heavy woolen socks, 1 pr duck pants, 1 roll-neck sweater, 1 towel, 1 pr light canvas shoes, 1 rubber sheet, 2 pr 8-lb blankets, 1 mosquito bar. *Tools*—1 pick, 1 shovel, 1 Hudson Bay axe, 1 geologist's pick, 1 long-handled striking hammer, 1 blacksmith hammer, 1 gold pan, 1 mortar and pestle, 3 drills, $^{3}/_{4}$-in steel of different lengths, dynamite, fuse and detonators. *Miscellaneous*—Tent, canoe, packsack, map, compass, linen tape (66 ft), magnifying glass, blowpipe, watch, jack-knife, fish-hooks and line, toilet kit, first-aid kit, candles, matches, soap. *Cooking Utensils*—1 frying pan, 1 coffee pot, 1 plate, 1 tin cup, 1 knife, 1 fork, 1 spoon, 3 tin pots with cover and bail, 1 large tin pail, 1 can opener, 2 bread pans, 1 large mixing spoon.

Frische also compiled following from aver of several parties in Quebec gold belt, figures being on a man-day basis (504).

Flour	0.75	lb
Bacon	0.50	"
Beans	0.25	"
Sugar	0.40	"
Rice and barley	0.15	"
Desiccated eggs	0.15	"
Macaroni	0.10	"
Oatmeal	0.10	"
Cornmeal	0.12	"
Dried fruit	0.25	"
Butter	0.08	"
Lard	0.03	"
Cheese	0.05	"
Tea	0.025	"
Coffee	0.01	"
Cocoa	0.01	"
Raisins	0.04	"
Jam and marmalade	0.03	"
Syrup	0.03	"
Salt	0.033	"
Pepper	....	
Baking powder	0.01	"
Per man-day	3.048	lb

Milk	0.25 qt	per man-day
Oxo	0.10 cube	" "
Yeast cakes	3 pkg	per summer
Soda	2 "	" "
Powdered jelly	12 "	" "
Mustard	1 "	" "

Total cost per man-day in 1925 .... $0.57

J. Y. Murdoch, in 1938, gives following list of tools provided for 4-months' work by 5 men described in Table 3 and text, Art 7: 1 prospecting pick, 3 rock picks, 3 grub-hoes, 2 round-point shovels, long handle, 2 same, short handle, 2 striking hammers (7-lb), 1 hand saw, 1 cross-cut saw, 1 buck-saw with extra blade, 4 axes (2.5-lb), 6 saw files, 6 flat files (10-in), 1 Buffalo blower, 1 anvil (20-lb), 1 pr tongs, 30 ft 7/8-in hex drill steel, 12 moils, 1 cleaning spoon, 1 pail for tempering, 1 pointed steel, 6-ft, for testing depth of overburden, 1 grindstone, 2 bags blacksmith coal.

Balanced diet for prospectors. Following list is recommended to last 1 man a week (16):

Evaporated milk	3 1-lb cans
Potatoes	2 lb
Other fresh vegetables	4 "
Citrus fruits (3 lb) or apples (or equivalent dried fruits)	6 "
Dry beans	3 "
Cereals (or whole-wheat flour)	6–8 "
Smoked meat	2.5 "
Sugar	3 "
Coffee	1 "
Salt	1/4 "
Butter	1/2 "
Baking powder	....

If water must be carried, 10 gal will suffice 1 man for drinking and cooking for 3 days in hot weather, or about a week in cooler weather.

Northern Ontario. A J. Keast and C. F. Jackson (325) give detailed costs of erecting and equipping a camp for 60 men on preliminary development of Central Patricia, 100 miles N of Savant Lake (Can Nat Ry) Ontario, in 1930. Lumber was sawn on property; sand and gravel were available for concrete. All other materials hauled 120 miles by tractor and sleds at 71¢ per ton-mile.

	Building		Equipment		Building		Equipment
	Size, Ft	Cost	Cost		Size, Ft	Cost	Cost
Bunkhouse 1	18 × 20	$218	$246	Storehouse	24 × 28	$1 060	$498
Bunkhouse 2	20 × 30	875	1 155	Powder magazine	18 × 30	633	....

Dry-house	18 × 28	854	157	Electric-light plant	....	......	1 083
Assay office	16 × 28	630	1 641				

(*a*) Including steel sharpener, $2 553. (*b*) Hoist, compressor, and two 110-hp boilers with feed-water heaters and pumps; cost installed given.

Development from Mch 5 to Sep 20, 1930, included: 500 ft of 6.5 by 16-ft shaft, with 4 shaft stations and sump: 1 776 ft drifting; 1 019 ft crosscutting. Roadmaking, surface exploration, and some diamond drilling were done the previous year. Total cost of buildings, surface and underground equipment, including some items not listed above, $89 854.

Underground exploration, Montana. R. H. Sales furnished following list of supplies and equipment for a crew of foreman, 4 miners and cook working in Flathead Co, Mont, from Dec 1, 1913, to May 15, 1914. They drove 555 ft of tunnels and crosscuts, and sank a 4 by 6-ft shaft 32 ft, using a windlass. Rock, soft porphyry; no water; no timbering required. Wages: foreman, $5; miners

on tunnels, $3.50; on shaft, $4. Two frame shacks were built, each requiring 1 000 bd ft of lumber. Total cost, labor, supplies, and equipment, about $5 500. The list was made by a man of wide experience in this sort of work in the NW and includes no unnecessary items (see also Bib 326).

Mining tools and supplies

1 prospecting hammer
2 4-lb striking hammers
1 7-lb '' hammer
1 8-lb '' ''
3 18-in hammer handles
6 30-in '' ''
3 long-handled round-point shovels
3 5-lb drift picks
4 $4^{1}/_{2}$-lb '' ''
12 pick handles
1 all-steel wheelbarrow
200 lb $^{7}/_{8}$-in drill steel
5 lb $^{3}/_{8}$-in mild steel
19 lb $^{5}/_{8}$-in round iron
600 lb 40% gelatine dynamite
200 lb 60% '' ''
4 200 ft fuse
1 100 6 X caps
3 boxes candles
50 ft $^{5}/_{8}$-in manila rope
1 5-lb wedge
1 7-lb ''
Mine car and rails

Small supplies

1 keg 10d nails
2 lb 3d ''
10 lb 8d ''
5 lb 20d ''
30 lb 40d ''
2 pair 4 by 4 steel butts
2 door locks
4 $^{1}/_{4}$ by 1 $^{1}/_{4}$-in carriage bolts
15 gal kerosene
1 qt Boston coach oil

Miscellaneous

1 whiskey barrel
4 dinner buckets
1 lantern
1 No 8 Admiral stove
1 No 1 c Columbia heater
1 No 2 c Columbia heater
14 joints 6-in stove pipe
2 joints 6-in stove pipe, with check draft and dampers

Miscellaneous (Con't)

1 tent 12 by 14 ft, 12 oz
1 No 1 galvanized-iron tub
1 zinc washboard
1 Keystone clothesline
2 6-in tent flanges
3 pkg $^{6}/_{8}$ brass shoe nails
4 '' $^{4}/_{8}$ C H Hung nails
1 cobbler set
3 pair half soles
3 '' heel lifts
1 wash bowl
1 8 by 10-in mirror
1 8-in scrub brush
1 yd 48-in canvas
1 sq 2-ply Ruberoid roofing
1 $^{1}/_{3}$-pitch tin roof jack
2 yd 36-in oilcloth
25 bars common soap
10 bars hand soap
Medicine chest
Blankets

Blacksmith's tools and supplies

1 pair No 1 blacksmith tongs
1 pair G & D tongs
1 cold cutter
1 40-lb blacksmith vise
1 No 2 blacksmith hammer
1 70-lb anvil
1 No 400 blower
1 hardy
1 hot cutter
600 lb blacksmith coal
1 bottom swage
1 10-in flat file
3 6-in taper files
3 8-in M B files
2 10-in M B files
1 metal worker's crayon
1 10-in wrench

Carpenter's tools

1 No 3 hand axe
2 Jennings bits, $^{1}/_{2}$ and 1-in
1 saw set, No 12
1 10-in wood rasp
1 4-ft, 1-man Simonds saw

Carpenter's tools (Con't)

1 6-ft crosscut saw and extra handles
1 $4^{1}/_{2}$-D B axe
1 $3^{3}/_{4}$-S B axe
1 1.5-in framing chisel
1 level, No 50
1 steel square, No 14
1 10-in brace
1 26-in hand saw
1 clawhammer
1 iron jack plane, No 5
1 22-lb grindstone and hangers
1 adze and handle
1 No 60 axe stone
1 No 11 mason's line
4 pieces blue chalk

Cooking utensils, tableware

4 frypans, Nos 2, 4, 6, and 7
2 dish pans, 14 and 21 qt
2 8-qt milk pans
3 drip pans, 15, 20, and 21 in
1 1-qt pudding pan
6 2-qt pudding pans
4 4-qt pudding pans
3 preserve kettles and covers
2 large saucepans and covers
1 coffee pot
1 tea pot
1 tea kettle
1 pitcher
1 dipper
1 20-in butcher saw
1 10-in butcher knife
1 12-in butcher steel
1 kitchen knife
1 cake turner
1 cast griddle
1 can opener
1 coffee grinder
1 12-qt galvanized iron pail
2 14-qt '' '' ''
12 10-in tin pie plates
12 each, plates, cups, saucers, soup bowls, teaspoons, tablespoons
24 knives and forks
1 1-pt syrup pitcher

Provisions (65). Weight of rations, calculated to have sufficient food value to allow men to work and keep healthy, varies from 3.3 to 4.4 lb per man per day; actual consumption in mining camps is often 6 to 7 lb per man-day, difference being largely due to waste. D. E. Woodbridge has found by experience that supplies in the following list are suitable for REMOTE REGIONS and properly proportioned to come out even. Figures are in lb per man per month; wt, 3.3 lb per man-day. Where game is plentiful, cut down on ham and bacon, double the quantity of salt, and add onions and evaporated vegetables.

	Lb
Flour, cornmeal, hardtack, rice, grits, oatmeal, or similar foods, at least two-thirds of which should be flour prepared for self-raising	42
Clear mess pork, bacon, and ham, say one-half pork	27
Beans and split peas, two-thirds beans	7
Sugar	5
Evaporated fruits, mostly apple	4

	Lb
Butter	3
Canned milk	2
Cheese	2
Tea, coffee, and chocolate	2
Salt, pepper, celery salt, mustard, two-thirds salt	3
Baking powder, if self-raising flour is not used	1
Bottle of lime juice	

Other BALANCED RATIONS for prospectors in the West and SW are given in Bib (327); cost averaged about 50¢ per man-day, which is about a minimum for healthful subsistence.

The old U S ARMY RATION per man-day was: Bacon or pork, 12 oz (or fresh beef, 22 oz); soft bread or flour, 18 oz (or hard bread, 16 oz, or cornmeal, 20 oz). Following were also issued per day to 30 men: Beans or peas, 5 lb (or rice, 10 lb); sugar, 5 lb; vinegar, 1 qt; soap, 1 lb; salt, 1.5 lb; pepper, 1.25 oz. U S FOREST SERVICE recommends following list to serve 1 man 30 days; fresh meat, additional, to be purchased locally:

Bacon, salt	2 lb	Oatmeal	6 lb	Sauerkraut	3 cans
Bacon, smoked	10 "	Onions	5 "	Spinach	3 "
Baking powder	1 "	Pepper	1/4 "	Tomatoes	6 "
Baking soda	1/2 "	Potatoes	15 "	Green Chili	3 "
Beans	5 "	Raisins	2 "	Chili powder	1 small bottle
Butter	2 "	Rice	3 "	Jam	1 jar
Cheese	1 1/2 "	Salt	1 "	Syrup	1 gal
Coffee	4 "	Sugar	12 "	Candles	6
Dried fruit	9 "	Corn	6 cans	Matches	2 large boxes
Flour	24 "	Evap milk (tall)	10 "	Soap, laundry	1 cake
Shortening fat	4 "	Peas	6 "	Soap, hand	1 "

D. J. Williams (328) gives following list of provisions consumed in 30 days by crew of 25 men working for the Hirst-Chichagof Co, at Juneau, Alaska, in 1930. The more important staples are:

Apples and apricots, evap	18.7 lb	Rolled oats	18.8 lb	Beef	632.0 lb
		Salt	48.0 "	Pork	159.6 "
Prunes and figs, evap	37.5 "	Shortening fats	30.0 "	Bacon	85.1 "
Baking powder and soda	5.0 "	Macaroni, spaghetti	17.6 "	Ham	134.8 "
		Sugar	416.3 "	Canned fruits (10's)	89 tins
Beans, dry	43.8 "	Tea	2.0 "	Canned vegets (10's)	72 "
Peas, dry	11.5 "	Yeast	4.0 "	Cond milk (tall)	400 "
Butter	105.0 "	Cabbage	104.0 "	Sardines (16's)	29 "
Cheese	20.0 "	Carrots	79.0 "	Soap, white	71 bars
Coffee	70.1 "	Onions	100.0 "	Crackers	10 lb
Flour, white	475.0 "	Parsnips	30.0 "	Cereals, dry	40 "
Flour, graham	16.7 "	Potatoes	558.3 "	Vinegar	4 1/2 qt
Raisins & currants	15.0 "	Turnips	50.0 "	Salad oil	1.7 "
Rice	12.5 "	Eggs	130 doz		

Principal additions to above: spices, condiments, and flavoring extracts. Gross wt averaged 7 lb per man-day. Bib (328) also gives size and wt of standard packages.

At Iron Mt, Idaho, 20 men, including cooks, consumed following supplies during 4 winter months. Fresh vegetables gave out and canned goods were used. Double the amount of cabbage, turnips, parsnips, and one-half more onions and carrots should have been provided.

Fresh beef	2383 lb	Salt	105 lb	Molasses	2 gal
Fresh pork	581 "	Dried peaches	30 "	Jelly	3 buckets
Fresh mutton	167 "	Dried apples	65 "	Vinegar	6 gal
Fresh fish	100 "	Dried apricots	50 "	Baking powder	8 lg cans
Fresh chickens	112 "	Dried prunes	100 "	Pickles	1 keg
Fresh eggs	69 doz	Raisins	150 "	Lard	25 lb
Case eggs	6 cases	Condensed milk	23 cases	Catsup	1 gal
Ham	472 lb	Canned corn	3 "	Tea	30 lb
Bacon	258 "	Canned tomatoes	5 "	Chocolate	5 "
Butter	330 "	Canned peas	5 "	Cocoanut	6 "
Flour	29 sacks	Canned peaches	1 case	Soda	2 "
Graham flour	50 lb	Canned pears	1 "	Yeast foam	10 pkg
Corn meal	2 1/2 sacks	Canned pumpkin	1 "	Cornstarch	6 "
Coffee	322 lb	Canned oysters	1 "	Chowchow	8 qt
Potatoes	40 sacks	Maple syrup	3 cases	Pepper sauce	2 bot
Carrots	200 lb	Crackers	4 "	Currants	9 pkg
Turnips	100 "	Macaroni	3 "	Hominy	20 lb
Cabbage	200 "	Cheese	77 lb	Matches	1/2 case
Onions	248 "	Sugar	9 sacks	G S soap	1 "
Parsnips	100 "	Oatmeal	3 "	Tar soap	1 "
Apples	600 "	Beans	1 1/2 sacks	Ivory soap	1 "

H. L. Carr, in prospecting placer gravel in Guatemala (work very heavy, negro labor, isolated camp), found weekly food consumption per man as follows:

Black beans	1.4 lb	Lard	0.5 lb	Coffee	0.3 lb
Plantain	3.0 "	Flour	5.0 "	Salt	1.0 "
Ground provisions (sweet potato, cassava, etc)	3.0 "	Rice	2.1 "	Baking powder	0.17 "
		Sugar	1.3 "	Beef, live wt	10 to 15 "

Menu was designed to attract and keep labor; beef, salted and dried immediately after killing. Work done between April and July. (See also *Trans* A I M E, Vol 29, p 157.)

DEVELOPMENT

14. GENERAL

Systematic development. Purposes: (*a*) to provide openings for stoping and transporting mineral; (*b*) to obtain further and more detailed information as to character and size of orebody. Relative importance of these functions depends on type and size of orebody; the second is more important in orebodies of irregular shape and tenor, and in general during early stages of development. Two problems are presented: MODE OF ENTRY, which involves a decision between vert or inclined shafts, drift or crosscut tunnels, or a combination of these, for reaching the orebody from surface, and LATERAL OR SUBSIDIARY DEVELOPMENT, which deals chiefly with workings within the orebody.

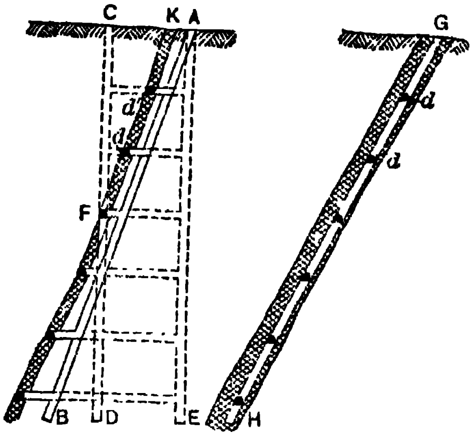

Fig 102

Fig 103

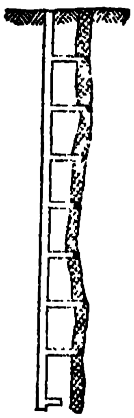

Fig 104

(After Hoover)

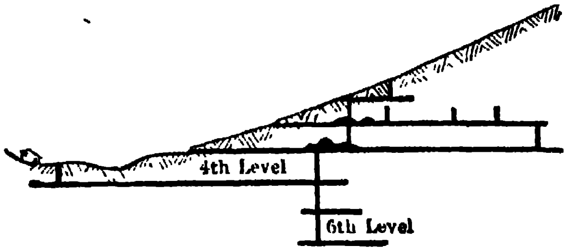

Fig 105. Section in Plane of Vein

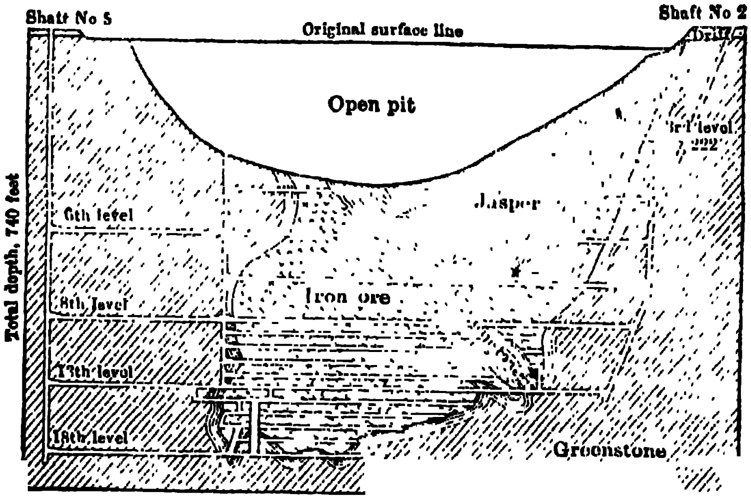

Fig 106. Chandler Mine, Mich (after Leith)

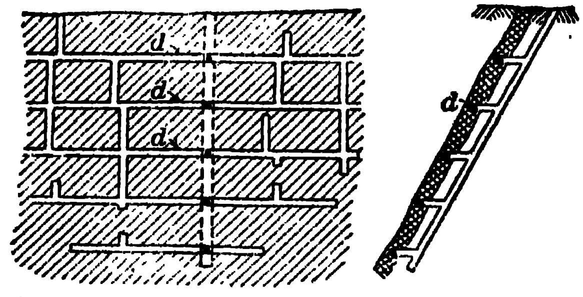
Modes of entry for PITCHING VEINS are (Fig 102): a vert shaft *CD* started in hanging wall; a footwall vert shaft *AE*; a footwall inclined shaft *AB*; or an inclined shaft *GH*, in the vein. Except in the last case, crosscuts are necessary at intervals to reach the vein (Art 19). A vert shaft is the correct mode of entry for FLAT OR VERT DEPOSITS, lying under flat topography (Fig 103, 104). In MOUNTAINOUS REGIONS, entry to veins or other deposits may sometimes be made by crosscut tunnels (*p*, Fig 5) or drift tunnels (Fig 105). Fig 106 shows entry to a massive orebody, by both vert and inclined shafts. It is common to find 2 or more openings of the same or different kinds on a single orebody (Art 15 to 18).



LONGIT SEC IN PLANE OF VEIN CROSS-SEC

Fig 107

Lateral development. Fig 105 and 107 show typical forms for VEINS, independent of mode of entry. Drifts *d*, in the vein, are connected by raises following the vein from level to level (Art 19). Development in THIN BEDS is similar; the ore is divided into blocks by drifts roughly at right angles to one another. Fig 108 shows development in a BEDDED DEPOSIT, 10 to 25 ft thick; drifts outline the orebody in plan, raises give its vertical extent, and both are used later in connection with stoping.

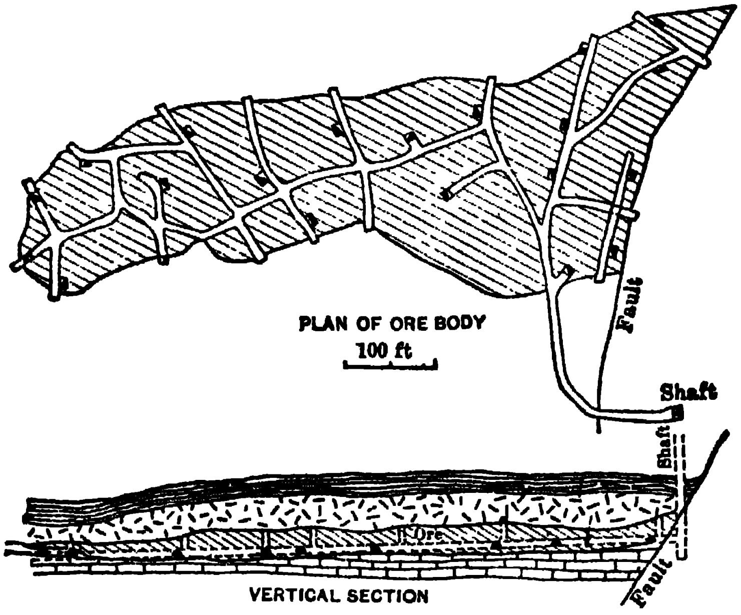


Fig 108. Bedded Deposit, Leadville, Colo

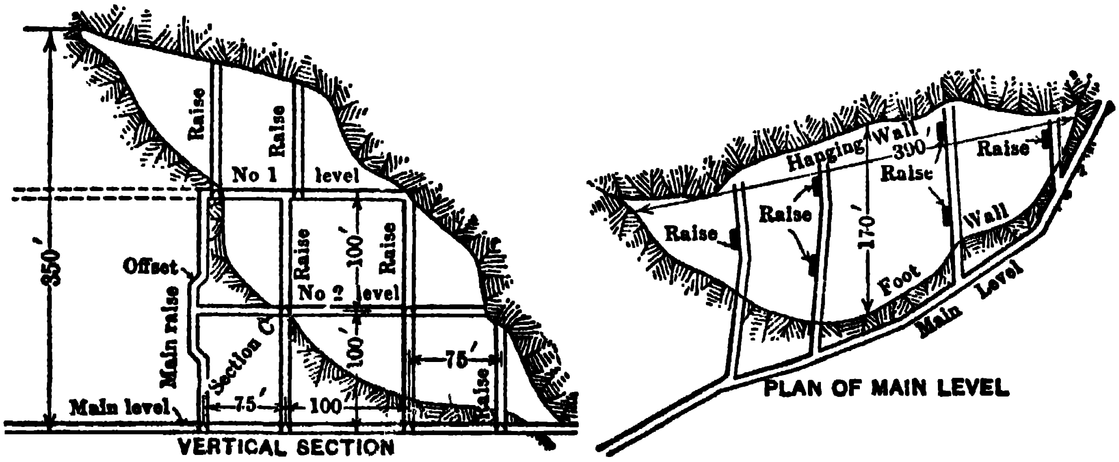

Fig 109. Massive Deposit, Bingham, Utah

Fig 109 shows somewhat similar development of an irregular massive deposit (66). Methods of mining exert a dominant influence on mode of lateral development, especially in large orebodies (see Art 19 to 23). In general, lateral development divides an orebody into blocks, the edges or corners of which afford numerous points of attack and the tonnage and value of which may be computed; the openings also outline payable areas and aid ventilation and drainage.

15. CHOICE OF MODE OF ENTRY

Openings in orebody *vs* those in country rock. (*a*) Ores are often softer than adjacent country rock; if so, it is cheaper and quicker to make openings in them, but cost of maintenance in soft ground may outweigh this advantage. (*b*) Openings in the deposit have an exploratory value; chance of losing orebody is reduced. (*c*) Mineral extracted may pay part of cost of work. These advantages are greater when funds are limited and preliminary exploration has not been thorough. Crosscut tunnels and vertical shafts are in country rock; drift tunnels follow orebody and allow stoping to start at any point.

Inclined shaft in orebody *vs* inclined shaft in footwall. Inclined shafts for large tonnages must be straight. Gradual changes in dip are allowable, but if numerous or sudden they increase hoisting cost and decrease shaft capacity by limiting hoisting speed. A straight incline can not be sunk in a deposit of irregular dip; at some point it must extend into country rock. Hence, in such orebodies the footwall location (*AB*, Fig 102) is generally preferable for large shaft capacity. For small output, a straight shaft is less important and the exploratory value of a shaft in the deposit often recommends its use. In fairly regular deposits, large outputs can be handled through shafts in either location; choice is then based on other factors (see below).

Michigan copper mine practice (67, 68, 486, 487, 488, 489). The native copper occurs in conglomerate and amygdaloid beds; dip in northern part of district is 37° to 42°. Operators differ as to which shaft location is better. ADVANTAGES OF FOOTWALL SHAFT: (*a*) Bins for loading skips can be placed directly over the shaft, and for the most part are cut in ore; this advantage disappears if skips are loaded direct from cars, as is done in many mines. (*b*) Less timber is required in upper part of a footwall shaft than for a shaft in the vein; hence, there is less danger from fire. Fire is prevented by substitution of concrete and steel supports for timber. (*c*) Footwall location obviates necessity for shaft pillars, which must be left on each side of a shaft sunk in ore, and which tie up large amounts of ore during life of shaft. Mining operations may throw great pressures onto shaft pillars, and, if a "creep" starts, it may destroy the shaft. DISADVANTAGES OF FOOTWALL SHAFT: (*a*) it costs more to sink; (*b*) it requires crosscuts and stations cut in rock; (*c*) it produces no ore while sinking and gives no information as to character of the deposit. Some footwall shafts cost more to maintain than those in the vein and *vice versa* depending on local characteristics of rock and ore; most shafts have been sunk in the lode. It is an open question whether in new mines a small shaft should not be sunk in the vein, and lateral work carried on from it far enough to prove the orebody. The working shaft could then be raised simultaneously from several levels, and placed in vein or footwall in the light of information obtained.

Tunnels *vs* shafts. Drift and crosscut tunnels can be driven faster and cheaper than shafts. Wet ground increases this advantage, as a tunnel drains the overlying ore and eliminates pumping. Hoisting plant also is not required until operations extend below the tunnel level.

Crosscut tunnels prospect the country rock and may disclose parallel deposits (Art 3). Drift tunnel is usually preferable, if a choice exists. Risk involved in driving crosscut tunnels is higher than for other methods of entry; it increases with length of tunnel and its depth below known ore. It is unwise to begin development with a long crosscut before exploration has shown an adequate tonnage of ore, and either proved or given strong geological evidence of its extension to the tunnel level.

Several long and deep crosscut tunnels have been driven, to provide drainage and economical transportation for groups of mines. They are justified when the saving on known orebodies will amortize cost of tunnel at a profit during life of properties affected.

Drift and crosscut tunnels serve mainly for extraction of ore lying above them; shafts must be sunk from tunnel level or from surface to develop deeper portions of a deposit. Internal shafts require large excavations for hoisting plant, and the latter must be operated by elec or compressed air; underground hoists, however, are increasingly common. When steam hoists are used and power is generated at the mine, saving is effected by placing the hoist on surface close to boiler plant. Combined cost of tramming and transferring ore to tunnel cars is often more than cost of hoisting the extra distance to surface. Questions of convenience in handling ore on surface may modify choice of method. Hoisting plant on surface, but delivering loads to a tunnel at some distance below, is a frequent arrangement in rugged country. Tunnels preserve their drainage function after mining above them has ceased; surface water may be intercepted at the tunnel level, and the head on pumps at lower levels is reduced by difference in elevation between collar of shaft and tunnel level. Saving in pumping may warrant the cost of a new and deeper adit, or the driving of a tunnel to tap workings already opened by a shaft, even though the tunnel is used for drainage purposes only. Length of such a tunnel which it will pay to drive = present value of total saving in pumping cost during probable life of mine ÷ cost per ft of tunnel; for example, with power @ $60 per hp-yr, cost of tunneling @ $20 per ft, and a 10-yr life, it will pay to drive 600 ft of tunnel per 100 000 gal water per day per 100 ft head saved. For recent examples of long drainage tunnels, see Ojuela, Trepca, and Halkyn, Art 20 and Bib (483, 484, 498).

Vertical *vs* inclined shaft. A typical example requiring a decision between the two kinds of shaft arises in case of a pitching vein, as in Fig 102. An inclined shaft is generally sunk in footwall (*AB*). Vert shaft may be at *CD* or *AE*; either location requires more crosscutting than the inclined shaft, and from this standpoint the inclined shaft has an advantage which varies with dip of vein and with depth; this advantage is partly offset by the greater length of incline required to reach a given level. Shaft *AE* always requires more crosscutting than *CD*; for *CD*, the total length of crosscuts is a minimum when *CF* = *FD*. Depth *CD* must be assumed in comparing merits of alternative locations. Factors to be considered are:

(*a*) **First cost.** Vert shafts cost more or less per ft than inclined shafts, according to local conditions and the way in which ground breaks. Sometimes drill holes in one or the other can be placed to take advantage of planes of weakness, thereby increasing speed and decreasing cost. Sinking very flat inclines resembles drifting; they usually cost less per ft than a vert shaft of same cross-sec (see Sec 7). Cost per ft of crosscutting (Art 20) is same for either mode of entry. A comparison of total costs is made by applying unit costs to total footage of the different openings involved. For given depth and unit costs of sinking and crosscutting, an angle of dip will be found at which the cost of hanging-wall shaft *CD* (Fig 102) with its crosscuts is same as that of footwall shaft *AB* with its crosscuts; on flatter dips, an inclined shaft entry is cheaper, and *vice versa.* Critical angle in most cases is about 70°. For all dips permitting a choice, a footwall vert shaft *AE* and its crosscuts cost most.

(*b*) **Cost of equipment.** To reach a given level, vert shaft requires less hoisting rope, piping, wiring and timber, than an incline. Cost of surface plant is related to type of shaft in a very general way only; it should be determined for each alternative.

(*c*) **Cost of operation.** Hoisting in vert shafts is usually cheaper than in inclined shafts, because hoisting distance from a given level is less; hoisting ropes last longer; there are no rollers to wear out and replace; rails, and skip wheels, axles and boxes are troublesome; expense of axle lubrication is avoided. As against this, aver length of tram to vertical shaft is greater; extra cost of tramming may more than compensate extra distance to be hoisted in the inclined shaft. Comparisons of operating cost can be made in a manner similar to those of first cost as outlined above.

(*d*) **Relative capacity.** Danger of derailing the skip limits rope speed in inclined shafts to max of 3 000–3 500 ft per min, which is possible only with straight shafts, good rolling stock and well built track. Rope speed in well constructed vertical shafts has reached 6 000 ft per min; hence, they have a larger potential capacity for a given cross-sec. Large skips can be used in inclined shafts without material increase in cross-sec of shaft, and large outputs obtained in spite of lower hoisting speed. Since the track supports a portion of the load, the power for hoisting a given output may not be greater than in a vertical shaft handling same output in smaller loads at higher speed.

(*e*) **Maintenance.** Hanging-wall shaft *CD* (Fig 102) requires pillars of ore for support between points *F* and *K*. In weak ground or over thick orebodies, even if pillars are left, cost of its maintenance may eliminate it from consideration and limit choice to shafts *AE* or *AB*, which are unaffected by mining operations. Usually vertical shafts cost less for maintenance than inclines; in the latter, also, it is more difficult to set timber and keep it in alinement. Soft or running ground prohibits the use of inclined shafts.

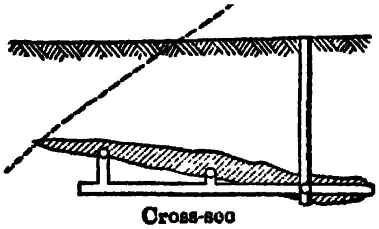
(*f*) **Depth** modifies the relative importance of the foregoing factors (Art 16). Deep vertical shafts, sunk in the early history of a mine, have same disadvantages as long crosscut tunnels.

(*g*) **Time.** Extra crosscutting required by a vertical shaft may increase the time to reach an orebody at a given level. This is important in planning development in small orebodies to keep ahead of mining; also in deep-level projects (Art 16).

16. FACTORS INFLUENCING METHODS OF DEVELOPMENT

This article deals with the conditions commonly affecting both mode of entry and lateral development. It should be noted that development methods are a compromise between many conflicting factors; local conditions often predominate in final choice.

Topography. It is only in mountainous regions that a tunnel entry secures sufficient backs of ore to warrant its cost. Few important producers have been able thus far to avoid hoisting entirely. Fig 110 illustrates the futility of positive statements. While orebodies dipping less than 15° are best entered by a vert shaft, with topography as indicated by dotted line, an incline might well be justified (Art 18).



Cross-sec

Fig 110

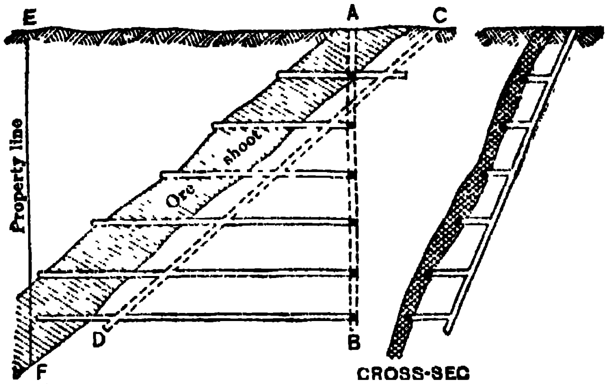


Fig 111

Local geology has a marked influence in determining the position of development openings where their exploratory function predominates (Art 3). Also, location of openings and mode of entry should be planned to avoid danger and expense of passing through faulted zones, water-bearing strata, or bodies of quicksand, which would increase maintenance cost. Many large mines maintain a geological staff; by cooperating with the mining department they can direct exploratory drilling, reduce total footage of development work required, and place the openings where they will have highest exploratory value and avoid bad ground.

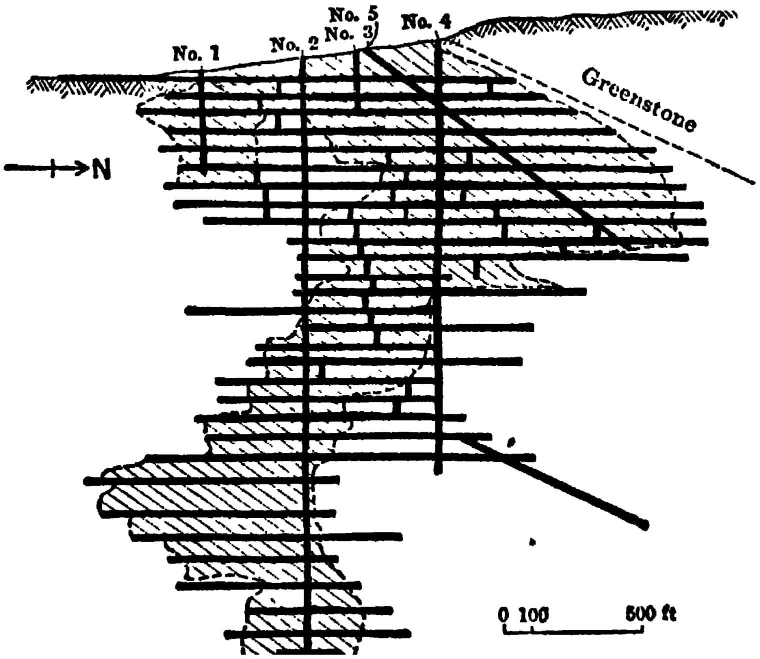

Fig 112. Central Copper Mine (Longit Sec in Plane of Vein)

Location of oreshoots. Fig 111 shows a single large oreshoot having a flat pitch in plane of vein. With shaft in position *AB*, length of drifts through barren ground increases rapidly with depth. Inclined shaft *CD*, if sunk in or under the orebody at an angle to the dip, will reduce amount of dead work; but, results of this plan are often disappointing, because of the usual irregularities of oreshoots. From other standpoints, a choice of the two methods is similar to that between vert and inclined shafts (Art 15).

Fig 112 is an example of such work. The oreshoot lay in a narrow vert fissure, pitching N across a series of conglomerate and amygdaloid beds, and passing into greenstone to the north. During first 6 years after discovery, 4 vert shafts were successively sunk to the 120-ft level. Inclined shaft No 5 was sunk in the vein to shorten lateral haulage to shaft No 4, and to avoid sinking another vert shaft through greenstone where fissure was barren and maintenance cost high; it also reduced surface tramming distance. The incline, which was begun when shafts 2 and 4 were about 500 ft deep, bottomed the shoot at between 700 and 800 ft; it was then abandoned and the shoot followed with shafts 2 and 4.

In case of a pitching oreshoot passing through the end line of a property, as at *EF* (Fig 111), the problem of entry on the adjoining ground is like that presented by deep-level mines. Position of oreshoots largely determines position of raises, as they are kept in ore to provide points of attack and ventilation for stopes (Art 19).

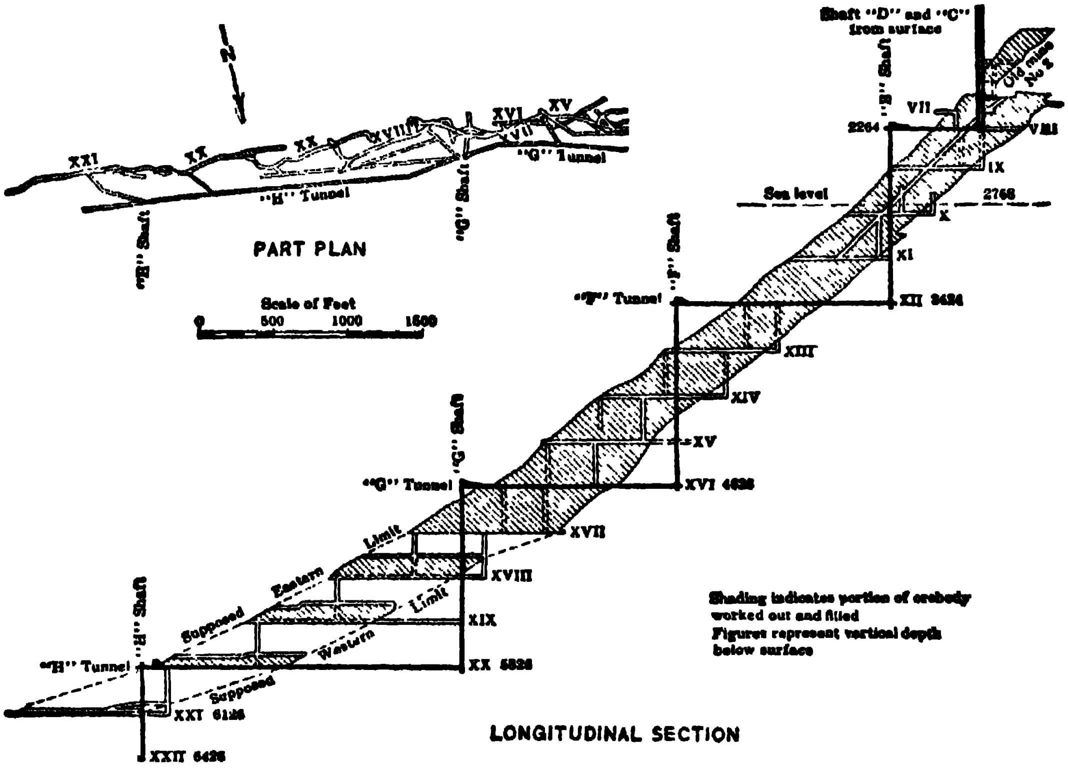

Fig 113. Development at Medium Depth, Morro Velho Mine, Brazil

An example of awkward development, caused by the position of an oreshoot and lack of confidence in its persistence, is found at the Morro Velho mine, Fig 113. The oreshoot lies in an almost vert vein; it pitches 45° at the surface, flattening to 19° at a depth of 6 100 ft, and becoming still flatter and more irregular at 6 700 ft. The 2 264-ft level is reached by vert shafts from the surface. Below this, is a series of vert shafts sunk from tunnels as shown (517). In 1928, the 6 900-ft (No 24) level was working and development had started at 7 000 ft. In 1937, total depth was reported as 8 050 ft.

Deep mines. Peculiar development problems arise where mining rights terminate at vert planes passed through surface property lines. Fig 114 illustrates conditions on the Rand. Gold-bearing beds, locally called REEFS, extend to great depths. Dips vary greatly; in the central Rand, aver dip at outcrop is 50° to 60°, flattening to about 30° in depth. Properties worked from the outcrop are called OUTCROP MINES; those covering adjacent extensions on the dip are known as first row, second row, etc, of DEEP-LEVEL MINES. There are 3 modes of opening a deep-level property underlain by an inclined deposit: (*a*) A vert shaft is sunk to the reef near the rise boundary, and continued as an incline in the footwall, the 2 parts of the shaft being joined by a carefully designed curve; called TURNED-VERTICAL or compound shaft (*XYZ*, Fig 114). (*b*) A CENTRAL VERTICAL SHAFT *AB* is sunk, and the reef reached by crosscuts. (*c*) An arrangement similar to (*a*) except that the vert and inclined parts of shaft are not directly connected. Inclined shaft, operated by an independent underground hoist, delivers ore to pockets which feed skips in the vert shaft. This is STAGE HOISTING (Sec 12). Fig 115 shows arrangement at Crown Mines, Ltd, Witwatersrand (71).

On the Rand the turned-vert shaft has been common for first and second rows of deep-level mines, largely because it brings the mine to the producing stage quicker than a central vert shaft, thus saving interest charges on the large capital necessary to open and equip a deep-level property. Other advantages as compared with central vert shaft, are: saving in crosscuts and raises, and ultimate utility of shaft to any depth. Disadvantages: cost of extra length of inclined section; slower hoisting, due to necessity for slowing down at curve; greater wear and tear on incline and on ropes, especially around the turn. From standpoint of first cost, choice is based on comparison of inclined shaft YZ (Fig 114) and vert shaft CB; result is governed by dip (Art 15); the flat dips of the Rand obviously favor inclined shafts (20). Some engineers favor the central vert shaft for all cases (for further detail and different points of view, see Bib 30, 70, 72, 73). In 1937, several new vert shafts were in progress, expecting to cut the reef at 6 000 ft or more. In 1934, Robinson Deep was stoping at 7 500 ft and developing at 8 500 ft, vert depth, the deepest mine in the world. At 7 large Rand mines, aver depth advanced per year, 1917 to 1935, was 160 ft (195).

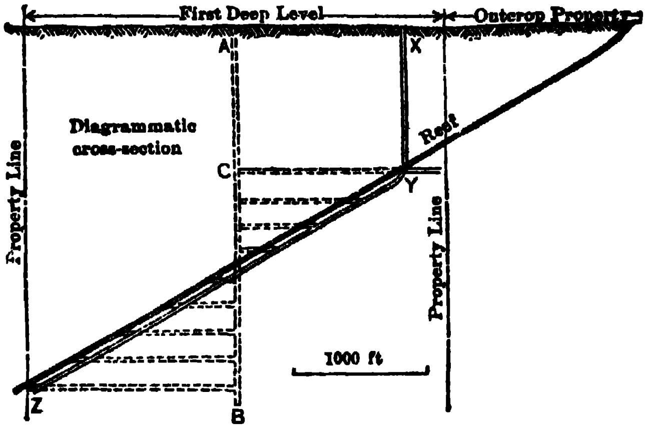

Fig 114. Outcrop and Deep-level Mines, Witwatersrand

Factors of reduced speed and increased wear on hoisting rope, etc, become serious as depth increases, and, combined with mechanical difficulties in deep hoisting, have led Rand engineers to favor stage hoisting for depths over 3 000 ft. If proper storage or rapid transfer is provided at transfer point, stage hoisting greatly increases the capacity of a shaft, since both parts of it can be hoisting simultaneously. Comparative costs of hoisting reported for turned-vert and stage hoisting are in favor of the former; this is to be expected unless depth is great and excess capac of the stage system fully utilized. A turned-vert shaft can be converted to stage hoisting, as in case shown by Fig 115. For stage hoisting designed for 7 000 ft depth, see Bib (516). See also Sec 12.

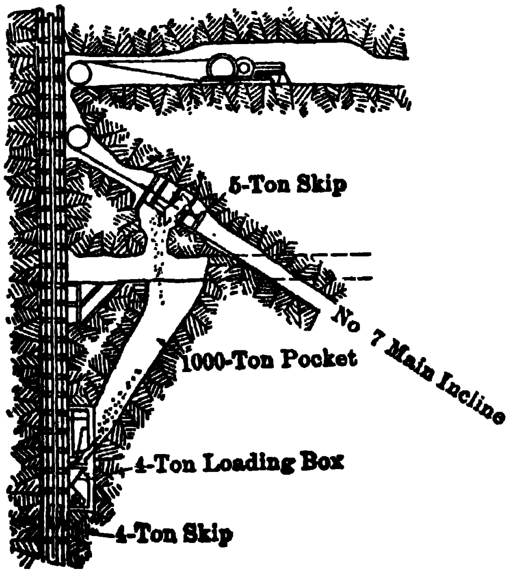

Fig 115

Michigan copper region. Fig 116 shows approx property lines of a group of mines covering outcrops of Calumet conglomerate and Osceola and Kearsarge amygdaloid beds. Dip of beds, 37° to 38°.

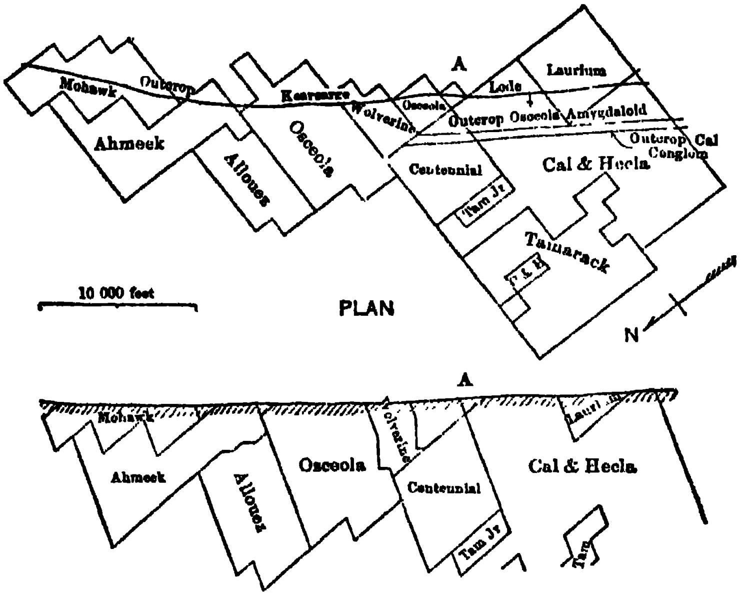
Tamarack Co worked the underlay of the Calumet conglomerate through 5 vert shafts, ranging in depth from 3 409 to 5 308 ft. No 5, the deepest, cut the vein at 4 062 ft; bottom of shaft was over 1 600 ft horizontally from the vein. From the bottom crosscut of No 3 shaft (depth 5 253 ft) an incline in the vein was operated by a compressed-air hoist. This was to save deepening the shaft and driving long crosscuts, which had high maintenance cost. Calumet & Hecla Co worked this conglomerate bed for length of 2 miles through 10 inclined shafts in the vein, deepest being 9 300 ft on dip (1937). There is also a vertical shaft, the Red Jacket, 4 920 ft deep, cutting lode at 3 287 ft, which handled copper rock from all northern shafts below 56th level; it had crosscuts to lode on every third level from 36th to 81st. Tract lying between Tamarack Jr and Tamarack (Fig 116), about 1 300 ft wide and 6 600 ft long was opened by an inclined shaft, 25 ft in footwall and sunk from 57th level. This shaft dips only 22°, due to position of property lines which forced the shaft to take a direction at an angle to dip of vein. Mine cars were

hoisted in this shaft and transported mechanically 1 500 ft on 57th level to Red Jacket shaft. This plan saved a very deep and costly vert shaft.

Lower half of Fig 116 is a projection of property lines on plane of Kearsarge lode, which outcrops as shown and dips 34° to 42°. Ahmeek Co opened its property with 4 shafts, 2 of which were sunk in the lode from outcrop. To develop northern part of property, where outcrop is owned by Mohawk Co, 2 shafts were sunk, starting on angle of 80°; at 980 ft, they curve on a 400-ft radius and enter the Kearsarge lode at 1 275 ft, on angle of 34°. There are 3 levels, reached by crosscuts, above point of intersection of shaft and lode. These 2 Ahmeek shafts start on surface close together, but diverge to N and W.

Allouez Mining Co sunk 2 turned shafts to Kearsarge lode, starting from surface at angles of about 80°. Depths to change of angle are 1 435 ft and 2 307 ft; total depths 3 544 and 3 407 ft (1915). Tamarack, Ahmeek, and Allouez mines are controlled by Calumet & Hecla Co. The turned shafts were sunk in the light of experience gained from the deep Tamarack and Red Jacket vert shafts and their long crosscuts.

Centennial mine has a small tract *A* (Fig 116), covering outcrop of Kearsarge lode, and a right of way 100 ft wide connecting it with the large underlay property shown. Due to these conditions a novel mode of entry was adopted. Two inclined shafts were started in the outcrop, close together; southerly shaft runs straight down the dip; other is parallel until the underlay property is reached, where it curves 15° to the north in plane of vein. A compound curve, 300 ft long, has a slight reverse at each end to keep the rope on idlers, and skip slows down in passing the turn. The hoisting rope has shown greater wear than on the straight incline; otherwise the arrangement is satisfactory (67). For further data, see Bib (486, 487, 488, 489).



PROJECTION ON PLANE OF KEARSARGE LODE

Fig 116

North Star mine, Cal. Here a turned-vert shaft had a different purpose. A gold-quartz vein dipping irregularly, but at aver of 26°, was opened by an inclined shaft. Later a 1 592-ft vert shaft was sunk to intersect vein at 4 000 ft on dip and thence continued as an incline to 6 300 ft, or 2 412 ft vertically. This shaft reduced haul to surface by 2 370 ft, and its first cost was justified by saving in hoisting cost. This vert shaft has since been deepened to just below 3 495-ft level for working of deeper veins with opposite dip, and turned-vert hoisting is no longer employed (481). High maintenance cost of a long incline through old workings may also justify an opening of this kind. Red Jacket shaft, of Calumet & Hecla Co, is an example of a vert shaft used as an auxiliary opening with similar purpose. It saved about 2 100 ft hoisting distance, and maintenance cost of a 5 400-ft inclined shaft.

Reopening an abandoned mine on an inclined deposit, the upper parts of which are worked out, presents a similar problem. Choice is between vert, turned-vert, and inclined shaft, and is guided primarily by depth to virgin ground and dip of deposit. Mt Lyon mine, N Y, is an example showing the numerous factors to be considered. Orebody is a mineralized zone 100 to 200 ft thick, containing a concentration of magnetite at or near upper border; workable width 24 to 40 ft; aver dip, 60° to 65°; country rock, very hard gneiss. Mine was worked out to depth of 700 to 900 ft vert. In 1914, it was decided to reopen with an inclined footwall shaft (dip 63°), 25 to 50 ft below deposit Proposed depth of shaft, 1 200 ft; to be extended ultimately to 1 800 or 2 400 ft. Reasons for choice were: high cost of crosscuts and ore pockets for a vert shaft, because of the very tough rock; cheaper and faster sinking in the lean mineralized footwall zone; freedom of footwall location from subsidence due to mining operations; a vert shaft to develop territory below the old mine would be 100 ft lower than, and 1 000 ft distant from, present concentrating mill, while inclined shaft would deliver ore direct to mill (74).

Handling ore underground. To secure economical handling, haulage drifts and crosscuts should be straight or change direction by easy curves, and should be driven on regular grade. Importance of these points varies with size and output of mine and method of haulage. Following are extreme cases:

(*a*) In mining narrow veins, as those in Gilpin Co, Colo, the tonnage per shift from any level is small; tramming is done by hand, and drifts properly follow the ore with little regard to straightness. (*b*) At Crown Mines, Ltd, Rand, a main haulage level, 14.5 ft wide and extending full length of property (about 3 miles), connects 2 shafts at a vert depth of 2 200 ft. This drift is straight and lies in footwall. It was designed for elec haulage to handle 9 000–10 000 tons per day. Other main haulageways are to be driven as required at vert intervals of 600 ft. There are also the regular drifts in the reef.

Haulage problems, especially in flat orebodies, influence location of openings. If the shaft or other opening enters orebody at its lowest point, all grades in the haulageways will be in favor of loaded cars. A location favorable for lateral haulage is also favorable for drainage, and *vice versa.* Methods of handling in stopes, dip of orebody, and plans of development are also interrelated (Art 19).

Drainage. In some cases, development work can be planned to reduce pumping costs (see Tunnel entry, Art 14, 15). Drainage also makes it desirable to locate shaft or other openings to tap the lowest point of flat-dipping or basin-shaped orebodies; lateral workings then drain toward shaft and auxiliary sumps and pumps are unnecessary. One function of lateral development is to drain overlying ore. In soft, wet orebodies, like some Michigan iron deposits, this influences amount of development done in advance of mining. New levels are opened in time to let the ore drain before extraction begins. This also tends to regulate flow of water and make pumping operations fairly uniform (76).

Ventilation may require that all development openings be run in duplicate. This is done in collieries, and allows complete control of ventilating currents (Sec 14). In metal mines using little timber, or in very wet mines, proper ventilation may mean a mere supply of fresh air to remove foul air and powder fumes. Then ventilation is often obtained by arranging openings to cause natural draft. In relatively dry mines using much timber, the danger of mine fires demands close control of air currents; usually secured by fan installation, systematic layout of openings, and proper placing of doors. Development headings are often ventilated by auxiliary fans, with metal or canvas tubing carried to the working face (Sec 14).

17. NUMBER OF OPENINGS

Determining factors. VENTILATION AND SAFETY demand at least 2 openings to surface; they are required by law in many districts. In metal mines, stopes reaching the outcrop often afford an adequate second opening; in collieries, rigid ventilation requirements compel at least 2 openings. Other conditions to be considered: (*a*) Required OUTPUT may be in excess of capacity of a single shaft; this is unusual at ordinary depths, as a shaft can be designed to handle large tonnages. In deep shafts, the time required to get men on and off shift through a single shaft is serious; this, together with time for handling timber and supplies, greatly reduces ore-handling capacity. (*b*) SEPARATE OREBODIES may require separate shafts; depending on their size, distance apart, depth below surface, and surface conditions. Separate shafts are sunk to effect a saving over cost of entry from, and handling through, another shaft farther away. This is a matter of estimate in each case; size of orebody concerned must be sufficient to return excess cost of separate shaft out of the saving effected. Cost of shaft sinking increases with depth, that of drifts and crosscuts does not; hence, increasing depth should reduce the number of shafts and increase the area served by each. Topographic or other conditions affecting surface transport may prohibit separate openings; conversely, they may show a saving in surface over underground transport which alone will justify a separate shaft. Above statements apply also to veins in which several oreshoots occur, separated by wide barren or low-grade areas. At a large group of lead mines in S E Mo, formerly producing through 21 shafts, workings have been connected underground and entire output is now hoisted in 1 shaft near mill (155). H. C. Hoover points out that if cost per ft of shaft sinking is 4 times that of drifting, 4 levels through 1 000 ft of barren vein cost no more than 1 shaft 1 000 ft deep (20). (*c*) METHOD OF UNDERGROUND HAULAGE. Fig 117 is a diagrammatic section in plane of an inclined vein in a property of considerable length. If ore occurs scattered throughout whole vein, question arises whether it is better to sink 1 central shaft *A*, or 2 shafts *B* and *C*, placed at quarter points, or several shafts. This is

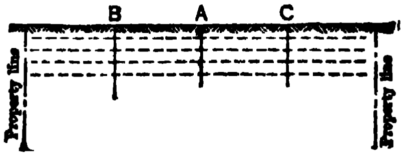


Fig 117

determined largely by method of haulage on levels. Cost of hand tramming per ton increases rapidly with distance; there is a limiting length of tram beyond which a new shaft will save its cost; economic limits for animal and mechanical haulage are higher. Tonnage produced per shift on 1 level affects method of haulage (Sec 11). Where small, it may be possible to install mechanical haulage on every second or third level, ore from levels above being transferred to the haulage level through winzes at distances apart which are within the economic limit of hand tramming.

Michigan copper mines are illustrations of properties covering long distances along the strike of persistent lodes (Fig 116). Hand tramming was formerly universal, and a shaft was sunk about every 1 000 ft along strike. There are instances of 2 shafts 600 ft apart reaching depths of over 3 000 ft. Later shafts were farther apart; aver distance for the district in 1912, 1 600 ft. At Quincy mine, with elec haulage, aver tram is 1 800 ft.

Outcrop mines on the Rand. Where length of property along strike was less than 1 500 or 2 000 ft, only 1 main working shaft was sunk; on longer properties 2 shafts were deemed necessary to facilitate development and for ventilation (25). Transvaal law requires 2 exits. Shafts in first row of deep-level properties are as close as 1 000 ft, but usually 2 000 ft apart. Nearly all tramming is by hand, but labor is cheap. Many deep-level properties have been consolidated and cover large areas (400 to 900 claims of 1.4 acres each); where possible, in such cases, distance between shafts is 3 000 to 4 000 ft (78). Occasionally, where connection could be made with adjoining property, large areas were opened by 1 deep shaft. Mechanical haulage concentrated on a few levels has been introduced as area controlled by one shaft is increased (Art 16). Brakpan mine, East Rand, illustrates the application of the same principles to a flat orebody of large area; property is 6 000 by 14 000 ft; reef dips only 7°. Two shafts were sunk 4 400 ft apart in direction of dip; No 1 cuts reef at 3 098 ft; No 2, at 3 707 ft. They are connected at bottom by an incline 4 500 ft long on dip of reef, from which levels are opened (79).

From standpoint of UNDERGROUND HAULAGE, ideal location for a single shaft is one giving minimum aver tramming distance. It is obviously impossible to determine exactly such location in advance. In massive orebodies like porphyry coppers, the tonnage and shape of which are determined by boring in advance of development, gathering points on each haulage level can be found to which ore can be brought with minimum aver tram, taking into account the required lateral development; the nearest feasible location of shaft to these points gives shortest aver tram.

18. LOCATION OF OPENINGS

Underground conditions affecting location of openings with respect to dip and strike of deposit, and from standpoints of geology, maintenance, haulage, drainage, and ventilation, are discussed in Art 15–17, 19. Shafts for massive deposits, especially those mined by caving methods (Art 70–88), should be located beyond the possible limit of ground movement around the orebody.

Surface conditions. TOPOGRAPHY affects location of openings. Sites for necessary buildings must be available; shaft and tunnel locations are often planned with reference to a mill; permanent mine openings should avoid gulches or places where flooding would result from cloud-bursts; in mountain regions, the location must be planned with reference to possible slides of rock or snow.

Topography is also related to questions of SURFACE TRANSPORT. Lowest location possible for mouth of a tunnel is desirable, as it gives the highest backs of ore above tunnel level; it is often determined by position of a R R for shipping ore, or by topographic conditions affecting position of a spur track to be built from an existing road. A shaft location must also be planned with reference to existing or proposed R Rs, wagon roads, or other means of transport; this concerns handling supplies to the mine as well as ore from it. PROPERTY LINES and their relation to outcrops may affect location of entry (Art 16, Deep mines). In combination with topography, they may limit dump room below a proposed opening and modify its location.

In general, ore and waste should be delivered from a mine opening at a point high enough above the surface to allow gravity transfer to surface transport. Such elevation may be obtained artificially, or position of entry planned to secure it in connection with topography. Ideal location is not possible; a compromise is always necessary.

19. LATERAL DEVELOPMENT

Interval between levels in inclined orebodies varies from 50 to 300 ft; commonest interval, largely the result of custom, is 100–150 ft, but practice tends towards greater distances where feasible.

Factors limiting distance between levels: COST. Drifting is NARROW WORK, costing more per cu ft than stoping; each drift requires timbering, track, pipe, and ditches, which must be maintained during life of stopes above. Cost of shaft stations, and plats or bins, can be reduced by concentrating haulage on alternate or third levels. Possibility of using electric-driven primary breakers underground, together with improvements in mechanical haulage, has increased tendency to concentrate haulage on one or a few levels, especially where large blocks can be broken and handled from stopes. From standpoint of first cost, a long interval between levels is desirable. TYPE OF OREBODY. High-grade, spotted or pockety mines require levels to be close together to avoid missing orebodies; a wide interval in such cases also adds to cost of reaching and extracting scattered pockets. SUPPORT OF HANGING WALL. Levels sometimes form one side of pillars left to support roof; allowable area of unsupported hanging wall then limits level interval, unless some form of filled stoping is practicable. SPEED OF STOPING and character of ground are related factors; level interval should be such that stopes are completed and abandoned within the time that they can be kept open without undue maintenance cost. Thus, at Leonard mine, Butte, Mont, a 200-ft interval in vert, filled, square-set stopes increased cost and decreased speed of mining in the upper 100-ft lift to an extent which warranted driving intermediate levels at 100-ft intervals (80). METHOD OF MINING. A retreating system, where stopes are started at property lines and abandoned as they are carried back toward entry, may allow a larger level interval than an advancing system. Cost of maintenance of levels themselves generally increases with the time they are kept open. This is again related to speed of stoping and method of mining, and may determine the max interval. In small-scale work, on a short, high-grade oreshoot, the time required to stope one lift determines time available for sinking and drifting through the shoot on next level, and consequently determines level interval; such conditions arise in leasing. DIP OF OREBODY, if over 40° to 45°, allows broken ore to fall by gravity to level below; if less than 10°, cars can generally be run to working faces. In these two cases, the dip does not limit max level interval. On intermediate dips, if ore is shoveled to drift, the level interval should be small; for economic limits of distance with other handling devices in flat stopes, see Art 91 and Sec 27. REGULARITY OF DEPOSIT influences handling methods and therefore the level interval; an irregular footwall increases the limiting angle on which ore slides and always requires some shoveling. Badly faulted deposits require levels placed to reach displaced blocks regardless of other factors; such conditions at Golden Messenger mine, York, Mont, were overcome by numerous, short sub-levels connected by raises to main levels 250 ft apart, on dip (69).

Economic level interval in any mine is a matter of experiment. The deeper levels are usually spaced farther apart than the upper, because early work determines the mining factors, and reduces the exploratory function of these openings. On the RAND, the level interval in some properties has been increased to a startling extent. At Modderfontein B mine, ore is developed in blocks 800 by 1 000 ft; at New Modderfontein, level interval is 500 to 600 ft, with footwall main haulage drifts 1 700 to 2 000 ft apart; at Brakpan mine, level interval varies from 300 to 1 200 ft. This practice, due to an attempt to cut down development cost, has not been uniformly successful. It is made possible in these mines by: (*a*) very flat dips (7° to 10°), allowing cars to run to stope faces; (*b*) regularity of vein; (*c*) knowledge of reef characteristics, resulting in confidence in the continuance of value and size over large areas (75, 79, 81, 82). At MAGMA, ARIZ, a nearly vert vein was developed at 100-ft intervals to 2 000 ft; next 2 intervals were 250 and 300 ft. On failure to realize expected economies, due to difficulties with ventilation, handling timber, and maintaining chutes, subsequent intervals were 200 ft, and the larger intervals were each subdivided by an intermediate drift (77).

Raises and winzes. For following indications or exposures of ore up or down from a level, the location of raises and winzes depends entirely on ore occurrence. To determine outline and value of shoots, raises are often made at fairly regular intervals. For this purpose the interval should not exceed that over which ore may be expected to persist without material change in thickness, character, and tenor.

Closer spacing than the level interval is not justified; max distance, 100 to 500 ft or more (see Modderfontein B mine, above), depends on experience with a given orebody. In connection with method of mining, raises and winzes provide entrance to stopes; serve for handling ore, waste for filling, and supplies; stoping usually starts from them. For these purposes, their location varies greatly (see individual mining methods). In veins where ore occurrence is regular, the output required, combined with distance to which development has been carried in advance of stoping, may determine the raise interval. Each stope has a limited tonnage possibility; number of stopes that can be opened simultaneously depends on available points of attack and extent of development. Regarding WEST AUSTRALIA PRACTICE, E. D. Cleland states that, when development is considerably in advance of ore requirements, the winzes (or raises) in lowest level may be 300 to 500 ft apart, and are sunk merely as a guide to future stoping. In upper levels where stoping is in progress, or about to begin, the raise or winze interval must be 125 to 150 ft. This holds for veins having fairly regular ore occurrence; where ore is irregular, no figures can be given (83). S. J. Truscott (30) states that in deep-level RAND mines, where development is kept well ahead of stoping, winzes are 400 to 500 ft apart; throughout the district, the interval is from 200 to 500 ft. Up to the limit fixed by loss of interest on money spent in advance development, the smaller the number of winzes (that is, the greater the interval between them), the less the cost of development.

Ventilation. Connections between levels are essential where natural ventilation (Sec 14) is relied upon. Raises for stoping usually suffice for ventilation; ventilation requirements may control their location. For example, delays while waiting for smoke to clear after blasting limit speed and increase cost of drifting; with natural ventilation, delays increase with length of drift beyond a raise holed to level above. On important work, blowers are used, and make the raise interval independent of ventilation; but, with natural ventilation, there is an economic limit beyond which either increased cost or slowness of drifting makes a new raise advisable. This limit, controlled largely by local factors and policy, is 250 to 500 ft or more. Mechanical ventilation in metal mines is increasing, especially in large or deep mines. Experience proves that its expense is justified by increased effic of labor and operations (Sec 14).

20. DRIFTING AND CROSSCUTTING

Sec 6 gives data on choice of drills, mountings, and explosives; comparison of 1-, 2-, and 3-shift work; methods of charging and firing; mucking; driving through soft ground.

Mine drifts and crosscuts differ from tunnels as follows: (*a*) usually of smaller cross-sec; (*b*) less emphasis laid on precise alinement and shape of sec; (*c*) in breaking ground, advantage may be taken of relative softness of orebodies and adjacent rocks, of planes of weakness due to banding, slips, or well marked walls; (*d*) tunnels are usually more permanent than drifts and crosscuts, and hence may require more elaborate timbering; (*e*) some tunnels bear entire cost of installing and operating the plant for drilling, ventilation and transport; for drifts and crosscuts, such overhead is usually distributed over many openings.

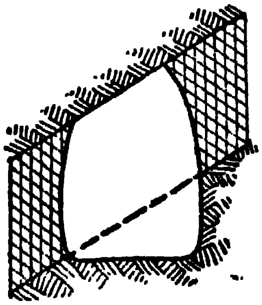

Fig 118

Shape of cross-section of CROSSCUTS is same as that of tunnels (Sec 6). UNTIMBERED DRIFTS and crosscuts should have an arched back, which tends toward self-support and reduces subsequent spalling. Importance of arched shape is less in strong rock and narrow openings; in flat-dipping or bedded deposits the hanging wall often forms the back of drift and gives no trouble if not broken into (Fig 118). Shape of TIMBERED DRIFTS varies with irregularities of ore occurrence and method of mining (Fig 141–147; see also Art 30 42).

Size of cross-section for typical drift sand crosscuts is given in Table 18. It depends on following factors: (*a*) In EXPLORATION (Art 12), cross-sec is made small; this lessens cost, largely by reducing amount of muck to be handled. Smallest section advisable is 6 to 6.5 ft high by 3.5 to 4 ft wide. Smaller openings rarely effect a saving, because cramped space reduces efficiency of labor. (*b*) SIZE OF CAR determines minimum width of development drifts and crosscuts (see Sec 11, Art 3, 4, 6); small cars for hand tramming, 24 to 28 in wide and holding 1 600 to 2 000 lb, require a minimum clear width of 4 to 4.5 ft for single track, and 7.75 ft for double. For larger cars, cross-sec of opening is designed to fit. Clearance between sides of car and posts of drift sets is usually 12 in minimum; this gives 18 to 24 in between car and lagging, or room enough for a man to stand without being caught. For safety in untimbered openings, at least 24 in should be left between car and wall on one side of drift; clearance on other side may be only 4 to 6 in. Minimum clearance between cars on double-track is 6 to 8 in. Larger clearances are always desirable, especially for high speed and heavy cars. (*c*) METHOD OF LOADING. Shovelers need a total width of about 7 ft to work on both sides of a small car at face of a drift. Some mechanical loaders (Sec 27) will work in an opening 6 by 4.5 ft in clear; many require more room. (*d*) DRAINAGE DITCHES for handling large amounts of water may increase width of drift or crosscut beyond that required by car. (*e*) Requirements for VENTILATION (Sec 14) may determine minimum size of opening. (*f*) In veins to 8 or 10 ft wide, drifts in oreshoots are often carried full width of vein, thus reducing cost per ton of ore obtained.

(*g*) **Height of drifts** and crosscuts is a matter of headroom; 6.5 ft clear is the minimum. Height of trolley wire above rail in haulageways is fixed by statute in some states.

Drifting and crosscutting by hand drilling is done in connection with exploratory work (Art 12) in small mines, where expense for plant is not justified, and in districts where skilled labor is not available for running machine drills. Drill holes are not spaced systematically, but placed to take advantage of all irregularities in the face. Drilling is done double-hand in hard ground and single-hand in aver ground; hand auger is cheapest and best for soft ground containing few hard streaks, and in coal.

In small drifts, 7 to 12 holes, 2 to 2.5 ft deep, are necessary to advance face 1.5 to 2 ft. These figures vary widely with hardness and toughness of rock; in aver ground an advance of 0.7 to 1 ft per shift in a 1-man drift or crosscut is good work.

Examples. At Bodie, Cal, 1 miner drilling single-hand in 5 by 7-ft drifts and crosscuts, width of veins 3 to 30 in, vein rock varying from hard banded to soft granular quartz, country rock firm, fairly hard andesite, advanced 1.304 ft in drifts and 1.187 ft in crosscuts per 8-hr shift (84). At Rhyolite, Nev, 1 miner drilling single-hand in drifts 4.5 by 6.5 or 7 ft, in fairly soft mineralized porphyry, made 0.5 to 3 ft per 8-hr shift, aver 1 ft (tracklaying, mucking, and tramming was done by other men). Following data apply to a tunnel driven by hand in Ariz (1913): cross-sec, 5 by 7 ft; length, 374.5 ft; aver tram to dump, 875 ft; rock, fairly soft porphyry; no timber required; 3-shift contract work by Mexican labor, 1 miner and 1 helper on each shift doing drilling, blasting, mucking, and tramming. Tunnel was completed in 500 man-shifts in 91 days. Aver advance per man-shift, 0.75 ft, varying from 0.359 to 0.852 ft; aver progress per day, 4.12 ft; explosives consumption, 2.32 lb of 40% dynamite per ft of advance.

Table 15 gives data for Mexican labor (1910). Daily advance (3 shifts) was fair, but progress per man-shift low. Ventilation was poor in timbered drifts No 3 and 4. Dynamite consumption was low, due to character of rock and size of cross-sec.

Table 15. Drifting and Crosscutting, Esperanza Mine, El Oro, Mex, 1910 (85)

		Width, ft	Height, ft	Kind of ground	Distance driven, ft	Aver daily advance, ft	Lb 60% dynamite		Labor per ft		Aver advance	
							Per lin ft	Per cu ft	Miner shifts	Peon shifts	Per man-shift, lin ft	Per man-hr, cu ft

6	Drift.....	5	7	(*b*)	143	2.58	0.43	0.012				

(*a*) Fairly hard andesite. (*b*) Friable quartz (*c*) Soft swelling andesite. (*d*) Moderately hard shale. (*e*) Hard, tight andesite.

A. L. Oke gives following data on hand work by native labor at mines in Mexico and Argentine (86): Mexican mine; double-hand drilling; 7/8 and 3/4-in steel; long handled, 8-lb hammers; Mexican dynamite, 40% and 60%, depending on ground; dry, hot, poorly ventilated mine; aver ground tough, rather than hard; fairly clean hanging wall to break to; 8-hr shifts. Aver progress per man-shift in softer drifts, 0.76 to 0.91 ft; in hard ground, 0.31 ft. Max advance in drifting in a week of 11 shifts, 3 men on day and 2 men on night shift, 32 ft. Men drilled about 9 ft of holes per shift in soft ground; 3 to 3.5 ft in hard ground. Argentine mine; single-hand drilling; 7/8-in steel; short-handle hammers, 6 to 8 lb; English gelignite and gelatin; dry, cool mine, poor ventilation, rock andesite and granite; shifts 8–10 hr. Aver progress per man-shift in drifts and crosscuts in soft ground, 0.91–1.22 ft; in hard ground, 0.37 to 0.55 ft. Usual advance in drifts, 2 shifts, 1 man on each, excluding Sundays, was 50–60 ft per month in softer ground; 20–30 ft in hard ground. Men drilled about 10 ft of hole per shift in soft ground; 5–6.75 in hard ground.

G. L. Schmutz in 1920 (523) compares powder consumption at a Mexican mine, in hand and machine drilled drifts, as follows (figures in lb per ft advance). Hand: min 3.0, aver 4.5, max 7.0. Machine: min 5.0, aver 8.0, max 14.0. By more careful control of powder, aver was cut to 3.61 and 7.39 respectively.

Table 16 shows how hand work economizes powder by skilful but unsystematic placing of holes, an advantage offset, however, by slower speed per man-shift (492). Machine drilling was by light, mounted drifters; hand drilling all 1-man work, in slightly softer ground. Machine drifts, 4.5 by 6.5 ft, 10% timbered; machine raises, 5 by 5, or 5 by 10 ft. Hand drifts, 4 by 6 ft; raises, 5 by 5 ft. Two expert hand-drillers on opposite shifts in a drift averaged 1.2 ft advance per shift each, tramming 600 ft.

R. B. Dickson records (56) hand driving of 60 ft of 3.5 by 6.5-ft drift in a fairly soft vein at high elev in San Juan district, Colo. Round of 10 15.8-in holes was drilled at 83 in per shift; aver advance, 0.682 ft per man-shift (about 20% of time being otherwise occupied); explosive (40% gelatin), 4.21 lb per ft advance.

C. L. Larson gives data (in 1914) from Chiksan mines, Korea (87); Drifts 5 by 7 ft, in quartz veins; 3 shifts, 4 men (Koreans) per shift, double-hand drilling. From 4 to 7 ft of hole is drilled per man-shift. Two 10-hr shifts give cheaper work, but less speed. Monthly advance, from 30 ft in hard to 70 ft in good ground. Dynamite consumption (gelignite, 60%), 2 to 2.5 lb per linear ft. Cost per ft, excluding hoisting, about $3.40, of which $0.16 is for timbering. Cross-cuts, 4 by 6 ft, are untimbered; 2-shift work of 2 men each; in soft schist, dynamite consumption was about 2.2 lb per linear ft; in hard schist and granite, about 4.8 lb; cost per linear ft in soft ground, $2.67; in hard ground, $4.14. Wages: hand drillers, $0.25; muckers and trammers, $0.20 per shift.

Table 16. Hand *vs* Machine Development, Questa, NM

Period of 6 mo in 1930	Machine work	Hand work

Supervision	.28	.28
Total direct cost	$6.81	$6.46
Interest and deprec on compressor and drills	.60	....
	$7.41	$6 46

Practice in drifting in Mesabi iron mines, Minn, illustrates speed obtainable with hand auger drill in soft hematite. C. E. van Barneveld (35) gives following data (in 1912). Work was on contract; two 10-hr shifts; 2 men on each shift. Men did their own timbering, track-laying, and local tramming to distances of 300 ft. Drilling was done with hand augers, 3.5, 4, 6, and 8 ft long; hard streaks were broken up by 3 and 6-ft gads, of 1.25-in drill steel. Main drifts were 9 ft wide by 8 ft, inside timbers of unframed 3-piece sets. A round consisted of 5 to 7 6-ft holes. A 6-ft hole was drilled in 10 to 30 min; back holes were loaded with 7 to 10 sticks 40% dynamite, lifters with 6 sticks. Upper holes were fired and mucked first. This reduced powder cost, but entailed delays, twice a round, for smoke to clear; where ventilation was poor, entire round was fired at once. Aver monthly progress, 100 to 125 ft. Rate of advance in smaller drifts was from 200 to 225 ft per month on a 4-man contract. Progress in hand-driven rock drifts, 25 to 40 ft per month.

Machine drills. In this and other articles, terms are used as follows: Drifters, hammer drills attached to cradle, mounted on bar or column, usually run wet; rotation, automatic; feed, either automatic or by hand. Piston-drills are now virtually obsolete. Jackhammers, light, hand-held hammer-drills, but often mounted for drifts or crosscuts in soft to medium ground. Stopers are of hammer type, with an air-operated feed leg; some types automatically rotated; others, hand-rotated; usually unmounted; occasionally mounted by attaching air-feed cylinder to column or bar (Sec 15).

Machine-drill rounds. The term round means location, direction, depth, and number of holes for breaking a given face of ore or rock. Rounds for development openings are classified according to type of "cut." Term cut refers to location and direction of holes blasted first to provide a free face (Art 26) to which other holes may break. Drift and crosscut rounds are draw-cut, inverted or top draw-cut, vert V-cut, horiz V-cut, pyramid-cut, and burned cut, with various combinations and variations.

Data in Table 18, generously contributed by managements and engineering depts of mines listed, show the effect of character of ground and size of cross-sec on number and arrangement of holes, type of drill, powder consumption, and duty of labor. They cover present practice (1938) in important districts of U S, Canada, and Cuba, and include examples in Mexico. Of the 79 examples, 13 are draw-cut rounds, 2 inverted draw-cuts, 11 vert V-cuts, 7 horiz V-cuts, 20 pyramid cuts, 11 burned cuts, 5 of which combine a burned cut with a very acute pyramid, 1 uses no cut, 1 has no system, and 1 uses both draw and burned cuts. Hardness of rock does not seem a controlling factor in choice of cut, since all types are found in hard, medium, and soft rocks. Theoretically, the angle of wedge or pyramid should increase in proportion to toughness of rock; but it has been found that a burned cut is better adapted than any form of angled cut to certain tough rocks. No definite rules can be laid down as to type of round, number of holes and depth of round; choice is determined by experience (also see Table 17).

Fig 120–137 show some rounds to which Table 18 refers. Numbers at holes indicate firing sequence.

Pointing holes is of prime importance. Successful breaking requires locating charges at most efficient points in face. Much experimental work has been done at individual mines to determine best practice under varying conditions (89, 519, 520, 531, 536). Table 17 gives data for spacing and pointing holes.

Note.—Use of table. Ex 1. Round 7 ft deep, distance between collars of 2 cut holes 48 in; in table on 7-ft line find 24 in (0.5 spacing) in 16° column, indicating that 2 holes will intersect if drilled toward each other at this angle; table also shows that holes will each be 7 ft 3 in deep at point

of intersection. Ex 2. It is desired to bottom a 6-ft lifter 4 in below bottom of drift, collar of hole being 6 in above bottom: opposite 6 ft in table find 10 inches under 8°, which is the required angle for lifter.

Table 17. Displacement and Length of Drill Holes. After C. H. Waters (519)

(a) Numbers in bold-face type indicate distance in inches which, when added to depth of round, gives length of hole required to reach that depth.

Hole directors, as used in 7 by 8-ft drift headings by Crown Mines, Witwatersrand, have improved speed and effic, and reduced cost; during a test period of 20 mo, with 6-ft holes in headings of same size, aver advance in 403 " directed " rounds was 4 ft–11.5 in, against 3.5 ft per round in undirected headings (89). Customary pyramid-cut round of 20–24 holes requires a set of 3 directors (of which 2 are shown in Fig 119), with radial lengths of 24, 32, 44 in. Supporting ends of the Y-s form open saddles, the axes of which are permanently fixed (by welding) at such angles with horiz axis of drift as experiment shows most effective. The 50-lb mounted jackhammer is alined in a saddle by aid of a short piece of drill steel, or the starting bit. After clamping the drill, the " director " is swung aside, revolving on the 1-in axial bar previously secured by arm and clamps on the vert column and a shallow hole at center of face.

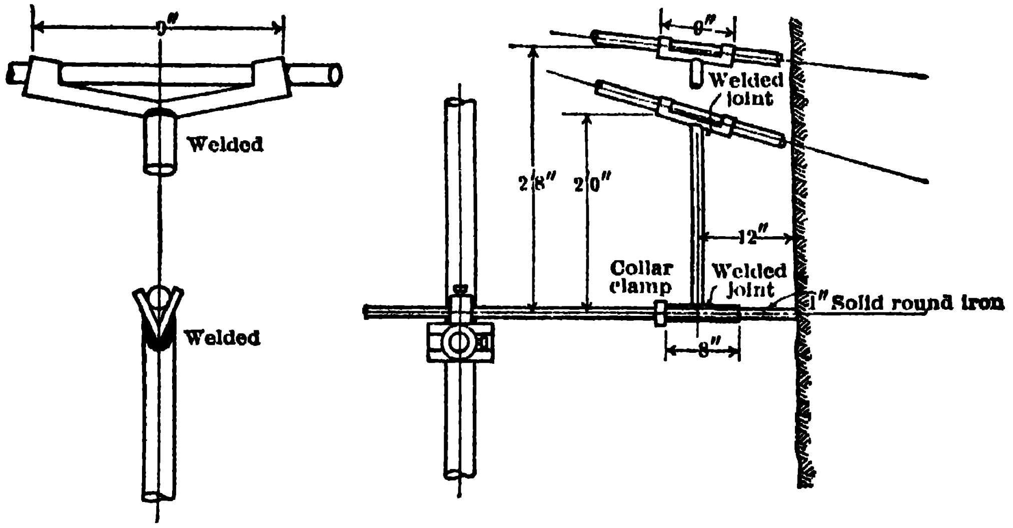

Fig 119. Hole "Directors" for Headings

Drill mountings. Table 18 contains 57 examples of drifts or crosscuts drilled from a vert column, as against 7 cross-bars, 2 tripods, 5 drill carriages, and 8 unmounted drills. With a COLUMN, work is almost always arranged so that drillers have a clean face for starting. The examples of CROSS-BARS, except one, are where speed is sought through simultaneous drilling and mechanical loading. Uppers are drilled from a bar set above muck pile, while the loader cleans bottom of face. On completing mucking, bar is re-set for the lower holes. By this procedure, Lloyd mine, Ishpeming, Mich, advances a 10 by 10-ft drift with a pyramid cut through cherty slate at 375 ft per month, working 3 shifts 5 days per week. CARRIAGES, mounting 4–6 drifters (generally automatically fed) and

(*a*) Incl time for setting-up and dismantling drills. (*b*) Bulk strength. (*c*) Crosscuts only. (*d*) Drifts only. (*e*) 423 ft working 2 shifts and Sundays; 173 ft working 1 shift weekdays only. (*f*) Inclined at 15°–20° downward. (*g*) Lower center breast hole points up slightly. *h* = hard. *m-h* = medium hard. *s* = soft. *m-s* = medium soft. *ls* = limestone. *sh* = shale. *sch* = schist. *dol* = dolomite. *por* = porphyry. *sul* = sulphide. *grnstn* = greenstone. *peg* = pegmatite. *gn* = gneiss. *dr* = drifter. *h-f dr* = hand-fed drifter. *a-f* = automatic-fed drifter. *j'ham* = jackhammer. *col* = column and arm. *bar* = crossbar. *pyr* = pyramid cut. *bur* = burned cut. *b-dr* = bottom-draw cut. *t-dr* = top-draw cut. *v-v* = vert or center V-cut. *h-wdg* = hor V-cut. *gel* = gelatin. *semi-gel* = semi-gelatin dynamite. *am-dyn* = ammonia dynamite. *m-shov* = mechanical shovel. *oc'l* = occasional. *var* = too variable to permit averaging.

used in conjunction with scraper loading, tend to rapid work in large headings in Lake Superior iron district; one mine advances a 9 by 11-ft drift 500 ft per month through quartzite, completing a 7-ft round per shift on a 7-day week, 3-shift basis. At 2 mines near Birmingham, Ala, in drifts 14 and 20 ft wide and 10 and 14 ft high, respectively, drills are mounted on TRIPODS on top of muck pile, working at one side while scraper cleans the other. Unmounted JACKHAMMERS are employed in both large and small headings in medium-soft schist at Inspiration, Ariz; occasionally in the softer ground at Ruth, Nev, using bottom-draw cuts in both; also in sub-levels through medium-tight hematite at Montreal mine, Wis, with V-cuts. Oliver Iron Mining Co uses unmounted jackhammers in headings at 3 of its soft-ore mines (Table 18); at Godfrey mine, Hibbing, a 10 by 10-ft drift is advanced 6.3 ft per round without use of angled cut holes.

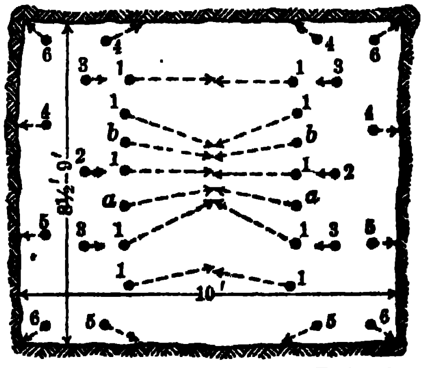

Fig 125. Vert V-cut in Dolomite, Bonne Terre Mine, Bonne Terre, Mo. Holes a, a and b, b, sometimes omitted; 8 side holes are 7.5 ft deep; all others, 9 ft

An unusual mounting sometimes used in 7 by 6-ft headings at Vipond mine, Ontario, when speed requires 2 rounds per day, consists of a horiz bar set 3 ft below roof of drift (or just above muck pile), with a short vert column supported by clamp at middle of bar and braced against roof; drill is carried by cross-arm on the column. Upper holes can

thus be drilled during mucking, on completing which, the vert column is swung down and braced against floor for drilling lower holes. Runner, helper, and 2 muckers advance 5 ft per shift with a 20-hole round, pyramid-cut (493).

Choice of drills for drifting and crosscutting. DRIFTERS are customary for hard ground. Practice favors the lighter, 1-man drills when ground can be drilled efficiently by them. As JACKHAMMERS are lighter, cheaper, and consume less compressed air, they are favored in soft ground, either mounted or hand-held; for a round of very few holes in soft ground, time for set-up may not justify use of mounting. STOPERS, though not designed for drifting or crosscutting, are occasionally useful for this work. Fig 138 shows an inverted draw-cut drilled with stopers at Cripple Creek, Colo (92); except the lifters, all holes point upwards. In using stopers for drifting, it is necessary to support tail piece of drill; Fig 138 shows a simple device, consisting of a sprag, wedged across drift, 4–6 ft from face and 3 ft from floor, a loose piece of 2 by 10-in plank furnishing a base for drill.

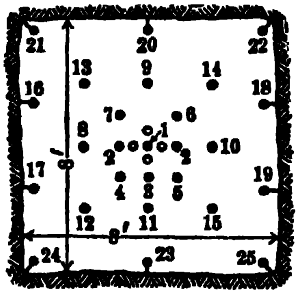

Fig 134. Burned Cut in Tough Limestone, Balmat Mine, Balmat, N Y. Holes average 6.5 ft deep

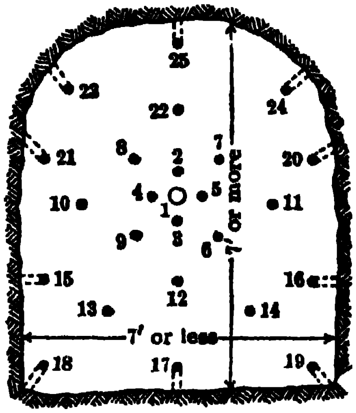

Fig 135. Burned Cut, Franklin Mine, Franklin, N J. Central holes, 8.5 ft deep; others, 8 ft. Center hole, unloaded, has 3-in diam. Holes fired in sequence, as numbered, using fuses all of same length. Loaded and fired in 4 rounds: Nos 2–5, Nos 6–9, Nos 10–14, Nos 15–25

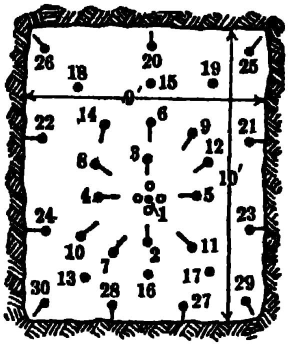

Fig 136. Burned-pyramid Cut, Creighton Mine, Ont

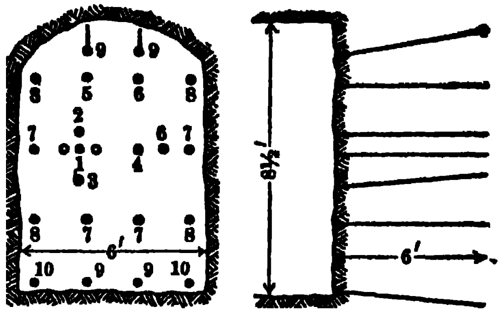

Fig 137. Burned Cut in Cherty Limestone. Junction Mine, Bisbee, Ariz

An A-frame of 2 by 10-in plank (indicated by dotted lines) forms a better support. Fig 139 shows an inexpensive foot-plate, for setting a stoper at any angle from horiz to vert; it is of $^3/_8$-in plate, with ears turned down at corners to hold plate to a plank; to the plate is riveted an angle iron bent to U-shape (94). At Butte, Mont, drifting with JACKHAMMERS, leasers rested the drill in a wooden trough 6 ft long, laid against face in line with hole to be drilled. Drill was held to its work by a short steel lever fitting into holes in bottom of trough (126). Similar device for drilling low, flat holes in S E Mo is like a narrow ladder, with sides at such distance apart that drill can slide on their inner edges (see Art 31); cross pieces on under side, 2 in wide and 2 in apart, offer leverage for end of a pinch bar holding jackhammer to its work. In this easy-drilling limestone, 80–100 ft of hole (starting at 1.75 in) is aver per machine-shift. The jackhammer, when used for higher holes, can be carried by an S-hook of heavy wire hanging from the lugs on end of a piece of drill steel of suitable length standing with its bit on the floor.

Of the 68 DRIFTERS listed in Table 18, 33 are hand-fed and 21 automatically fed (others not specified). The data are not definitely comparable, but it is noteworthy that automatic feed has become widespread. Drifters of medium wt are most numerous; 50 are between 150 and 185 lb, as against 10 lighter and 8 heavier. The heaviest drills in the list, 250 lb, are mounted on a carriage and drill a V-cut round in a 9 by 16-ft heading in greenstone at Montreal mine, Wis; also used with column mounting in a 9 by 10-ft drift at same mine. Of 11 jackhammers, 3 are mounted, 8 unmounted.

Hand mucking and tramming. Speed of drifting and crosscutting is often more dependent on time required for mucking than for drilling and blasting. It is usually cheaper to alternate drilling and mucking crews at any one face, thus giving drillers a clean drift in which to set up, and avoiding interference between drillers and muckers. This is especially important if drilling is difficult, or a large footage required per round.

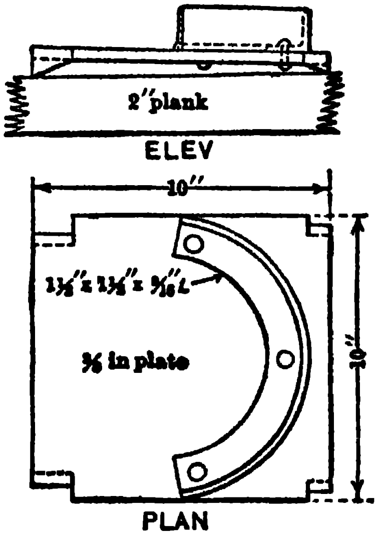

Fig 139. Foot-plate for Stope Drill in Drifting

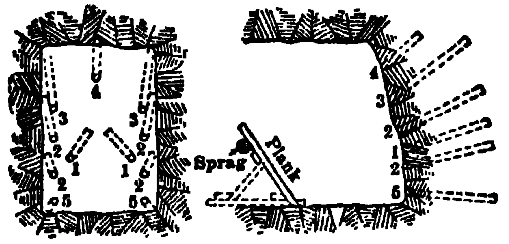

Fig 138. Inverted Draw-cut

General points as to mucking in tunnels (Sec 6) apply here also, especially where speed is desired. Table 19 gives mucking and tramming duty. A plat of sheet iron or plank,

Table 19. Data on Mucking and Tramming by Hand (55, 67, 106–111, 122, 522, 532)

	Location	No of men	Size of car	Distance trammed, ft	Cars per shift	Length of shift, hr	Tons per man-hr

(*a*) Bucket, capac 800 lb. (*c*) On basis of 20 cu ft = 1 ton. (*d*) Lower duty, probably because of insufficient work to keep 2 men fully occupied. (*e*) Negro labor. (*f*) Bonus work, record for 2 months. (*g*) Aver for year 1916. (*h*) Aver range, 24–42. Bonus for speed of advance.

laid on floor close to face before blasting, increases output per mucker-hr. Data on loading and tramming from chutes are included for comparison and for use in estimating on raises (Art 21 and Sec 11). Rate of mucking is also affected by size of pieces; observations by author in Colo gave following data:

Car, 28 by 28 by 54 in; capacity, 2 500 lb; 1 man mucking small material on rough floor filled car at rate of 3 tons per hr; with good floor, 5–6 tons. In loading muck containing many big pieces, which had to be lifted into the car, 1 man loaded 4 tons per hr; 2 men loading mixed material from rough floor and taking their time handled 2.9 tons per man-hr. 2 men, 1 picking and 1 shoveling, made following rates per man-hr: in large and small material mixed, 2.9 tons; all big pieces, 3.2 tons; all fine muck, 3.5 tons.

A detailed study of underground shoveling, made by Phelps Dodge Co, was described by G. T. Harley in 1919 (539). Shovel found best adapted to mining work is shown in Fig 140, the blade holding an aver of 21 lb broken ore, and having a plain welded back. Harley concludes that to obtain highest shoveling effic underground, every shoveler should be placed in a particular stope or working place, directly in charge of a shoveling boss. This boss should have had large experience in shoveling, have learned correct shoveling methods, and should be able to instruct men and gain their confidence. Each man should be taught: (*a*) necessity of using correct type of shovel for given work; (*b*) proper way to handle a shovel; (*c*) range of usefulness of wheelbarrow and car; (*d*) advantage of using a platform to shovel from; when shoveling has progressed beyond the platform, time should be taken to shift it and scrape the broken ore forward on to it; (*e*) the broken ore should be thoroughly loosened with a pick; effort is wasted in trying to shovel packed material; (*f*) shoveling should be done at a good steady pace, speed depending on length of job; it is waste of time and energy to try to rush through the work; (*g*) besides the amount of rest inherent in the work itself (rest gained while picking down, tramming, etc), definite rest periods should be maintained. When each man has been thoroughly instructed in the methods of shoveling, he should be placed in general run-of-mine work among the more experienced shovelers, so that another new man may take his place for instruction. For further details, see Sec 3.

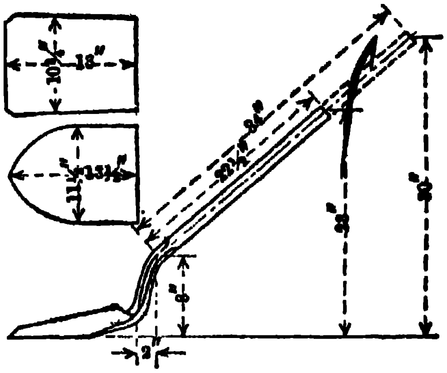

Fig 140. A Mining Shovel

Mechanical loading in drifts and crosscuts.

For current practice in design and operation of loaders, see Sec 27. The following examples illustrate their applications in metal mining.

Scrub Oak magnetite mine, N J, has used a Nordberg-Butler shovel in its tramming drifts, 8.5 ft high by 11 ft wide; in 1 shift, shovel loaded about 57 tons from each of 2 headings at opposite ends of same drift. Advance, 6.5 ft per shift by each drilling crew. Ore averaged 16 cu ft per long ton. Loading equipment included shovel, storage-battery locomotive, and 5-ton Granby car; all operated by 2 men, who also extended track in 5-ft sections; shovel and car were both transferred from heading to heading by locomotive. Previously, loading crew had been 4 muckers and 1 locomotive engineer per shift per heading; shovel thus saved 8 man-shifts (costing $3.16 per ft of drift) at an expense of 60¢ per ft for deprec, interest, power, repairs, and supplies; net saving, $2.56 per ft (494).

Ojuela, Mex. A 9 by 8.5-ft drainage tunnel was advanced 714 ft per mo (during 7 mo) in limestone, shale, and several diorite dikes 10–80 ft thick (484). Speed was gained by continuous 3-shift work, carriage mounting of drills, and mucking by Nordberg-Butler (No 109) air-operated shovel, loading 34 tons per hr into 40-cu ft dump cars; height of car above rail, 4 ft–7 in. Haulage by 2.5-ton Mancha storage-battery locomotive. Aver round of 8 ft required 5 hr–37 min, of which: drilling, 1 hr–50 min; loading 20 cars, 2 hr.

Mineville, N Y, magnetite mines have advanced footwall haulage drifts 10 ft high by 15 ft wide at aver of 5 ft (max 7 ft) per 8 hr, with 4 men. Two drillers complete a wedge-cut round of 28 holes, 7–7.5 ft deep, and blast, in 5.5 hr; operators of air-driven shovel and elec loco (both meanwhile employed elsewhere) then load about 50 tons in 3 hr, to pocket at incline. Explosive, 125 lb 40% gelatin per round (495).

Humboldt mine, Morenci, Ariz, using a Conweigh shovel, advanced a 9.5 by 10.5-ft heading on 14th level 2 343 ft through porphyry in 8 mo of 1928, or at aver of 11.3 ft per day, compared with previous hand-mucking rate of 7.3 ft. Water collecting in the downgrade heading hindered mucking. With 2 drills on vert columns, a horiz V-cut round of 21 holes, 8–9 ft deep, plus 1 short bottom hole for ditch, was finished and fired in 5.25 hr; usual break, 7.5–8 ft, or 9 tons per ft. After 45 min for smoke to clear, shovel crew of

3 men loaded 70 tons in 6 hr; hence, 2 complete rounds per day. Double track, with transferable cross-over switch, expedited handling cars (99).

Magma mine, Ariz, drives haulage levels in diabase wall rock, 8 by 8 ft where untimbered. Two drifters, on horiz bar, drill upper half of a 13-hole pyramid-cut, while air-driven shovel is mucking. Depth of holes, 7 ft, is adjusted to break about 38 tons, which can be mucked by comp-air shovel into 2-ton cars while holes are being drilled, requiring about 5 hr, including first set-up; shoveling takes 4 hr. Bar is then moved down, and lower holes are drilled in 1 hr. Charging and blasting, 1 hr, lunch and lost time, 1 hr, makes 8 hr for a 5.5-ft advance. Crew of 2 drillers, 2 helpers, 1 loader operator does whole job, including laying track and pipe lines. One helper operates storage-battery loco (77).

Trepca Mines drove a development and drainage tunnel 8 776 ft (all but 945 ft in weak schist requiring steel support clear to the face) between Oct 19, 1929, and May 12, 1931 (496). Arched heading, 9.8 ft high at center by 12.8 ft wide, usually required a horiz V-cut of 22–26 holes, 7.9 ft deep, drilled in 1.5–2 hr by 4 drifters on a carriage. Aver advance, 6.6–7.5 ft per round; explosive (65% ammonia dynamite) 16.8–20.2 lb per ft. Nordberg-Butler shovel, air-operated, loaded 60 met tons from an aver round into 41 cars (25–30 cu ft) at 3.5 min per car, or 2.25–2.75 hr per round. Entire cycle, during 4 mo free from unusual delays, averaged 6.5 hr. Ditching done independently by hand work. Of total crew of 132 men underground, in 3 shifts, 51 worked at face, 21 erecting steel, 15 concreting. Record advance for 1 month, 879 ft; aver for 8 mo in 1930, 778 ft per mo.

Siscoe Gold Mines (in 1935) advanced an 8 by 8-ft crosscut, in medium schist intersected by hard porphyry dykes, 3 086 ft in 4 mo continuous 3-shift work except Sundays, which were used for repairs, pipe and switch installation, and misc work. Little timbering was necessary. Crew per shift: 2 drillers, 1 helper, 1 shovel operator (Eimco Finlay), 1 switchman, 1 motorman (storage-battery loco), 1 trainman. Two 3.5-in drifters, mounted on horiz bar above muck pile, drilled 12–14 holes to max 10-ft depth in 1.3–2.5 hr, while shovel was at work; drills then idle for 1 hr, while shovel was loading last 12–20 tons of muck. Lower holes were then drilled from new set-up in 1–1.5 hr. Total round of 20–24 holes, pyramid-cut, broke from 7.5 ft, in hardest, to 10 ft in softest rock, using 60% gelatin forcite in cut and 40% in square-up holes. Never less than 3, and often 4 rounds were broken per day; best aver for 27 days, 27.7 ft. Labor was contracted on bonus system, aiming at speed: $5.50 per ft for (2 weeks' aver) advance under 6 ft per round, to $7.50 per ft for 10 ft or over; Co supplied explosive. Switches for the 20-cu ft cars were installed every 200 ft (497).

Champion mine, Mich, drove haulage levels 8 ft high, 9 ft wide in barren rock and 13–14 ft wide in ore; little timbering needed (488). In 14-ft drift, a wedge-cut of 34 or 35 holes, breaking about 5.5 ft, was drilled from 2 vert columns. Two horiz holes near upper corners were the deepest, to leave stubs to receive split pins for attaching tail-rope block of scraper. "Osana" scraper slide was 6 ft wide at bottom and 4.5 ft over car; incline, 30°. Hoe scraper, 43 in wide. Motor, d-c, 15 hp. Two drillers and helper on each of 2 shifts performed whole operation, including tramming and dumping into skip. Aver 2 hr to muck a round (about 50 tons). Aver advance, 0.56 ft per 8-hr man-shift; explosive, 17 lb per ft.

Britannia mine, B C, driving a main haulage tunnel 10 ft high by12 ft, with a 3 by 3-ft ditch, used 4 drills on carriage for a pyramid-cut of 29–33 holes, 7–8 ft deep, in 2–2.5 hr (498). Crew on each of 2 shifts: 1 boss, 4 drillers, 2 muckers, 1 motorman, 1 brakeman; additional crew, on day shift only, 2 trackmen, 2 steel sharpeners, 1 ditcher; total 23 men in 24 hr. In all but hardest ground, advance was 6 ft per shift. "Osana" slide loaded a 6-ton (120-cu ft) car in 3–4 min; switching car, 1–3 min. Hoe scraper, 42 in wide, was operated by tail-rope block hung from chain stretched between Lewis wedges in 2 upper corner holes, after firing. Permanent rail was kept 30 ft back from face to permit clean scraping; temporary rail for drill carriage was laid in advance. Ditcher, in rear, drilled and fired at will.

Eureka-Asteroid mine, Gogebic Range, Mich, used scraper slides in headings: main levels, 9 ft high, 11 ft wide; untimbered haulageway, 8 by 10 ft; sublevels, 8 by 9 ft (delivering to chutes). Slides have displaced power shovels, proving cheaper in first cost, operation, and maintenance, and simpler to handle. With them, untimbered rock 9 by 11-ft crosscuts have been advanced 800–900 ft in a month (499); one made 924 ft through hard rock in 31 days of 3 shifts, 32 man-shifts per day. Four drills, on 2 columns, could be set up, drill 24 wedge-cut holes, and torn down in 2.3 hr. After 40 min for charging, firing, and smoke to clear, scraper loaded 26 cars (of 60 cu ft) in 1.75 hr; total round, 4.75 hr.

Mt Isa, Queensland, uses scraper loading in haulage crosscuts (9 ft high by 10 ft wide, with side ditch) and stope sub-levels (10 ft high by 12 ft wide). Former is advanced with center-wedge cut of 27 holes 7.5 ft deep, breaking 7 ft with 110 lb 60% gelignite; latter with a pyramid-cut of 32 holes, 9 ft deep, breaking 8–9 ft with 70 lb of 60% and 70 lb of 40% gelignite. Working alternately in 2 headings, 4 drillers and 2 muckers make 1 round per shift. Hoe scraper, 34 in wide, is reinforced and weighted with 2 sections of 42-lb rail. Motor, 15 hp, a-c, 440 volt; rope, 0.5 in; cars, 75-cu ft capac (500).

Roan Antelope mine, Rhodesia, introduced in 1930 its own design of portable slide scraper operated by native labor, with great advantage over hand loading (501). One 10 by 12-ft main drift in ore advanced 277 ft in 25 days, drilling and loading alternately on two 8-hr shifts. Crew of 7 natives with European boss ran 2 heavy drifters with 13-ft steel; loading crew, 7 natives, one running the scraper, and 1 European. Haulage, by battery loco and Granby cars.

Muscoda No 6 mine, Bessemer, Ala, uses scraper slides, made in company's shop, for dragging Clinton hematite ore from gently pitching rooms to the rise, and advancing haulage levels (507). Latter are 20 ft wide by 10.5 ft high. Round of 13 holes, 6.5–9.4 ft (total 112.4 ft), arranged for vert-wedge cut, is drilled from a tripod over one side of muck pile, while scraper is clearing other side. Charge of 59 lb of 45% dynamite breaks 7.5 ft, or 1.494 ton per lb. Slide, only semi-portable, must be dismantled for moving; bottom is of 15-in channels, 18 ft long, flat side up, and bolted together, with upper ends resting on 12 by 12-in timber across props. It is set near one wall, leaving space on other side for movable hoist, which has 2 loose drums driven by clutches from 50-hp, d-c, reversing motor. Hoe scraper weighs 2 700 lb and drags about 2 tons.

Halkyn lead district, No Wales. A drainage tunnel, 10 ft wide by 8 ft high, with ditch 4.5 ft wide by 2.5 ft deep, was driven through tight limestone, requiring support only at long intervals (483). During a normal 4 weeks free from unusual delays, 101 rounds advanced 653 ft, aver 163.25 ft per week of 138 hr, with a crew of 53 men per day, 12 per shift being at the face. Rock was hoisted, and delays from inrushes of water and mud from fissures were frequent. Two drifters on horiz bar drilled 36 holes, 8 center-cut 7.5 ft deep, the rest 6.5 ft, in about 2.25 hr. Usually 5 other 5-ft holes, for the ditch, were drilled by jackhammer, and fired with the round. Aver break of 6.33 ft required 140 lb of 60% gelignite, including 9.5–13 lb for ditch. Box-type scraper, 38 in wide, proved better than hoe type for this finely broken rock. Two scraper loads filled a 1 600-lb (capac) car, 1 car per min. Aver cycle: removing scraper and setting up drills, 31 min; drilling 36 face and 5 ditch holes, charging and firing, 2.75 hr; waiting for smoke, clearing track, setting up scraper and slide, 48 min; loading 54 cars (43 tons), 79 min; total, 5 hr–26 min.

Miami Copper Co has considerably modified its mechanical mucking practice in drifts. As originally installed (see 1927 edn, p 521) a train of 8 cars was loaded without uncoupling, by scraper and a bridge sheet between every 2 cars. As described by A. J. McDermid (511) in 1930, cars are loaded singly, and switched by storage-battery loco from a distance up to 500 ft from face. "Osana" scraper slide, built in Co shop, has a 25-hp d-c motor, for a 2-drum hoist carrying 100 ft of 0.75-in rope for load and 125 ft of same size for tail rope; pulley for latter is held at face by 2 eyebolts set in plugger holes as soon as booms and caps have been advanced. Hoe scraper is 48 in wide, with Stellited cutting edge. Muck from an aver 6.25-ft advance fills 15 75-cu ft cars; with high pile, 4 scraper loads fill a car in 3 min; about the same time for switching. Scraper cleans up enough for laying track and timbering to face, but sides behind toe of slide are shoveled by hand. According to information from Miami in 1938, 2 automatic-fed drifters put in a wedge-cut of 17 holes (aver 6.7 ft) in 5 hr; this breaks 10 ft high by 9 ft wide with 50 lb of 40% gelatin; 3-piece drift sets of 10 by 10-in timber are spaced at 6.25-ft c-c. One advance is made in 2 shifts, as follows: setting up, drilling, blasting, 5.5 hr; clearing smoke, 0.5 hr; timbering (advancing booms and caps), 2.0 hr; mucking, 4.0 hr; timbering (posts), 4.0 hr; total, 16.0 hr. Working 2 shifts per day, aver monthly advance is 160 ft.

N'Kana mine, N Rhodesia, drives main haulageways in shales and sandstones, 12 by 12 ft with ditch, on 0.4% grade, drilling and scraper-mucking on alternate shifts (528). With 3 drifters on columns, 1 miner and 11 natives drill 30 holes, with 12–13.5-ft steel; firing with 60% gelignite breaks about 11 ft. Ditch drilled by jackhammer. Scraper crew, of 1 operator and 12 natives loads muck in 4 hr; rest of shift on misc work. Hoe scraper is 45 in wide, weighs 1 000 lb, and is dragged by 35-hp motor hoist with $^5/_8$-in wire rope. Track is kept within 30 ft of face; with 30-ft turnouts every 300 ft. A 6-ton storage-battery loco handles 180-cu ft Granby cars. Best monthly advance, 303 ft in 26 days (2 shifts) in an up-grade, and 265 ft in 25 days in down-grade heading (retarded by water). Costs per ft during 6 months: Breaking, \$11.67; mucking, \$6.67; timbering, \$0.30; track laying, \$3.79; elec equipment, \$1.87; total, \$24.30 (at \$1 = 4.11 sh).

Butte, Mont. Data from H. M. Courtney (615) in 1938. Mechanical shovels have practically displaced scrapers, as drifts tend to be narrow and crooked. Anaconda Co (end of 1938) had 75 shovels, of several makes; in first half 1938, 54 shovels loaded 270 545 tons, including ore from half of all silling operations. Untimbered drifts are 8–9 ft high and 6–7 ft wide; timbered drifts, 10–11.5 ft high and 8–9 ft wide, outside of timbers. In wide ore, drifts sometimes advance at full width of ore, 16–22 ft. All drifting is contracted, usually 2, sometimes 3 men (2 drillers, 1 shoveller) on a shift; wherever possible, 2 or 3 headings are worked by same gang, usually on 2 (sometimes 3) shifts. Working practice varies considerably, depending mainly on width of face; for details, see Bib (615). Cars are of 3 sizes. Aver loading times: 14–16 cu ft (0.75-ton), 1 min; 30 cu ft (2-ton), 2.5 min; 52 cu ft (4-ton), 4 min. In one case, 2 adjoining headings, 9 by 7.5 and 9 by 7 ft, were driven by 3 men on a shift, 3 shifts per day, making "burned cuts" with 2 drills on a carriage; in 1 week of 18 shifts, 458 holes totalling 2 960 ft were drilled for an advance (both headings) of 100 ft (aver 5.5 ft per round); week's work included tramming 811 cars to station, and cutting drainage ditch.

Routine of work in drifting and crosscutting. Effic is increased by systematizing operations. This presupposes reasonably uniform ground conditions, proper equipment, experienced men, and competent supervision. On completing a round the following is the cycle of operations: examining the face for missed holes, new set-up, drilling, tearing-down, charging, blasting, clearing smoke, and mucking. Inclusion of timbering depends on strength of ground. Track-laying and extension of air and water lines must be fitted into the routine in a way to avoid delay and interference. Number of drills used depends on size of opening, hardness of ground, and the limitations as to hour of blasting and time for clearing smoke; in some places, blasting may be done only at end of shift. Effic of mechanical mucking depends on keeping the loader supplied with empty cars. Procedure may be governed more by speed requirements than by consideration of cost; thus, 3-shift work is usually more costly, but may be desirable for speed. Routine may best be maintained if there be 2 or more headings in which individual crews may alternate their work. Following examples (numbers refer to Table 18) illustrate general principles.

Ex 22, Lake Shore mine, Kirkland Lake, Ont. Ground, hard porphyry; drift, 7.5 ft high, 7 ft wide; 2 drills at face; mounting, column; holes per round, 23; advance per round, 6.25 ft; hand mucking; advance per mo, 165 ft. ROUTINE: 7 am to 2:45 pm, setting up, drilling and blasting; 2:45 to 7 pm, heading idle, clearing smoke; 7 pm to 3 am, mucking and laying track.

Ex 62, Lloyd mine, Ishpeming, Mich. Ground, cherty slate; drift, 10 by 10 ft; 2 drills at face, on cross-bar; holes per round, 21; advance per round, 6 ft; mucking by power shovel; advance per mo, 375 ft. ROUTINE: 8 to 8:30 am, trimming sides and back; 8:30 to 9 am, setting up; 9 am to 1 pm, drilling upper half of round and mucking; 1 to 2:30 pm, drilling lower half; 2:30 to 3:10 pm, tearing down; 3:10 to 3:40 pm, charging and blasting; 3:40 to 4:00 pm, clearing powder smoke by blowing with 5-hp fan through water spray; same procedure on afternoon and night shifts.

Ex 41, Geneva mine, Ironwood, Mich. Ground, granite; drift, 8 ft high, 10 ft wide; 4 drills at face, on drill carriage; holes per round, 32; advance per round, 6.95 ft; mucking by scraper, slide, and 340-cu ft car; advance per mo, 524 ft (3 shifts per day, 26 days per mo). ROUTINE: 7 to 8 am, setting up; 8 to 11:05 am, drilling; 11:05 to 11:55 am, charging and blasting; 11:55 am to 12:25 pm, blowing smoke; 12:25 to 3 pm, mucking; 3 to 4 pm, setting up; and so on through 3 shifts.

Ex 53, Creighton mine, Ont. Ground, quartz diorite; drift, 10 ft high, 9 ft wide; 3 drills at face; mounting, vert column and arms; holes per round, 34; advance per round, 8.3 ft; mucking by power shovel; advance per mo, 224 ft. ROUTINE: 8 am to 4 pm, mucking previous round, drilling, and tearing down; 5 to 10:30 pm, blasting and clearing smoke; 10:30 pm to 1 am, timbering; 1 to 8 am, idle.

Ex 33, Magma mine, Superior, Ariz. Ground, hard diabase; drift, 8 by 8 ft; 1 drill at face on cross-bar; holes per round, 23; advance per round, 5 ft; mucking by comp-air shovel; advance per mo, 250 ft. ROUTINE: Work is on 2 shifts, drilling and mucking simultaneously. Drilling schedule: 8 to 8:30 am, traveling to working place; 8:30 am to 12:00 m, setting up and drilling; 12 to 12:30 pm, lunch; 12:30 to 2:30 pm, drilling; 2:30 to 3 pm, charging and blasting; 3 to 3:30 pm, counting explosions in round and replacing ventilation tubing into face; 3:30 to 4 pm, traveling to shaft collar. Mucking schedule: 8 to 8:30 am, traveling to working place; 8:30 am to 12:30 pm, mucking; 12:30 pm to 3:30 pm, laying track, cleaning ditch, making up primers, taking down ventilation tubing; 3:30 to 4 pm, traveling to shaft collar. Night shift repeats cycle.

Hand mucking *vs* mechanical loading. In about 76% of 79 headings listed in Table 18, some form of mechanical loading is used. A similar table of 105 headings, in 2nd edn (1927) of this book, showed 13% mechanical loading. Small mines are probably not adequately represented in either table to make these percentages truly representative, but the data suffice to indicate a marked increase of mechanical loading in recent years. This does not necessarily signify that mucking costs are always reduced by adopting mechanical loading, but saving has often been effected, especially in headings of large cross-sec (see Sec 27). Loaders may be used where speed is essential, even though hand mucking might be cheaper. Sacrifice of cost to speed is often justified where labor is cheap but inefficient. Table 18 shows that mechanical loading is much commoner in large headings than in small. In 59 headings larger than 6 by 8 ft, loaders are used exclusively in 46 cases; in 4, the muck is hand-shoveled to a conveyer belt; in 20, having a sec 6 by 8 ft or less, loaders are used exclusively in only 4 cases; occasionally, in 4 others.

Scrapers *vs* power shovels. Table 18 indicates that both scrapers and power shovels are used widely in development headings. Scrapers find greater favor than shovels in the soft-ore iron mines of Lake Superior region, while the power shovel seems more popular in the " hard rock " mines. Data available are not conclusive; continued improvements in design are being made in both.

Timbering in crosscuts is similar to that for tunnels (Sec 6), but is generally lighter on account of smaller cross-sec and shorter life of these openings. This may be true also of drifts, but timbering in the latter is often designed to support filling or ore in the stope (Art 38–39). Usual forms of drift timbering: (*a*) HALF SET (Fig 141), cap resting in a hitch at one end and on a post at the other; used where back and one side of drift require support; (*b*) THREE-QUARTER SET (Fig 145, *A*) cap and 2 posts, used where back and both sides require support; is the commonest set; (*c*) FULL SET (4-piece), made by adding a sill to the three-quarter set, is used where the floor is soft (Sec 6). Longit mud sills, sometimes found in large tunnels, are seldom used in mines, due to difficulty of replacement. In important haulageways and drainage tunnels, lower side walls may be concreted, forming ledges on which to stand the posts. Posts of sets usually have a batter of 1.5 to 2.5 in per ft of vert height; increased where lateral pressure is heavy and sets must be maintained for a considerable time (Fig 142). Round or sawed timber is used for drift sets (for comparison, see Art 49; also Sec 6). SIZE OF TIMBERS. Round timber is usually 6 to 12 in diam; for heavy ground and large openings, up to 24 in diam or more.

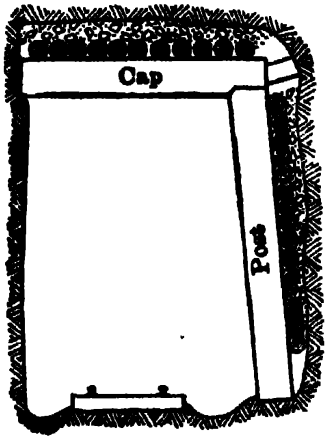

Fig 141. Half Set

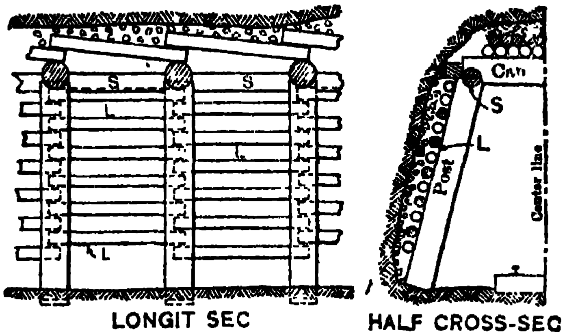

LONGIT SEC HALF CROSS-SEC

Fig 142

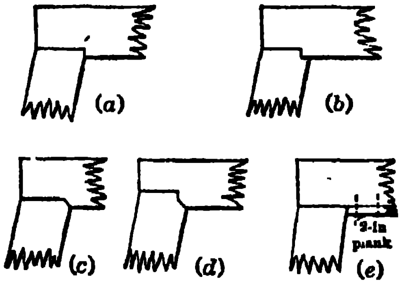

Fig 143. Joints between Cap and Post

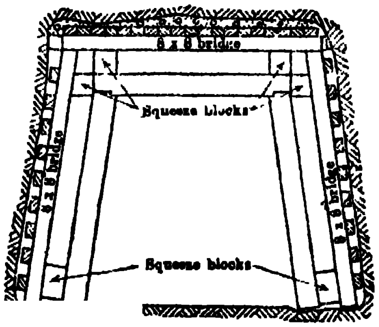

Fig 144. Timber Set for Heavy Ground

Ordinarily, lightest sawed timber used is 6 by 6 in; sizes to 12 by 12 in are common. SPACING OF SETS depends on size of timbers, weight of ground, and length to which available lagging will cut without waste; usual interval is 4 to 6 ft; in heavier ground, 2 to 3 ft; in extreme cases, sets are placed skin to skin. LAGGING (*L*, Fig 142), used to prevent falls of ground between sets, is of round 4 to 6-in poles, half-round mill slabs, or 2 to 4-in plank. Plank is used where tight joints are necessary, and in districts where all timber is imported and plank is as cheap as other forms. Length of lagging usually = distance *c* to *c* of sets; it may cover only back of sets, or back and one or both sides; in rare cases sills are lagged also. Lagging on back is usually placed skin to skin; on sides, open lagging (Fig 142) is generally sufficient. Space between lagging and walls is best packed with broken rock. SPRAGS (stretchers) (Fig 142, *S*) are distance pieces to brace the sets longitudinally; they are heavy lagging poles, or 4 by 6 or 6 by 6-in timber, cut to fit between sets at joint between cap and post, and spiked in place; in shifting ground, feet of posts are braced also. Sets are firmly wedged to wall; blocking and lagging often form adequate lateral bracing. Joints. Simple forms are desirable; **object is to get full strength of timbers with as little framing as possible. Fig 143 shows typical joints: (*a*) is cheapest to frame, but cap may split under vertical pressure; (*b*) avoids this danger; (*c*) is as good as (*b*) and cheaper to frame; (*d*) and (*e*) are designed to give both cap and post the strength of full cross-sec and are good where both vertical and lateral pressures are heavy.** Joint (*a*) is common for junction of post and sill in full sets.

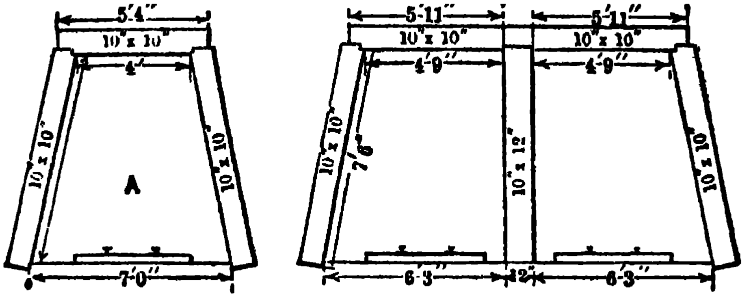

Fig 145

Special sets. In heavy ground, sets may be reinforced by diagonal braces between cap and post (seriously reducing head room unless sets are high). In some cases a second complete set is placed inside the first. For heavy moving ground, a set like that shown in Fig 144 was developed in the Southwest. Squeeze-blocks are put between bridge and set. Outside set is of lighter timber. Pressure can be relieved by removing lagging and picking out back and sides. The outer set will fail before main set, and may then be replaced without interference with tramming. Under a stope, to give height for placing chutes, the bridge in Fig 144 may be supported on short posts instead of blocks (318). In wide openings, various forms of rafter sets (Sec 6) are sometimes used, or center posts placed (Fig 145). At switches and turnouts special sets are required (Sec 11). In soft, swelling ground, press on sets can be relieved by letting loose material squeeze through spaces between lagging; at United Verde Ext mine, vert lagging of 16-lb rail spaced at 6 in was used in some places for this reason. A method for timbering drifts through swelling ground in United Verde and Braden mines (Fig 146) gives prompt relief of local press. Wall lagging, of plank cut to fit between posts, is supported on cleats sloping toward walls; planks can be lifted out for removing loose material behind them. Under very adverse conditions, in some parts of United Verde Ext mine, the bulkhead in Fig 147, composed of scrap ends of timber, proved more serviceable than reinforced concrete (90). For special methods of advancing headings in soft, heavy ground, where timber is required at the face, see Sec 6. In rock which disintegrates on exposure to air and moisture, guniting with 2 coats of cement mortar may often save expense of replacing timbers; but it is useless if ground is subject to even slight movement.

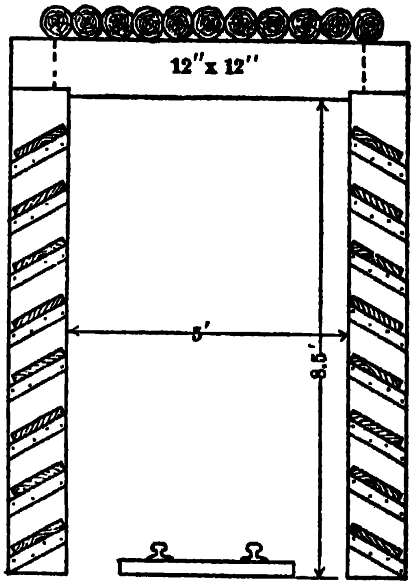

Fig 146. Shelf Lagging for Loose Ground

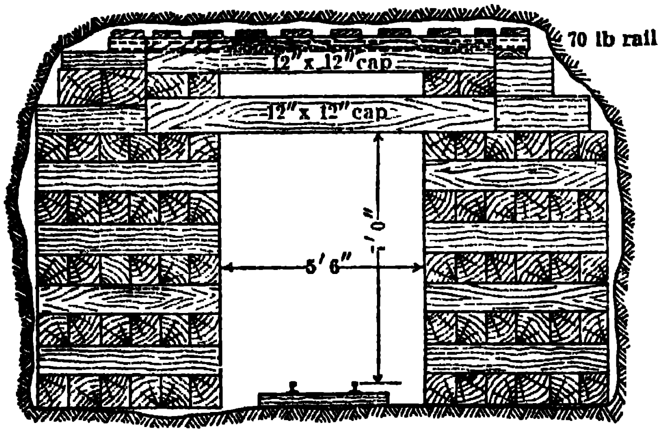

Fig 147. Timber Bulkhead, United Verde Ext Mine

Steel sets are less common in metal than in coal mines (Art 111). Frood mine (93) places 7-in Ni-steel I-beams, on 11.5-ft centers, across tops of its footwall haulage drifts 9 ft wide by 10.5 ft high. Ends of beams are cemented in hitches or rested on concrete pilasters. Lagging is of 4-in Ni-steel I-beams (usually 4, spaced across width of drift) with blocks and wedges supporting the back. Many mines utilize second-hand steel for support of shaft stations or other wide openings.

21. RAISES

General. Raises are preferable to winzes wherever feasible, as they can be driven faster and cheaper. When steeper than about 40°, there is practically no mucking cost, because broken material falls or slides to level below and is loaded into cars through a chute; on flatter slopes, mucking is necessary, but often done cheaply by scraper. In strong ground, little or no timbering is necessary where pitch is less than about 45°; in steeper raises timber is needed to support men when drilling. Raises at about 45° are usually cheaper per ft than those flatter or steeper, but advantage of lower cost over steeper raises may be offset by their greater length. Some mines find a pitch of about 60° most economical from all standpoints. Vert or very steep raises usually have 2 compartments, manway and chute, and are carried up like a shrinkage stope (Art 67), only the necessary amount of broken rock from each round being drawn to give working space at the face. Manway may be separated from chute side by lined stulls, or built of cribbing or lagged sets. " Pilot " raises are common as first step in sinking large shafts, where access is possible from one or more levels; raises are then enlarged, beginning at top, by methods resembling underhand stoping (Art 35) with great economy in labor of mucking. At Braden mine, pilot raises for a large vert shaft were zig-zagged at 50°. Fig 148 shows a method of stripping a pilot raise to full sec, starting at bottom (522).

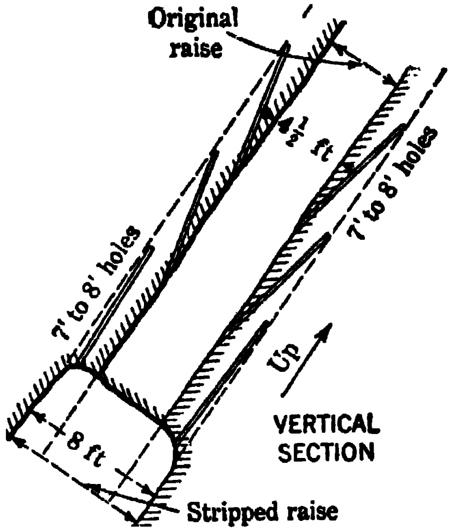

Fig 148. Enlarging a Raise by Stripping from Bottom

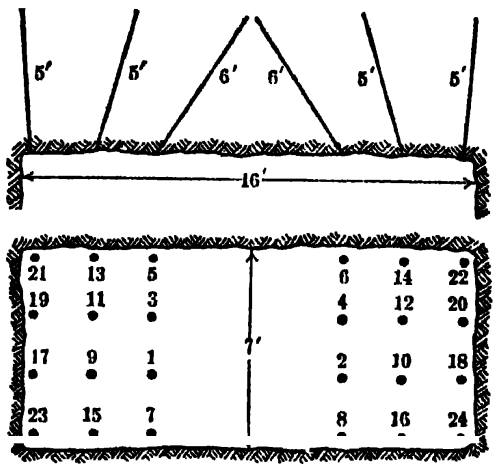

Fig 149. Simple V-cut, Sullivan Mine, Kimberley, B C

In certain foreign countries, native labor is more adept at sinking winzes than driving raises. In such cases winzes are often sunk to meet raises from below, thereby increasing development speed without increasing cost of work.

Data on raises in Table 20, generously contributed by the managements and engineering departments of the mines listed, show present practice (1938) in raising in the U S, and give information on cross-sec, drill rounds, explosives, speed of advance, etc.

Cross-section of raises is usually square or rectangular. Width in narrow veins is often full width of vein; minimum possible width is about 2.5 ft; 3.5 ft is better; must be increased on dips less than 45°.

Cross-sec should be long enough to provide room for 2 compartments and the necessary timbering, also to allow cut holes to be placed efficiently; 5 to 7 ft is usual practice in small openings. Prospecting or exploratory raises, and those driven solely for ventilation in connection with mining, are kept small to reduce cost. Cross-sec of raises for handling ore or waste is adapted to amount of material passing and size of pieces. In connection with square-set stopes, dimensions of raises are often determined by size of sets (Art 48); if raise is for inside hoisting, cross-sec is computed as for shafts.

Drills and mounting. Unmounted stopers are used for raising unless the pitch is very flat, in which case bar-mounted drifters may be better. These are sometimes used in very hard ground, even in steep raises. Among the examples in Table 20, stopers with automatic rotation greatly outnumber hand-rotated stopers.

Arrangement of holes. In raising, all types of round are used, as in drifts; similarity between raising and drifting increases as the dip flattens. Table 20 indicates in general the rounds required for different rocks and cross-sec of raise. Fig 149–158 show some of

Table 20. Data on Raising Practice, as of 1938

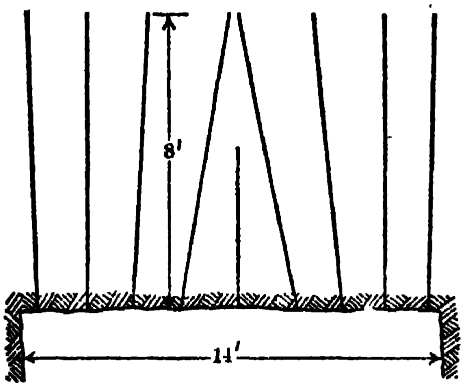
(*a*) Including time for setting-up and dismantling drills. (*b*) Bulk strength. (*c*) 80% are vert; 20% at 50°. (*d*) Same crew also does other work. *h* = hard. *m-h* = medium hard. *s* = soft. *m-s* = medium soft. *ls* = limestone. *dol* = dolomite. *gn* = gneiss. *peg* = pegmatite. *por* = porphyry. *sch* = schist. *grnstn* = greenstone. *sul* = sulphide. *a-r stop* = automatically rotated stoper drill. *h-r stop* = hand-rotated stoper. *h-f dr* = hand-fed drifter. *j'ham* = jackhammer. *t-dr* = top-draw. *pyr* = pyramid. *bur* = burned. *cent* V = central V-cut. *mod pyr* = modified type between pyramid and V-cut. *gel* = gelatin. *semi-gel* = semi-gelatin dynamite. *am* = ammonia gelatin or dynamite. *oc'l* = occasional. *var* = too variable to allow averaging; in case of monthly advance, variations occur with distance above level, but are due principally to irregular number of days devoted to raising.

the raise rounds named in the table; numbers at holes indicate order of firing. Where timbering is used, round should be planned to minimize injury to timbers; in 2-comp raises, cut holes are usually over the chute compartment rather than the manway (Fig 162).

Number of holes per round for raises is shown in Table 20. Distance between holes increases with size of cross-sec; larger space allows cut holes to be placed to better advantage with a drill of a given length, and deeper rounds can be pulled.



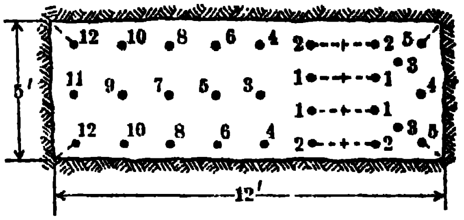


Fig 151. End V-cut, Wright-Hargreaves Mine, Kirkland Lake, Ont. Holes average 4.5 ft deep

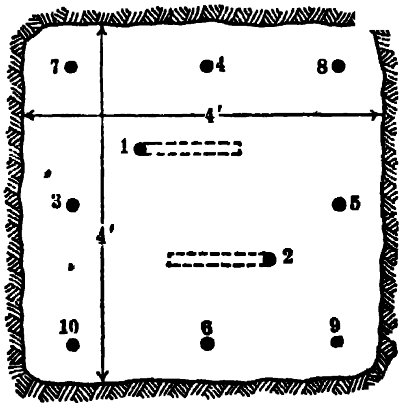

Fig 154. X-cut in Soft Hematite, Pioneer Mine, Ely, Minn. Holes 4.5 ft deep

Loading and tramming from raise chutes (see Table 19 for data).

Timbering and general procedure. Fig 159 shows mode of driving a small inclined raise (113). Up to dip of 40° no timber is required to support men; above 30°, it is best to place small horiz stulls 4 or 5 ft apart and 6–10 in above footwall. Muck collects behind these, forming steps which aid in climbing raise and supporting drills; the steps also catch steel and tools, dropped accidentally. Support for tail-piece of stope drill may be obtained from a plank brace, as in Fig 159. In steep raises, timbering is usually necessary to support platforms and ladders, even when the ground itself requires no support. In small, single-compartment raises, simplest timbering is a row of stulls across each end, to serve as footing for drilling platforms (Fig 160). The platform is moved up, round by round. Safety of driving raises in this manner decreases as height increases. For larger raises, even in strong ground, it is better to divide raise into 2 compartments, one for a pipe and ladderway; usually done by stulls or cribbing. Stulls are placed in pairs 4–5 ft or more apart along pitch of raise, one at one end of the raise and the other 2–4 ft toward the middle (Fig 161). Inside row is lagged to form a partition between manway and chute. Platforms may be left as desired in manway compartment and ladders staggered for safety. If manway is small, pockets (*P*, Fig 161) may be cut at intervals of 30–40 ft for storing drill and tools. Muck may be drawn completely after each round, but it is usually best to draw only enough to give working room at top. Fig 162 shows 2-compartment raise in strong ground, with cribbed manway. In weak ground, square-sets (Art 47) or "double" cribbing are often used. Fig 163 shows a double-cribbed raise at Magma

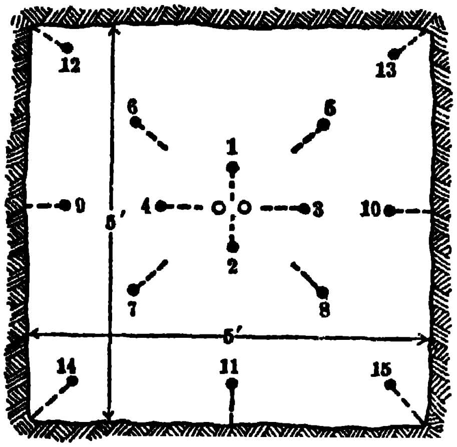

Fig 155. Pyramid Cut with Blank Center, Burra Burra Mine, Ducktown, Tenn. Holes 6.5 ft deep

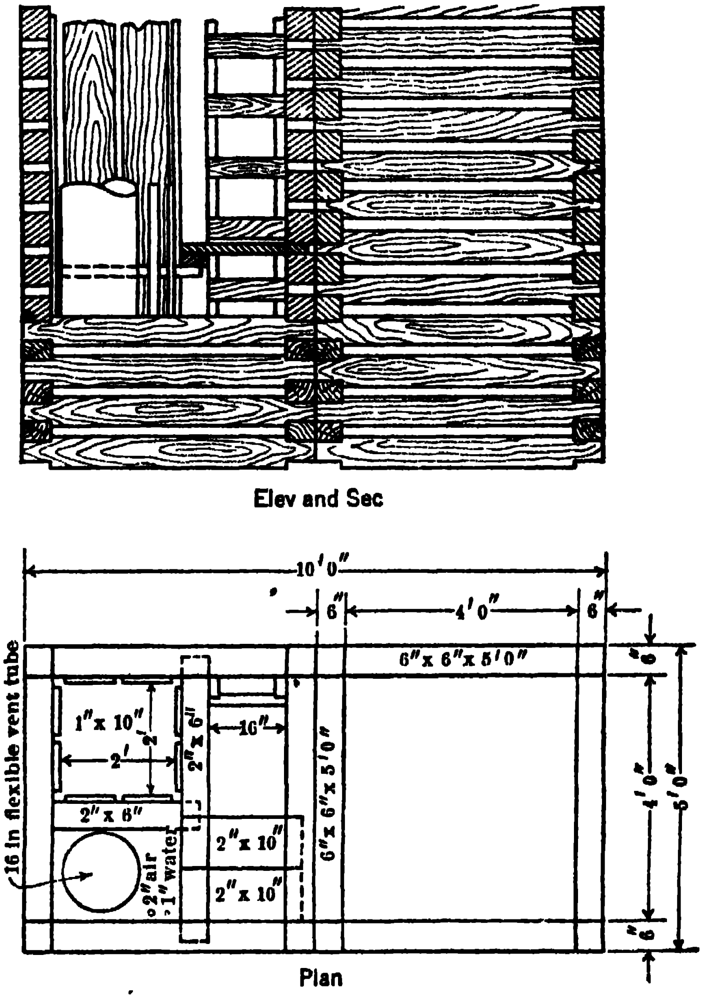

Fig 163. Cribbed Raise, Magma Mine, Superior, Ariz

mine, Aris (77), with 2 sets of 5-ft cribbing. At some other mines side members are single pieces, 10–11 ft long, dapped for 2 end pieces, and a single piece to divide the compartments. The example in Fig 163 is suitable for high lifts in weak ground; a small compartment is provided for a flexible ventilation tube, and another, lined with 1 by 10-in plank, for hoisting cribbing and drill steel. Platforms are 20-ft apart, and ladders offset at each platform. Vert raises for filling of square-set stopes (Art 47) are usually timbered with standard sets, forming part of the regular stope timbering (Fig 165).

Ventilation of raises, especially those carried up in shrinkage fashion, may be by auxiliary fans, delivering air to face through canvas tubing. Often, ventilation is only the small vol of air from comp-air line, or exhaust from drills. At Frood mine, Ont, a 1-in comp-air line is carried into raises solely for ventilation. Careful " blowing-out " of raises after blasting is essential to protect miners from CO or other gases. At Mt Isa mine, Queensland, 5 by 7-ft raises, pitching 55°–60° to max height of 120 ft above level, are ventilated by a diamond-drill hole from the level above, a piece of pipe being cemented into its collar and connected to a comp-air line. This is said to be better than other means of ventilation. The drill hole also serves as a guide for direction and inclination, and saves surveying work as the raise progresses (500).

Routine of work in raising. As in drifting and crosscutting (Art 20), effic is increased by systematizing work, and same principles of routine apply. Following examples are from Table 20:

Ex 33. Horne mine, Noranda, Que. Rock, hard rhyolite; raise, $6^1/_2$ by 7 ft; inclination, 45°; 2 stoper drills at face; holes per round, 23; advance per round, 5.23 ft; no timbering; advance per mo, 146.5 ft. ROUTINE: 7 am–3 pm, rig up and drill; 3–4 pm, nothing; 4–12 pm, complete drilling and blast; 12 pm to 7 am, nothing.

Ex 57. Creighton mine, Ont. Ground, disseminated to massive sulphide; raise, 7 by 11 ft; inclination, 65°–90°; 2 stoper drills at face; holes per round, 32; advance per round, 7 ft; timbering, cribbed manway; advance per mo, 97 ft. ROUTINE: (Monday) 8–10 am, setting up equipment; 10 am–4 pm, drilling; 4–5 pm, nothing; 5–8 pm, drilling; 8–10:30 pm, removing equipment and staging; 10:30 pm–1 am, blasting cut; 1–8 am, nothing; (Tuesday) 8–9 am, scaling, and cleaning bulkhead; 9 am to 1 pm, raising bulkhead; 1–4 pm, blasting squaring holes; 5–8 pm, scaling, and cleaning bulkhead; 8:00 pm to 1:00 am, cleaning and extending manway and building staging.

Ex 38. Montreal mine, Montreal, Wis. Ground, soft hematite; raise, 5 by 10 ft; inclination, 65°; 1 jackhammer on feed leg at face; holes per round, 10; advance per round, 4.5 ft; timbering, cribbing; advance per mo, 200 ft. ROUTINE: 7–8 am, mucking; 8–11 am, timbering; 11–11:30 am, lunch; 11:30 am to 1 pm, timbering; 1–3:30 pm, drilling and blasting; night shift, same. Work, 5-day week and 2-shift per day basis.

Ex 59. Idaho Maryland mines, Grass Valley, Cal. Ground, tough porphyrite; raise, 5 by 18 ft; inclination, 40°–90°; 2 stoper drills at face; holes per round, 24; advance per round, 5 ft; timbering, modified square-set for manway in center of raise (chutes on each side); advance per mo, 125 ft. ROUTINE: 8-9:30 am, clean off bulkhead; 9:30 am–3:30 pm, raise timber and replace bulkhead; 3:30–5 pm, nothing; 5 pm–1:30 am, rig machines, drill, tear down, and blast; 1:30–8 am, nothing.

22. EXAMPLES OF RAISING

Frood mine, Ont. Data from operating staff of Internat Nickel Co of Canada, Ltd, in 1937 (93). For geol conditions and method of mining, see Art 46. Levels 200 ft apart to 2 800 ft; below that, 150 ft. Raises, 7 by 11 ft driven from level to level for filling raises for flat-backed square-set stopes. Inclination, 70° or steeper. Raises are driven by shrinkage method, with a cribbed manway on one side (Fig 164), to serve later for access to stope from level above, and as foul-air outlet; chute side serves as passageway for fill to the stope below. EQUIPMENT: 2 self-rotating stopers with 3-in pistons, sets of 1-in quarter-oct steel in 1-ft changes from 2 to 10 ft, and timbering, scaling, and shoveling tools. Air and water for drilling supplied through 50-ft lengths of 1-in and $^1/_2$-in hose, respectively; pipe lines, 2-in for air and 1-in for water, are carried up the manway to within 30 ft of face; also a separate 1-in air line for ventilation. ROUND of 32 holes to depth of 7–10 ft, depending on ground conditions, is blasted with 250–350 sticks 40% forcite, with wooden spacers and clay tamping. Blasting with electric delay-action caps and battery. A 6-hole burned-cut (Fig 164), with holes 2 in apart, is used. Cut is drilled over chute side and is blasted separately. Raises are usually driven on 1 shift per day by 2 men, usually completing a round in 3 days. ROUTINE. Cut holes drilled and blasted the first day. Cribbing is raised to within 3 ft of face, and the remaining holes blasted on second day. Chute is drawn, bulkhead over manway cleaned off, drill rigging set up, and drilling begun on third day. TIMBERING. Cribbing consists of

5-in squared jackpine, dapped back 6 in from each end. Two pieces of 7-ft cribbing are placed from foot to hanging wall about 8 ft apart, as bearers to hold cribbing in place during later stoping. Chute side of cribbing is lined with 4 by 8-in by 7-ft plank. A 20 by 24-in plank-lined compartment is carried along the footwall side, in corner of manway for hoisting materials during raising. Platforms built every 15 ft, with staggered ladder along the footwall. A control chute (Fig 164) is constructed about half way between levels, so that the raisemen can more effectively control drawing off broken rock. Chute at foot of raise is drawn periodically by the motor-haulage crew.

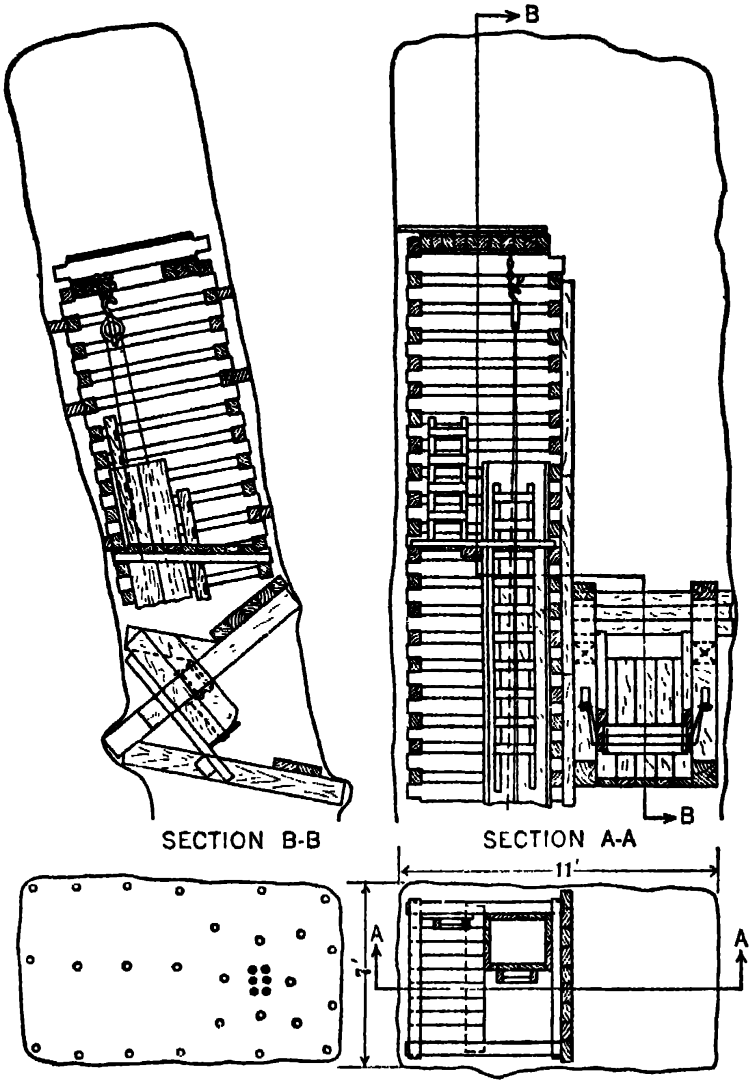

Fig 164. Plan and Sec of Fill Raise, Frood Mine, Ont

Lake Shore mine, Ont. Data from L. S. Weldon in 1936 (95). For geol conditions and method of mining, see Art 46. Square-sets are used in driving vert raises for delivering waste fill to square-set stopes. Raises are both 2- and 3-compt, with manway for access from level above. In 3-compt raise, manway is in center set; chutes on both sides permit simultaneous filling of both sections of a double-rill stope. Fig 165 shows 2-compt raise. Sets are 8 ft high, with posts on 5-ft 4-in centers; caps and girts, 8 by 8-in; posts of light, round timber; chute lining, 3 by 8-in. Round is of 22–28 holes, double-pyramid cut over the chute end of raise being commonest. Two drillers and a helper drill the round and blast cut holes in one shift. Aver advance, 5.8 ft per round, but skilled miners can break 6.25 ft per round. Two timbermen, on next shift, draw the chute, raise and block the sets, blast the remaining holes, and prepare for next round. A novel feature in square-set raises is a 16 by 22-in opening ("pigeon hole"), cut in chute lining below the bulkhead; it serves as a vent to release the force of blasting concussion, as an exit after placing the bulkhead, and to aid the clearing of blasting fumes by blowing compressed air.

United Verde mine, Ariz. Levels, 150 ft apart, are connected by vert or steeply dipping, 6 by 11-ft raises. In soft ground, manway at one end is cribbed, 56 in sq in clear, with 5 by 8-in pine, set on edge and notched at corners; lined stulls suffice in harder ground. Round for hard ground, usually of 32 5–6-ft holes, end-draw cut, drilled with stopers, takes 95 lb of 50% gelatin to break 4.75 ft. Two contract miners, in 1 8-hr shift, complete raise at rate of 0.91 ft per man-day. Cribbing or stulls are set to within 7 ft of face after blasting 2 rounds. Broken ore is drawn from chute by motor crew on another shift. Steel and timber are hoisted through manway by tugger and rectangular bucket.

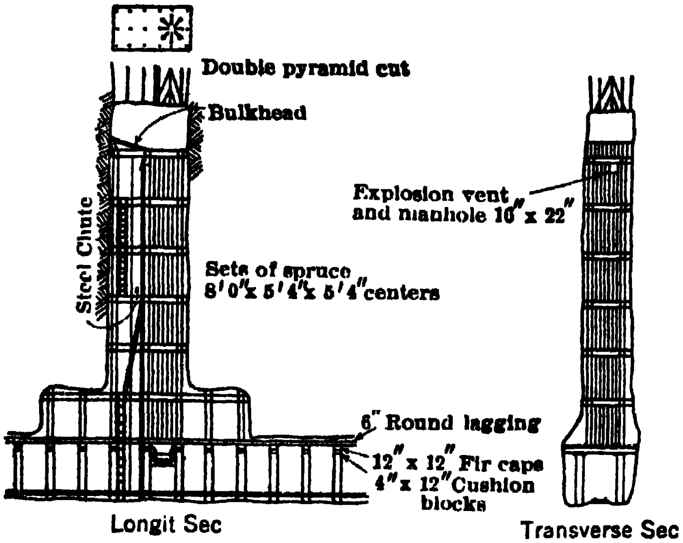

Fig 165. Two-compt Square-set Raise, Lake Shore Mine, Kirkland Lake, Ont

Champion mine, Mich, connects levels, 100 ft apart on 70° dip, by 4 by 8-ft raises usually 200 ft apart in a productive oreshoot (488)., Two miners, with self-rotating wet stopers, drill and blast a "burnt-round" of 26 6-ft holes in 2.5 shifts, working day-shift only; in the firm, hard rock, drilling speed in 1.5-in holes is 3.9 ft per hr. A round takes about 84 lb of 40% gelatin. Raise is divided by a row of stulls 3 ft from one end, 3 ft apart, and lagged on the chute side (Fig 166). Uppermost stull is never more than 30 ft below face, a wire-rope ladder being used to reach staging resting on 2 stulls about 7 ft below face. A temporary bulkhead protects the manway, and planks are laid across top of chute while men are working. Per ft of raise: drilling and blasting, 6.6 man-hr; boss, 1.1 man-hr; explosives, 14 lb; timber, 8 bd ft.

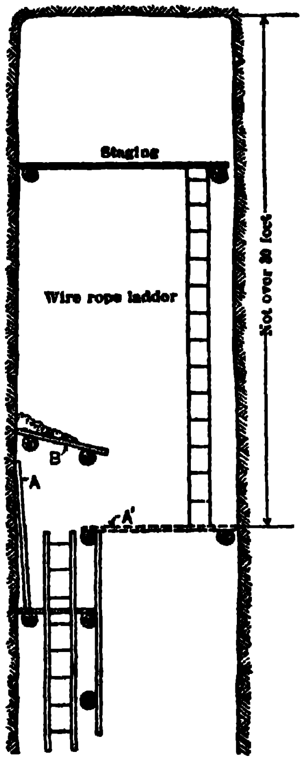

Fig 166. Top of 4 by 8-ft Raise, Champion Mine, Painesdale, Mich. (Planks A are laid across at A' when men ascend to start a new round. Sollar B is to protect main ladderway)

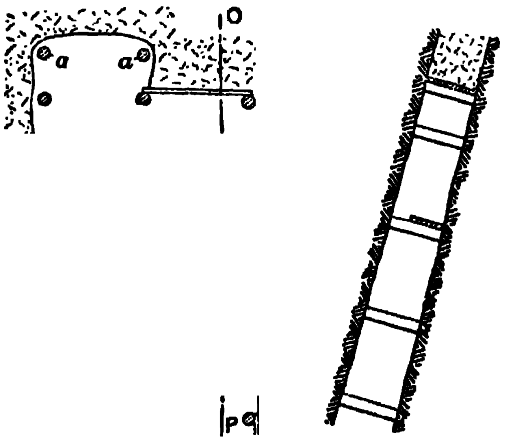
Raising through an old filled stope at Silver Plume, Colo (Fig 167). One side of raise was next to solid rock, but same plan was used where raise was entirely surrounded by loose material. Filling was well packed, and would not run in large amounts. Original vein, 2 to 4 ft wide; walls, fairly strong. Timbering consisted of 3 rows of short stulls about 4 ft apart, set in hitches, and dividing raise into a manway and chute. 2-in plank was spiked to middle row of stulls, to form a tight partition between compartments. Plank was also



SEC IN PLANE OF VEIN SEC O-P

Fig 167. Raising at Silver Plume, Colo

used for lagging the outside spreaders. Only half the face of the raise was advanced at one time, topmost stulls on other side being covered with planks to form a roof for protection of miner when at work. Excavation was done with a bar, loose material falling into chute below. When face had been advanced about 2 ft, temporary stulls *a* were put in and covered with plank. Miner stood under these and barred down face on other side of raise. Permanent stulls were put in when raise had advanced far enough, the lagging and partition being kept as near as possible to face. Ore in chute was kept as low as possible, so that a sudden cave would not fill up chute and imprison men.

Data on hand drilling in raises and winzes, given in Table 21, are for work done at Esperanza mine, Mex, in 1901 (85); Mexican labor, 3 8-hr shifts. Figures show clearly that the duty of this labor, in cu ft excavated per man-hr, is higher in raising than sinking; they also indicate a slightly higher aver duty in raising than in drifting and crosscutting (Table 15). Raise No 4 (Table 21), driven by machine drill, shows higher powder consumption per cu ft than others; this is generally true of machine-driven as compared with hand-driven openings.

Table 21. Raises and Winzes (Hand-drilling)

No		Width, ft	Height, ft	Kind of ground	Total length raised or sunk, ft	Aver daily advance, ft	Lb dynamite, 60% Ngl		Labor per ft		Aver advance

* Driven by machine; all others, hand-drilling. (*a*) Friable quartz. (*b*) Fairly hard quartz. (*c*) Fairly hard andesite. (*d*) Hard quartz. (*e*) Moderately hard shale. (*f*) Hard andesite. Ventilation poor in No 1, 3, 7; fair in No 4 and 8; good in other openings.

G. L. Schmutz in 1920 (523) gives comparative data in Table 22 for powder consumption in hand- and machine-drilled raises and winzes at a Mexican mine.

More careful control cut the aver powder consumption per ft in hand-driven winzes to 2.92 lb, in hand raises to 3.02 lb, and in machine-driven raises to 5.08 lb.

Table 22. Lb Powder per Ft Advance in a Mexican Mine

	Raises		Winzes	
	Hand	Machine	Hand	Machine
Minimum	3.0	3.0	3.0	3.0
Average	4.5	5.5	4 5	5 5
Maximum	7 0	9 0	7 0	8 0

23. WINZES

General. Work is same as for sinking small shafts (Sec 7). Hoisting is done by windlass, to small depths. Below 30–50 ft, 2 men are required, and small air or elec hoist is best (Sec 12, 15, 16); in some regions this may entail hiring of certificated engineman. In U S, winzes are less common than raises and are seldom for other than exploratory purposes, as they incur expense for hoisting and possible pumping, and can be advanced less rapidly. In So Africa, Mex, and wherever native labor is familiar with underhand working, winzes are commoner. They are sometimes drilled by hand, but usually with jackhammers, making an end or center-wedge cut like those in shafts. Examples follow.

Edwards zinc mine, N Y, sunk a 10 by 7-ft winze, inclined 42°, 300 ft through silicified dolomite footwall (253). Round of 33 holes, of which 8 formed a center-wedge cut about 6 ft deep, was drilled by 3 men, 1 with a mounted jackhammer and 2 with unmounted sinkers, on day shift. Same crew laid track of 30-lb rail on steel ties fastened to footwall by 1.5-in pins; permanent track ended 20–40 ft from bottom, slide rails spanning the interval; protective bulkheads were built 60 ft apart. No timbering required, but hoist compt was separated from ladderway by stulls and plank. Round charged with 100 lb of

gelex, fired electrically with instantaneous caps and 6 delays, usually broke 4.5 ft. Mucking done on night shift by 3 men, 2 shoveling into 1-ton skip, while 1 operated 50-hp elec hoist and trammed to shaft.

Elkoro mines, Jarbidge, Nev. Entry is through adits. Winzes up to 150 ft deep have been much used for both exploration and production; vein averages about 6 ft wide and dips 70° (112). Winzes have 2 timbered compartments, 4 by 4 ft clear, hoisting with single 24-cu ft skip which dumps into 100-ton pocket above tramming level. While sinking, a bucket, of 1 200-lb capac and sliding on round poles, is used. Table 23 gives costs per ft (1930) for sinking 646 ft of 7 by 11-ft winzes at 0.36 ft per man-shift in fairly hard ground, moving 2 665 tons of rock and ore. Wages, $5.25–5.50 per 8 hr.

Table 23. Cost per ft of Winze Sinking, Elkoro Mines, Nev

Labor	$15.146	Man-hours:	
Supervision	.293	Drilling and blasting	5.350
Compressed air	.936	Timbering	3.443
Steel sharpening	.315	Shoveling	5.696
Power	.434	Hoisting and tramming	7.443
Explosives (@23¢ lb)	2.106	Supervision	0 310
Timber	2.762	Total labor	22 242
Other supplies	.799	Explosives (40%) lb	9.177
Outside, incl assaying	.463	Timber lin ft	3 065
General exp	.565	Lumber bd ft	19.576
	$23 819	Labor was 69.71% of total cost	

Mt Hope magnetite mine, N J. Ore below the 1 000-ft level is developed by inclined winzes, 8 ft high by 9–10 ft wide, pitching at 14°; rock, hard granitoid gneiss (529). Two 150-lb drifters mounted on columns make a 22-hole round, including a 5-hole pyramid-cut about 5 ft deep, which is then blasted with 100 lb of 40% dynamite. Mucking usually starts in same 8-hr shift and is finished, together with rail laying, in next shift. Crew of 2 drillers, 1 helper, 3-4 muckers, aver 4.8 ft advance in 2 shifts. Contract price, $11.75–$12.50 per ft, Co supplying all but explosives. Cost of 809 ft sunk 1930, $19.72 per ft.

Tezuitlan mine, Puebla, Mex, uses winzes sparingly to explore massive sulphide deposits (533); sunk 5 by 8 ft with jackhammers, hoisting in 250-lb buckets with air tuggers. Hoist compt, 5 by 5 ft, is separated from ladder-way by planked stulls. Cost per ft of 46 ft sunk in 1930–31, at rate of 0.59 ft per 8 hr, is compared in Table 24 with cost per ft of 862 ft of raises, of same dimensions and timbering, advanced at 0.921 ft per 8 hr.

Table 24. Winzes *vs* Raises, at Tezuitlan, Mex

	Winzes, per ft		Raises, per ft	
Drilling and blasting	8 101 man-hr	U S $ 2 540	10.880 man-hr	U S $ 2.245
Timbering	1 514 "	.472	1.399 "	.260

Timber	27 304 bd ft	.758	26 212 bd ft	.728
Power (mainly air-comp)	251.43 kw-hr	.769	188.58 kw-hr	.577
Other supplies		4 870		2.960
Total direct cost		$22 546		$13 855

For other comparisons between winzes and raises in Mexican mines, see Tables 21, 22, Art 22.

Mexican Corp. Winzes proved more satisfactory and but slightly more expensive than raises for developing steeply pitching sulphide veins in graywacke and shales, at Fresnillo, Mex (535); this result is due partly to familiarity with jackhammers and scarcity of good timbermen. Winzes are 5 by 7 ft, and divided by stulls and planking into a 4 by 5-ft hoisting and a 3 by 5-ft ladder compt. Buckets, of 5.5–9-cu ft capac, sliding on 4 by 6-in skids, are hoisted with 7.5-hp elec, single-drum hoists. Contract prices (1935) were $5–$7 (U S) per ft, to depth of 150 ft.

Mt Isa mine, Queensland, sinks 5 by 7-ft untimbered winzes, usually to connect with raises from below, and seldom more than 75 ft deep· inclination, 58°–60°. Ore is shale, carrying sulphides. Jackhammer round, of 6 pyramid-cut and 10 wall and corner holes, 5 ft deep, breaks 4–5 ft with 30 lb of 60% and 20 lb of 40% gelignite. Windlass used for hoisting, as Gov't regulations require certificated engr for power hoists, and he does nothing else. Of 3-man crew, 2 are at bottom while drilling, and at top while mucking (500).

Alaska Juneau. Data from L. H. Metzgar in 1932. To develop the north orebody down to 1 000 ft below haulage level, 2 winzes at 60° inclination were sunk through slates, gabbro, and quartz stringers (564). One, 7 by 11 ft, had two 4 by 4.5-ft compartments, the other, 7 by 13 ft, 2 hoisting compartments and a manway. V-cut rounds were drilled with wet jackhammers; 8 cut holes were fired first with 40% gelatin and their muck hoisted before drilling rest of round. In smaller winze 3 men, in larger, 4 men drilled and blasted on one shift, and a like crew mucked into 0.75-ton buckets on next shift; another man ran air hoist. There were 3 shifts per day. Same crews placed 8 by 8-in timber sets at 6-ft centers. Small flow of water was bailed by hand; 10-in exhaust fans provided ventilation. For other data see Table 25.

Winzes sunk with Calyx drill, United Verde mine, Ariz. Data furnished 1939 by C. E. Mills, Chief Engr. Calyx drilling at this mine has been for: (*a*) sinking vert waste chutes for filling stopes (Art 62); (*b*) ventilation openings, where vol of air passed does not exceed 60 000 cu ft per min; (*c*) exploratory shafts. The Calyx is not intended to displace usual drilling in raises, and is not applicable to following of irregular orebodies; it is limited also to nearly vert holes. A drill making a 4-ft hole began in Oct, 1937, and to end of 1938 made 863.5 ft, mainly on 1-shift (2 or 3-man) work; one hole, 241 ft, was for shaft development; another, 281.5 ft, for ventilation; and 4 holes were for passing fill.

Calyx drilling of large holes is described in Sec 7, 9. Fig 168 shows arrangement in United Verde mine. Usual design of drilling barrel was improved by making it of 2 concentric 0.5-in shells spaced $^3/_8$ in apart by a filler plate slotted so as to deliver water and shot directly under cutting edge. Total equipment, incl rods, weighed 14 tons; cost, $12 800. For a 10-ft drill spindle, station excavation is about 22 ft high, 4 by 6 ft at top, and 8 by 16 ft on floor. SPEED AND COST. Footage per drill-shift depends on hardness of ground, its condition as to fracturing, cementing required, and vol of water raised. Badly fractured ground, which can not be cored or pulled, incurs delay for hand mucking. Best month's progress at United Verde, 133.5 ft in 51 shifts. Table 26 gives effic data and direct operat-

ing costs. Chief advantages of calyx drilling (where applicable) compared with raising are: (*a*) relative safety; (*b*) avoidance of dust and difficult ventilation; (*c*) in case of waste passes, no interference with stoping. Chief drawbacks are cost of cutting drill stations, moving and setting up equipment, and relatively high price of drill.

Winzes sunk with Calyx drill, Butte, Mont. Data in 1939 from J. A. O'Neill, Eng Research Dept, and J. J. Carrigan, Gen Supt, Anaconda Copper Mining Co. At Butte, Calyx holes are used for ventilation during development of lower levels. On starting a new level from a shaft, a hole is drilled from the next higher level at a point 100 ft or more from shaft, and used to exhaust air from lower level; this leaves the whole shaft area free to furnish fresh air, and eliminates partitioning it for up-cast and down-cast. A second hole, 1 000–2 000 ft farther from shaft, or near the main orebody, serves same purpose when development has proceeded that far. The first hole, near the shaft, may then be used for pipes or other service. Holes are 100–150 ft deep, and can pass 20 000 cu ft of air per min by using a high-speed fan.

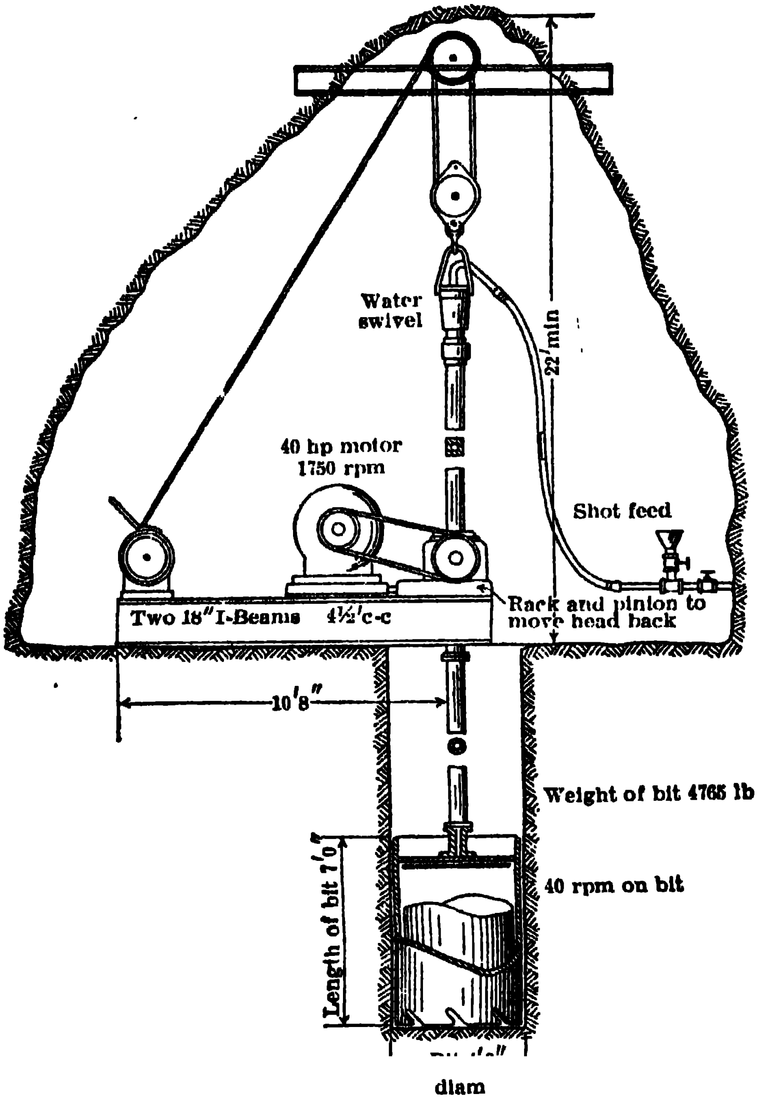

Fig 168. Set-up of Calyx Drill, United Verde Mine, Jerome, Ariz

The drill bit used at Butte is 36 in diam, over-all length, 6 ft; rotated at 100 r p m by a 30-hp elec motor. Equipment includes a single-drum air hoist for handling pumps, mucking bucket and cementing ring. Two sizes of shot used: $^1/_{16}$-$^1/_8$-in in soft ground, and $^1/_{16}$-in or finer in hard ground. The bit developed at Butte consists of a cast-steel cutting shoe with 1.25-in wall, having shot tubes extending from tops of slots in the cutting shoe to top of core barrel; this avoids introduction of shot between inside of bit and the core. A special hoisting bail, for pulling bit out of the hole, has an air connection which admits air under press and assists in raising the bit to the water level in the hole. Water is pumped from the hole by a high-head, single-stage centrifugal air-driven pump, using 3-in fire hose for discharge, and 1-in air hose for power. Mucking of broken cores is done with short-handled tools and a special bucket. Solid cores are handled as usual, with a core puller when necessary. In weak ground, walls of holes are cemented with quick-setting cement, using a collapsible steel-ring form 4 ft high, thus avoiding re-drilling of cemented sections. Drilling station is usually a crosscut from main drift; floor area, about 13 by 14 ft. To pull and store 20-ft rod sections, an excavation 20–25 ft high and 7 by 7 ft horiz sec is necessary over the hole to be drilled. Operating cycle: (1) drilling; (2) pumping; (3) pulling core or mucking; (4) cementing if required. Drilling (incl pulling bit) takes about 40%, pulling core and mucking about 30%, pumping 10%, cementing 10%, and misc work (delays and repairs) about 10% of total operating time after drilling begins; these figures vary considerably from hole to hole, depending upon the kind of ground, amount of cementing required, and water encountered. In hard ground, drilling speeds of 10-12 in per hr have been made. Shot required, 11-25 lb per ft. Between 1.5 and 3 ft of hole is finished per shift. Cost per ft of hole, $15 to $25, incl cost of machine, installation, and operation.

EXPLOITATION

24. GENERAL CLASSIFICATION OF MINING METHODS

Fundamental differences between underground methods of mining metals and coal, and between placer and other forms of surface mining, suggest the following general classification:

I.	Underground Metal-mining Methods.........	(Art 25 to 93)
II.	Open-cut Methods..........................	(Art 94 to 101)
III.	Coal-mining Methods......................	(Art 102 to 111)
IV.	Placer-mining Methods....................	(Art 117 to 131)

25. CLASSIFICATION OF UNDERGROUND METAL-MINING METHODS

General. These methods are based largely on the means of supporting the COUNTRY ROCK, and the ore itself, during stoping. Timber is generally required for auxiliary or temporary support. In some cases, timber is used only locally, to support men or slabs of rock or ore; in others, large amounts are employed, as an integral part of the method.

General plans underlying most of these mining methods are: (*a*) Surface and overlying rocks are supported by permanent PILLARS left in the orebody; chambers or STOPES are excavated between pillars, the removal of the ore being incomplete. (*b*) Chambers are excavated in the orebody, with or without use of timber, and filled either contemporaneously or subsequently with waste (as broken rock, sand or gravel). Under the support afforded by FILLING, the pillars are mined; filling, if contemporaneous, serves also to support men and stope walls during mining. (*c*) A small section of the orebody is mined and overlying material allowed or forced to cave, the process being repeated in adjacent sections. Or, successive portions of the deposit are undermined and then broken down by weight of the overlying rocks, sometimes assisted by their own weight. CAVING METHODS make no attempt to support the surface above the deposit.

These general plans are combined and varied in many ways. In veins or masses, the blocks of ore between LEVELS are usually mined in descending order; to facilitate supervision, stoping is concentrated on as few levels as possible; number of levels (lifts) worked simultaneously depends on the size of deposit, distribution of "pay" ore, and output required. In large, uniform deposits, the ideal procedure is to develop one lift while that above is being mined, and at same time to sink the shaft to the level below. Relative times required for these 3 operations, together with the nature of orebody, determine sequence and extent of development work in advance of mining. Development on a level is often not completed before stoping has been started on that level. In flat beds, mining and development may proceed almost simultaneously, the workings being extended outward in all directions from point of entry; such methods are called ADVANCING SYSTEMS of mining. In RETREATING SYSTEMS, development openings are first driven to the property boundaries, where mining begins, the working faces being carried back toward point of entry. These terms apply also to work in veins and masses.

Factors determining applicability of underground metal-mining methods: shape, size, regularity, and dip of orebody; mineralogical character and value of ore; distribution of pay ore; strength and physical character of ore and of wall rock or overlying material; relation of deposit to surface and to other orebodies and to existing shafts on same property; class of labor; availability, character, and cost of timber and material for filling.

These factors are interdependent and of varying importance. The method chosen must be safe and should give maximum profit and extraction. Last 2 factors are closely related, since a method which sacrifices part of the orebody often yields maximum total profit. High-grade orebodies usually call for some form of a selective and relatively high-cost method of mining that results in max extraction. Low-grade orebodies usually call for low-cost methods, which may yield a relatively low extraction. If possible, such methods should be so planned that low-grade ore and pillars, left on first working, may be recovered in the future if desired. Improvements in mining and metallurgical processes constantly tend to lower the tenor of profitable ores. Moreover, extended periods of high prices of metals may permit profitable mining of ore left standing in times of lower prices.

Classification of underground metal-mining methods. A logical classification, based on the factors outlined above, is impossible, because of their complex relations. TYPE OF STOPE is used here as a basis of classification; the stopes themselves are grouped, according to modes of supporting walls and men, as follows:

I. Open Stopes.........	(Art 29 to 44)
II. Timbered Stopes.....	(Art 45 to 57)
III. Filled Stopes........	(Art 59 to 66)
IV. Shrinkage Stopes.....	(Art 67 to 69)
V. Caving Methods.....	(Art 70 to 82)
VI. Combined Methods...	(Art 83 to 88)

This arbitrary classification is adopted for presenting the details with a minimum of duplication. For more detailed classification of metal-mining methods from standpoint of their applicability to different types of orebody, under different conditions as to character of ore and wall rocks, see Art 93.

26. BREAKING GROUND IN STOPES

Breaking ground covers the work of blasting, including locating, drilling, charging, tamping and firing drill holes. For charging and firing, and choice of explosive for different kinds of work, see Sec 4 and 5.

Fig 169 shows a drill hole *AB* in vertical section; top *A* and bottom *B* of a hole are called its COLLAR and TOE. Holes pointing downward are DOWN HOLES or WATER HOLES, water being usually kept in them while drilling; horiz holes, or those at a slight angle above or below, are FLAT HOLES (*FT*, Fig 173); holes drilled steeply upward are UPPERS (*UP*, Fig 173); flat holes which will not hold water, and uppers, generally were called DRY HOLES prior to development and general use of "wet" stoper and hammer drills (see Sec 15). In Fig 169, the rock surfaces *CD* and *DG* are FREE FACES, and *EF* is the LINE OF LEAST RESISTANCE of hole *AB*. Length of line *BG*, at right angles to *AB*, is the BURDEN on the toe of the hole. (For further data on blasting, and remarks on Theory of blasting, see Sec 5). In practice, the arrangement of holes and weight of charge are matters of judgment, based on experience under similar conditions and modified by experiment with the rock or ore to be broken. Methodical placing of holes, guided by a mechanical device (Art 33), improved stoping effic in certain So African gold mines; adjustment of the device is based upon experiment.

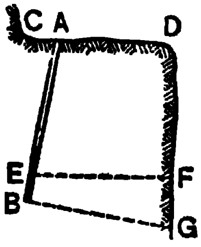

Fig 169. Vert Sec

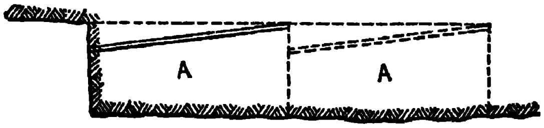
Breast stoping. Ore is broken by flat or slightly inclined holes, drilled in a vertical face (or breast) of considerable lateral area, which is being advanced in a horiz or nearly horiz direction; work resembles that of advancing the face of a very wide drift. This method is used in flat, thin beds; also in parts of masses or wide veins, to provide openings for other methods of attack (Art 30).

Slabbing is a term often used to designate breaking ground by taking a slab off a free face as at *A*, Fig 170. It is also called SLASHING or SIDESWIPING.



Horiz sec

Fig 170. Slabbing

Underhand stoping. Ore is broken in horiz slices, in descending order; miners stand on ore and drill holes downward; for different forms of stope which result, see Fig 205 to 211, Art 35. Certain applications of underhand stoping are called BENCHING. See Fig 182, 183, 188, and accompanying text.

Overhand stoping. Ore is broken in horiz or inclined slices, in ascending order; miners work beneath and close to back of stope; holes may be flat, uppers, or down holes. For different forms of overhand stope, see Art 38, 39.

Underhand and overhand methods are employed under widely different conditions as to size and nature of orebody; in both, the stope faces are usually maintained in steps or benches (Fig 205, 222, 224). Ore is blasted in blocks from free ends of benches; in nearly all cases there at least 2 free faces, to which a hole can break.

Caving (Art 70–82). A portion of the orebody is undercut and allowed to fall and crush under its own weight.

Objects sought in breaking ground are: (*a*) to break ore from stope face; (*b*) to break ore into pieces of a size suitable for handling.

Very large pieces of ore clog chutes and mill-holes and can not be handled in cars; they must often be broken in stopes by sledging or BLOCKHOLING (Sec 5), thus requiring additional labor and explosive. On the other hand, while shallow holes, close spacing of holes, and high grades of dynamite, all produce fine breaking, they do so at greater cost. These factors are usually easily adjusted in narrow stopes; in wide deposits and in large-scale operations, tendency is to increase depth and spacing of holes and to blockhole large lumps (extreme case, Fig 174). Use of large loading chutes and gates (Art 90), large mechanically hauled and dumped cars, and primary crushers underground, permits coarser primary breaking and reduces amount of blockholing. Ideal practice is that in which cost of breaking from face plus cost of blockholing to a size that can be efficiently handled is a minimum; plans adopted depend on costs of labor, explosive and power; the jackhammer drill has greatly cheapened blockholing. In general, breaking of ore in stopes to a smaller size than necessary for handling should be minimized.

27. BREAKING GROUND IN STOPES BY HAND DRILLING

General. Conditions for hand drilling: (*a*) in narrow veins, for breaking ore with minimum admixture of waste; often, narrower stopes can be carried by hand than by machine; stope-drills compete with hand drilling in this respect; (*b*) in mines of small output, usually of high-grade ore, where tonnage does not justify cost of compressor and machine drills; (*c*) where power is costly and labor is cheap and unskilled; such conditions led to former extensive use of hand drilling in the Rand mines (Art 33) now almost completely replaced by jackhammers; (*d*) in very soft ores, where hand auger drills may be preferred to power augers or pluggers with auger bits; (*e*) in the early life of mines, where stoping is started to provide funds before exploration has proceeded far enough to warrant large investment for plant: (*f*) for various local reasons, as:

At a mine in Park City, Utah, ore was sorted in large stopes into smelting and milling grades; drilling was easy and hand work favored because it allowed careful breaking, which aided sorting. At another mine, orebody was so flat and thin that machine drills could not be used and most drilling was done single-hand. At the old and extensive mines of Potosí, Bolivia, newer workings have modern equipment. Amounts of ore left in old levels do not justify cost of installing air lines, hence, such ore is still mined by hand drilling. Before introducing wet stopers at Tintic, Utah, hand drilling was used to reduce dust in mining soft galena ores, which entailed danger of "leading" the miners.

Single-hand drilling is done in medium hard ore, a miner drilling 4 to 7 ft of hole per shift; speed of drilling varies widely with character of rock; in many districts, men on day's-pay drill a certain number of holes or footage and no more, regardless of kind of ground.

Fastest drilling is usually done in vert water-holes, speed decreasing as inclination of hole flattens and is least for horiz holes or flat uppers. Speed increases in steep uppers, provided: (*a*) ground is dry, so that cuttings run out freely; (*b*) skilled hammermen are available; (*c*) there is room for miner to get a full arm swing. These relationships vary with the rock, and should be considered in planning stoping operations. Speed of drilling decreases with depth of hole. Economic limit for single-hand holes is about 3 ft; usual depth in stopes, 2 to 3 ft; 3.5 to 4.5-lb hammers are used; drill steels, $^3/_4$ to $^7/_8$ in (Sec 5).

Double-hand drilling is done in hard ground; increase in speed is not proportional to increase in labor. It is best applied to nearly vert down holes, as in underhand stopes; rarely used for systematic stoping work in U S. Drill steel, $^7/_8$ to $1^1/_8$ in; hammers, 6 to 8-lb; ordinary depth of holes, 4 to 6 ft.

In very soft ores, churn drills (jumpers) or hand-augers are more effic than single-hand work (Sec 5). Churn drills are best in down holes, and under suitable conditions will do faster work than any other hand drill; they have a very limited application in stoping. Augers are used for breast and down holes; both auger and churn drills require soft ore, free from hard streaks or nodules. Where the latter are present, or where the ground "ravels," bits with pyramidal points ("bull points") struck with a single or double-hand hammer are sometimes used to break up such obstructions. Layout of hand-drilled holes is similar to machine drilling (Fig 171-175); stope faces are carried in benches 2-3 ft high; holes are roughly parallel to free faces, but work is not systematic, since a hand miner utilizes slips and irregularities of face to aid in breaking ground; hence, consumption of explosive per ton broken is usually less than with machines.

Minimum width of stope that can be carried by hand drilling is usually 2.5 ft; narrower stopes may be possible in thin, steeply dipping veins, with well marked slips on vein walls, but men work at a disadvantage in them; min limit of width is increased by flat dips.

Data on stoping by hand drilling. Following data, though old, still illustrate duty of labor in such work; the number of skilled hammermen in the U S has decreased greatly in the past 20 years.

Standard Consolidated mine, Bodie, Cal. C. E. Grunsky gives following data for 1912 (84). Narrow auriferous veins occur in firm, fairly hard andesite. As dips were steep, there was no handling in stopes except for shoveling to chutes. Vein matter was hard banded to soft, porous, granular quartz; sometimes a soft clay, containing quartz stringers. Drilling was single-hand. Stopes were back-filled with waste, excess waste being hoisted to surface. Stopes were kept as narrow as possible; minimum width, 1.5 to 2 ft. Table 27 shows effect of width of vein on output per man stoping; it is based on tons ore, not on tons of vein and wall-rock broken. Aver powder consumption was about 2.4 lb per ton broken, and in veins with hard ore and walls it exceeded 3 lb per ton. A small Mexican mine. Data from R. H. Allen (129). Vein, 10 to 80 ft wide; footwall, strong rhyolite breccia; hanging wall, badly broken andesite; as ore was soft or cut by clay seams, it required but little explosive. Overhand stopes were supported by square-sets (Art 45), filled with waste to within 1 floor of the back; vein was mined in 15 to 24-ft sections, along strike. All labor was Mexican; single-hand drilling; 9-hr shifts. Figures cover 7 months of 1912, during which time 17 253 tons of ore were mined. Table 28 gives details. Berlin, Nev. Very hard quartz vein, carrying gold and silver; aver width, 2.4 ft; dip, 22° to 43°; wall rocks, strong andesite; vein mined by overhand stoping in open stopes; very little wall rock was broken; drilling was single-hand, holes flat or pointing slightly down. A miner averaged 3 20-in holes per 8-hr shift; 33.6 pieces of drill steel dulled per miner-shift. In Apr, 1905, 948 tons ore were broken in 809.25 miner-shifts = 1.16 ton per shift. Daly Judge mine, Park City, Utah. In 1907, single-hand miners averaged 12 ft of hole per shift in soft ore and 6 ft in quartzite. Tintic, Utah. L. A. Palmer gives data on work in 1912 (135). At Sioux Consol mine, much ground was so soft that holes for blasting were made by a pointed steel ("bull-prick"); 1 man broke 25 tons per shift. At Iron Blossom mine, in overhand square-set stopes, medium hard ore, 1 single-hand miner broke 7 to 10 tons per shift. Franklin Furnace, N J. Before machine drills were introduced, 2 men, drilling double-hand in ore like tough limestone, put in 3 holes totalling 8 ft per 10-hr shift, breaking about 8 tons, or 4 tons per miner-shift (98). Negaunee, Mich. In 1904, speed of drilling 5-ft water holes, double-hand, in soft hematite, was about 4 ft per hr; bands of jasper in the ore reduced speed greatly (136). Cavour mine, Virginia, Minn (in 1914). Ore was soft hematite, somewhat harder than usual Mesabi ground. 2 miners with hand augers made 5 6-ft holes in about 2 hr. Air-driven augers averaged 1 ft per min (137). British Columbia. Double-hand drilling of 6-ft water holes in firm augite porphyry; starting bit, 1.75-in; finishing bit, 1.25-in; 7/8-in steel. 2 men averaged 14.8 ft of hole per 10 hr (133). Braden Copper Co, Rancagua, Chile. In 1909 native miners averaged 13.5 ft of holes per 9 hr, single-hand; ore is fractured and brecciated andesite and tuff, moderately hard (138). El Tigre mine, Sonora, Mex In vert quartz veins about 4 ft wide, Mexican contract labor, drilling single-hand in overhand stopes, put in about 10 ft of hole per shift. So Africa. Before introducing jackhammers in Rand gold mines (about 1920), most drilling in reefs less than 5 ft wide was done single-hand, in down holes, with 7/8-in steel. In hard, unoxidised ore (Art 33) a Kaffir "boy" made 1 3-ft hole per shift, breaking about 0.6 ton of ore; in stopes less than 3 ft wide, holes were usually 2 ft deep; in soft oxidized ore, drilling rate was doubled. Rhodesia. Quartz veins dip 65°. Native single-hand drillers make about 2 ft of hole per shift in hard quartz. Stoping is generally underhand; holes, 2 to 3 ft deep; a 2-ft hole in a stope 4 ft wide breaks about 0.6 ton of ore, if stope face is well

Table 27. Overhand Stoping by Hand. Narrow Veins

Width of vein, in			Vein filling	Dip of vein	Tons ore broken per man-shift

benched (139). Russia. Eiderlinsky gold mines (1915). Quartz veins 2 to 7 ft wide, dipping 28° to 71°, occur in granodiorite. In hand-mined stopes, 2 native miners, working double-hand on a bonus system, drilled up to 10 ft of hole per 8 hr. Min task per shift was 4.42 ft of horiz hole in overhand stopes, or 5.83 ft of water hole in underhand stopes. $^7/_8$-in steel was used, with cutting edge from 1 to 1.5 in (140). Chiksan mines, Korea (in 1914). Gold ore occurs in shoots in 4 to 8-ft quartz veins, dipping 65° or over; country rocks, schist and granite. Korean contract miners, working overhand in shrinkage stopes, drilled 4 ft of hole per shift, breaking 0.5 to 0.57 ton per man-shift; consumption of 60% gelignite was about 0.4 lb per ton (87).

28. BREAKING GROUND IN STOPES WITH MACHINE DRILLS

(For definition of names of machine drills as used here, see Art 20)

Breast stoping. See Art 30.

Underhand stoping (see also Art 35, 36). Fig 171 shows 1 bench of an underhand stope. All holes are down holes, usually in rows across the stope. Jackhammers are commonly used for this work, but occasionally mounted hammer drills are preferable; the latter are mounted on tripods in wide stopes or on bar mounting in stopes up to 8 or 10 ft wide. Height of benches depends on width of stope, nature of ground and size desired for broken ore; depth and spacing of holes vary widely, depending largely on last two factors. High benches can not be broken efficiently in narrow stopes; usual height in stopes up to 10 or 15 ft wide is 5–8 ft.

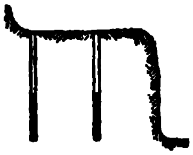

Fig 171. Vert Sec

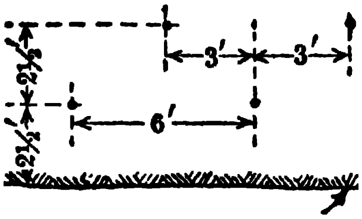

Fig 172. Plan

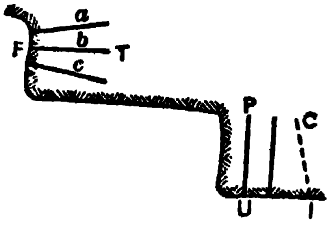

Fig 173. (In wide stopes, this is a vert, longit sec; in narrow veins, a sec in plane of vein)

Usual limit of depth of hole by either heavy mounted hammer drills or jackhammers, 16–20 ft. Deep holes make for cheap breaking; objections to them: (*a*) long steels are awkward to handle; (*b*) ore may break in large pieces difficult to handle along stope face. Objection (*a*) has been overcome in some mines by jointed drill steel. Objection (*b*) may not be serious; deep holes usually make steep stope faces, where large pieces come to rest at foot of bench convenient for blockholing. Usual depth of holes in wide underhand stopes is less than 12 ft. Burden broken with holes as in Fig 171 depends on local conditions and must be determined by trial. In easy ground, max distance between holes and between rows of holes is 0.75 to 1 × depth of hole (Art 26). In tight ground, at Alaska-Treadwell, 12-ft holes were 6 ft apart in rows 2.5 ft apart, and staggered as in Fig 172 (133). For further detail, see Breast stoping, Art 30.

Overhand stoping comprises stepped-face and flat-back stopes (Art 38). Fig 173 shows a stope face. Benches are broken by flat (breast) holes, running across stope, as *FT*, or by uppers, *UP*. Uppers pointed as at *IC* cause cuttings to fall clear of drill. In narrow veins, uppers are parallel to dip to avoid breaking into walls. For safety and economy, stope face should be kept normal to dip.

Uppers *vs* breast holes. In general, uppers are more apt to make a ragged stope back than breast holes. With breast holes, miner is less exposed to danger of ground falling from jar of machine. Hence, for safety, breast holes are preferable in wide stopes. In schistose ground, choice may depend on direction of schistosity, because in some mines holes parallel to it are difficult to drill and break badly. Improvement of stopers in recent years, including automatic rotation, makes uppers preferable where ground conditions allow their use. Stoper drills avoid the loss of time in setting up and "tearing down" mounted drills. Less skill is required to operate stopers than mounted drills.

Uppers are common in overhand narrow stopes on steep dips; breast holes are used in such stopes on low dips. This is true of both hand and machine drilling; type of drill used also affects choice (see below under Choice of drills for stoping). Uppers may be drilled with either mounted hammer or stope-drills, usually the latter; breast holes, with hammer drills, which, in stopes up to 8 or 10 ft wide, are mounted on bars; in wider stopes, usual mounting is a column braced between back of stope and filling or timber.

Height of bench in machine-driven, overhand stopes depends on same factors as for underhand work. In narrow stopes, benches are 3–6 ft high; in wide stopes, breast-hole

Table 29. Breaking Ground in

Example	Mine and location	Type of ore	Dip	Stoping method	Width of stope, ft	Drills

benches are 6–12 ft high, broken by 2–3 rows of 6–12 or 14-ft holes (*a*, *b*, *c*, Fig 173). Benches broken by uppers are usually 5–8 ft high and holes have corresponding depths. Table 20 shows practice as to depth of hole. In square-set stopes (Art 46), depth of either breast or upper holes is determined by dimensions of sets.

Character of ore may influence depth of hole, and therefore height of bench; comparatively shallow holes may be used in very soft ore, because blasting merely chambers the bottoms of deeper holes, failing to break. In cut-and-fill stopes, height of bench is usually limited to 7–8 ft, because of chute-timbering details (Art 47). Also, smaller height of bench lessens danger to shovelers working under high backs. In shrinkage stopes, height of bench depends largely on blockiness of ground, and means provided for secondary breaking. If blasting chambers are provided under stope and no block-holing is required in the stope, benches may be as high as 12 ft. If ground is blocky and there are no blasting chambers, height of bench may be limited to 3–4 ft (Art 67–69).

Fig 174 shows a cheap method of breaking ground, combining caving with ordinary overhand work, which has been used in large flat-back shrinkage stopes (Art 67), in several porphyry copper mines and with modifications at Homestake, S Dak. At Ray Consol mine, Ariz, vert shrinkage stopes are 10–15 ft wide in soft ore, and 15–20 ft wide in harder ground. Pairs of 6-ft holes, drilled along each side of stope (Fig 174), break shaded areas; this robs central portion *A* of its support and causes it to fall by gravity (61). This principle was also used in wide stopes at Alaska Gastineau (530) (Art 87). A similar method has been used at Braden mine, Chile.

Rill stopes (see Art 38). Fig 175 shows sections through stope faces (133) using the original "rill cut" which was designed for wet down holes to avoid dust and favor hand drilling. Holes are drilled in rows across stope. With introduction of "wet" stopers, this type of cut is largely outmoded. For more recent form of benches in rill stopes, see Art 65.

Ring drilling. Holes are drilled radially from within a raise or drift large enough to accommodate drilling. Holes break to free face generally parallel with plane of drilling. Fig 176 shows application to sub-level stoping (Art 43). For an example of ring drilling from raises, see Beatson mine, Art 68.

Choice of drills. Stope-drills are not used ordinarily for breast stoping, as they are awkward for flat holes. For this work, the choice depends on hardness of ore; in very hard ores, heavy mounted hammer-drills are required; under aver conditions these or lighter mounted drills are used; in very soft ores light jackhammers or air-driven augers are the logical choice.

Many of the remarks on choice of drills for drifting (Art 20) apply here. For down holes in underhand stoping, jackhammers are effic. In steep-dipping overhand stopes, where the holes are uppers, stope-drills are best under aver conditions. They are light and allow holes to be pointed as desired; delay in setting up, incident to mounted-drill work, is avoided and that due to changing steel is reduced. Question of safety of stope backs may dictate use of flat holes drilled by mounted hammer drills, instead of uppers drilled by stopers.

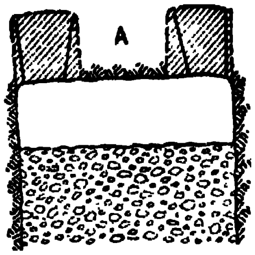

Fig 174. Vert Sec through Top of Stope

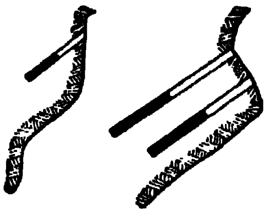

Fig 175. Rill Cut (after H. M. Thomas)

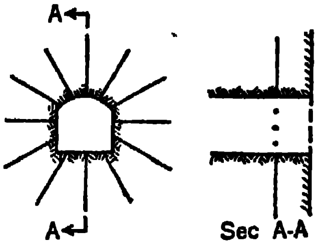

Fig 176. Breaking Ground by Ring Drilling

Breaking ground in overhand stopes on flat dips (20° to 30°) resembles breast stoping. In general, mounted drills are used: (*a*) in ground that is very hard or that fitchers badly, even if soft; (*b*) in large-scale blasting with deep holes in large stopes. MINIMUM WIDTH OF STOPE in which heavy or light mounted drills operate efficiently is about 4.5 ft; this width is apt to be exceeded, especially for large drills. Stope and plugger-drills can be used in stopes about 3 ft wide on steep dips, but constant supervision is required to maintain this minimum. Min stope widths on flat dips are ordinarily greater than above; determining factor is headroom in which men are willing or able to work efficiently. In narrow orebodies, where clean mining is desired, these factors influence choice of drill and also choice between hand and machine drilling (Art 27).

Underhand *vs* overhand breaking. (See Art 44).

Data on breaking ground by machine drilling in stopes. Table 29 presents data generously supplied in 1938 by managements and engineering departments of the mines listed. It applies only to stoping methods in which all or most of the ore is broken by direct drilling and blasting, as distinguished from those caving methods in which only a small part of the ore is thus broken. Differences in character of orebodies, mining methods, and local conditions cause wide variations in duty of labor, drills, and explosives. The table is valuable as showing present practice and results under widely differing conditions. For further information, see descriptions of individual mining methods.

OPEN STOPES

An open stope, strictly speaking, is a stope in which no timber or filling is used to support walls or men; a finished stope is an open cavity. Various authorities consider unfilled timbered stopes (Art 45–57), shrinkage stopes (Art 67), and some other forms as open stopes; as used here, the term comprises stopes in which walls are supported by pillars of ore, or by stulls and other simple forms of timbering.

29. GOPHERING

"Gophering" is a name applied to mining in irregular drifts or other openings, which "follow or seek ore without regard to maintenance of a regular grade or section" (1); the method is also called "coyoting" in western U S; in general, the term designates any small-size, irregular, unsystematic workings.

Gophering is a poor man's method, used in small excavations where walls require little or no support; obviously it may be employed in portions of veins, beds or masses, but has no place in systematic mining. If used to mine rich seams in a large orebody, gophering often results in temporary profit but eventual loss, as the irregular openings increase cost of, or prohibit, mining the remaining low-grade portions. On the other hand, gophering has a place in mining small irregular portions or isolated parts of an orebody, where cost of systematic development is not justified by probable tonnage to be won. This is especially true of small, high-grade, spotted deposits, and where Mexican or other native labor, skilled in this work, is available. Such work, done by "leasers," may be an important adjunct to regular mining.

Native miners in Mexico, South America, India, and elsewhere, are adepts at gophering; no stope development is done in advance; ore is followed up, down, or laterally, as values vary, and workings soon become intricate. Miners sometimes carry ore to surface in baskets or sacks, holding 75 to 150 lb; inclined winses or ladders connect workings at different elevations; Mexicans use "chicken ladders," logs 10 to 15 ft long, 8 to 10 in diam, set on end, and with notches cut on one side. Breaking ground in gophering is generally done underhand; openings are rarely timbered or filled.

30. BREAST STOPING

General. The term "breast stoping" denotes primarily a method of breaking ground in any stoping system by advancing nearly horizontally a vert face or "breast" of ore, usually 10–12 ft or less in height, which has not previously been cut off at top or bottom (Art 26). It logically becomes the name of the mining method used in horiz or flat-dipping orebodies up to 15–18 ft thick, when mined by open stoping. It is not applied to the method of mining such orebodies when caving, filling, or square-setting is involved, even though the ore is broken by "breasting." It does refer, however, to a method applied to thicker flat-lying deposits, in which the upper 6–8 ft is broken by true breast stoping, the lower portion by benching (Fig 182); in this case, the term "breast and bench" is more descriptive and is often used. Roof support in breast stoping is usually by permanent or semi-permanent pillars of ore.

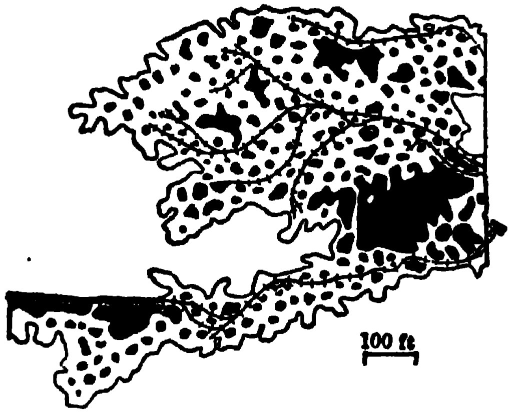

Fig 177. Plan of Part of a Mine in S E Missouri, worked by Breast Stoping

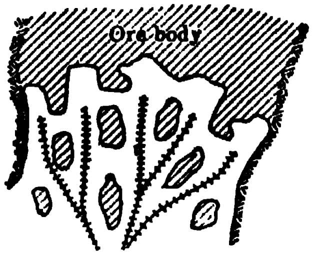

Fig 178. Plan of Breast Stope

Applicability. Breast stoping is usually applied to relatively thin, flat or low-dipping bedded deposits or veins where both ore and roof are strong. It is rarely used for thicknesses over 100 ft, though some older workings of S E Mo, where the method is common, are over 200 ft high. In this district, a stoping height of 40 ft is now rarely exceeded. It is a low-cost method, which usually sacrifices some ore in permanent pillars; hence, especially suited to low-grade ores where high extraction is not of first importance. As the method is moderately selective, in that areas of uneconomic grade can be left unmined, uniformity in distribution of values is not a requisite to its use.

Development. In flat-lying bedded deposits, a vert shaft is sunk to bottom of orebody; practically no lateral development precedes mining, although orebody may have been outlined by borings; stopes follow the ore outward from shaft (Fig 177). Where the method is applied to deposits of moderate dip, development usually depends on local conditions; for example, breast stoping may be used only as a supplement to another method in mining flat-dipping portions of a vein of variable dip.

General plan of work. In flat deposits less than 12–15 ft thick, the method resembles the driving of wide drifts, intervening ore being cut through at intervals to form pillars. Fig 178 shows different stages of work; obviously, the face can be advanced in any direction. Same general principle applies in flat orebodies of greater thickness; Fig 177 is a plan of a mine in S E Mo, showing application of method over a large area. In deposits with moderate dips, face of stope may be carried parallel to either dip or strike. As dip increases, the work of breaking ground may be the same as that of open stoping in narrow veins, either underhand (Art 35) or overhand (Art 38). Where the face advances downward, the openings are sometimes called DIP WORKINGS.

Breaking ground. Methods vary locally and with thickness of orebody; see examples of practice, Art 31, 32, 33.

Support of roof in breast stoping is by pillars; in low-grade uniform deposits (as beds of calcareous shale used for making cement or in beds of rock salt), systematic arrangement and uniform size of pillars are feasible and desirable (Art 34).

Pillars may be of any shape and size (Fig 177), but in metal mines are roughly circular in horiz sec. They are splayed out at top and bottom to increase area of support and bearing on roof and floor. Fig 179 shows a means of dealing with a shelly roof, or one which scales on exposure to air; it is feasible only for light pressures and in strong, low-grade ore. Where roof is fissured with parallel joints or cracks, stoping may unkey large slabs; this danger is partially averted by a systematic staggered arrangement of pillars.

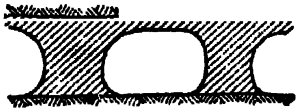

Fig 179. Vert Sec

In some S E Mo mines, ore occurs in overlapping beds separated by barren limestone. These are worked from separate levels, care being taken that the pillars in upper and lower beds shall be directly over each other.

In the TRI-STATE and S E Mo DISTRICTS, pillars are larger and spaced closer in weak ground and left where possible in low-grade or thin parts of orebody. They are placed with regard to haulage tracks to avoid awkward curves, and are 10 to 60 ft diam, with intervening roof spans of 18–80 ft. Slabs of rock scaling from roof between pillars cause serious danger and trouble in breast stoping; in thin portions of deposit, slabs are supported by vert props; in thick orebodies, all shelly ground is removed from heading roof before bench is advanced. Even with this precaution, roof-men are constantly employed in Mo lead mines to bar down slabs in worked-out areas near stope faces or over traveling ways; where possible, slabs are taken down with bars and gads; this costs more than blasting but is safer; black powder used for blasting; holes drilled by hand or plugger or stope drill. Fig 180 shows details of staging used to support men and drills taking care of high backs at Bonne Terre mine of St Joseph Lead Co; 3 men accustomed to the work can put up 3 or 4 sections, or take down 6 to 8, in an 8-hr shift. All material is reused except eye-bolts, which are left wedged into roof (163, 521). Much trouble from slabs is caused by accumulations of water under pressure in bedding planes of roof rock; at some mines vert holes ("drain holes"), 8–10 ft deep, are drilled from heading into roof every 8–10 ft, to allow water to escape (164). REINFORCEMENT OF PILLARS: Gunite has been used to stop slacking and crumbling of old pillars. Pillars have been enlarged and strengthened by building forms around them and filling with concrete. Old pillars have been reinforced with tie rods, or by placing vert steel rods against face of pillar and wrapping with old cable (155).

Handling ore. Tracks are laid on floor of deposit, from point of entry to the stope faces (Fig 177, 178). In thin deposits, tracks run into headings; in thick, they extend to foot of benches. Where more than 1 bench is worked, the heading ore is shoveled to foot of lowest bench; general slope of benches is kept steep to minimize handling. Broken ore is shoveled into cars by hand or machine, and trammed to shaft by hand, or by animal or mechanical haulage, depending on distance and output; in some mines, buckets ("cans") are mounted on light trucks, reducing cost of haulage and hoisting equipment.

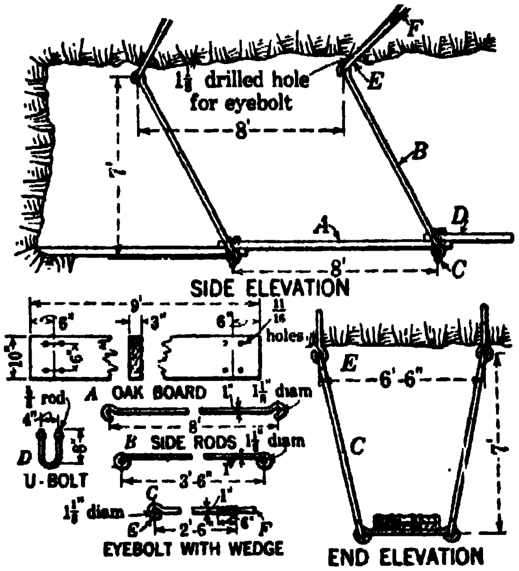

Fig 180. Hanging Scaffold or Staging

In some TRI-STATE MINES, shoveling plats of 2-in oak plank are laid at foot of stope bench. Work is usually done on contract. At Hartley mine, Kan, C. M. Anderson, Supt, states in 1932 that, in low ground, all loading is done by hand into cans holding 1 400 lb. In high ground, both hand and power-shovel loading are used. Aver rate of loading of shoveler is 35 tons per 8-hr shift (323). At Picher, Okla, a shoveler on contract loads into cars 30–40 tons per shift (115).

Machine loading, S E Mo. Conditions are favorable for mechanical loading. St Joseph Lead Co used the St Joe shovel (see Sec 27) for nearly all mucking in its Mo properties until 1936 (116), when scrapers were first tried and proved effic in robbing pillars, recovering ore left in floors, and in general supplementing power-shovel work. In 1937, standard scraper equipment comprised 35-hp double-drum hoists and 54-in scrapers. Ore is either scraped up a ramp to a loading platform over the cars, or pulled into chutes (127). Power-shovel operators work under a bonus system; a task is set at regular daily wage, with bonus for excess tonnage. Usual task is 42 2.5-ton cars, varying with conditions from 32 to 48 cars (155). In TRI-STATE DISTRICT, hand shoveling is common in small mines; mechanical loaders used in some large mines (see Table 30). At Barr mine, Kan, using 25-hp elec shovel, 10-cu ft dipper and 1.5-ton cars, usual performance in 1929 was about 100 cars per shovel-shift; occasional max of 116 cars in 4 hr (143). Scrapers have also been used to advantage in some Tri-State mines. See Art 31, 32.

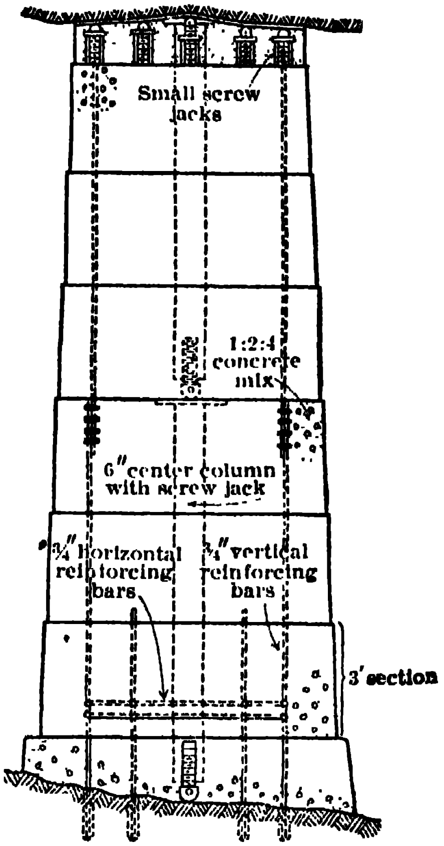
Table 30. Comparison of Cost of Loading with Power Shovel and by Hand at Hartley Mine, Kan, in 1932 (323)

Power shovel	¢ per ton
Connected energy charge	0.382
Power consumed	0.946
Depreciation and repairs	3.070
Interest charge	0.776
Labor (one operator with helper and extra trammer)	7.830
Total	13.004

Hand shovelers	¢ per ton
Contract price	21.202
Shovels and picks	0.167
Total	21.369

Note. Small revolving shovel driven by 15-hp elec motor, can operate in a 9-ft room, loading into cans holding 1 400 lb. Data for power shovel cover 127 working days, in which 16 565 tons were loaded.

Percentage of ore left in pillars depends on: (*a*) CHARACTER OF ROOF, which determines max allowable width of heading that will stand unsupported, and therefore the distance between pillars; (*b*) CHARACTER OF FLOOR. A soft floor requires pillars of large area, or closely spaced, so that their bearing power will not be exceeded; (*c*) STRENGTH OF ORE determines minimum section of pillars to withstand pressure of overlying rock; (*d*) DEPTH OF DEPOSIT determines total wt to be carried on pillars, where deposit has such lateral extent that overlying rocks do not arch, and become self-supporting (see Subsidence, Art 114). These factors are interrelated, their effect can not be definitely determined in advance in new districts; the percentage of ore left in pillars may be fairly constant in a given mine, but varies widely in different localities. For example: H. A. Guess in 1914 estimated, for S E Mo district, that 15% of area mined was left in pillars (55). C. F. Jackson, 1929, estimates 10% left in pillars at largest property in the district (155). At Hartley Grantham mine, in Kan, where ore occurred in brecciated, loose formation, O. W. Keener in 1930 stated that approx 40% of the area of developed orebody was left as pillars on first mining, but that a high total extraction is expected when pillars are pulled or robbed (157). At Barr mine, Kan, in 1929, 15–18% of area mined was left in pillars; it is planned eventually to mine pillars in good ore, but leave permanently those in lean ore (143).



Small screw jacks
1:2:4 concrete mix
6" center column with screw jack
3/4" horizontal reinforcing bars
3/4" vertical reinforcing bars

Fig 181. Concrete Column replacing Ore Pillar, S E Mo

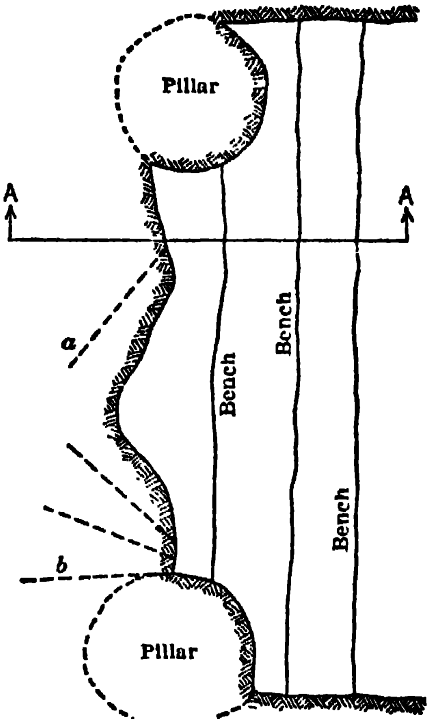
Recovery of ore from pillars. A mining-method like breast stoping is justified by its simplicity and cheapness and because, where properly applied, it yields a max profit in spite of sacrifice of pillar ore. Use of method is usually confined to low-grade deposits, where value of ore in pillars does not repay cost of replacing them by artificial supports. Some recovery of ore in pillars is often possible (see St Joseph Lead mine, below). Also, conditions may require leaving in pillars on first mining a relatively large percent of the ore; then pillar robbing or recovery becomes important. Recovery of ore from pillars is costly and requires extreme safety precautions.

In S E Mo, some pillars left years ago have proved unnecessarily large and considerable ore has been recovered by reducing their size. In 1937 the St Joseph Lead Co started to remove many high-grade ore pillars under the protection of concrete pillars (Fig 181) built and located with care near the pillars to be removed. Bottom of concrete pillar has a diam that permits tapering to a min of 8 ft. Base of pillar is doweled to floor by drilling 16 2-ft holes, in which are grouted vert reinforcing rods 9-12 ft high; these support circular forms 3 ft high, of 10-gage iron. Concrete is blown into the forms through a 4-in pipe by comp air. When the pillar is within 1 ft of the back, numerous 3-in screw jacks are placed on its top, with 2-in iron plates on top of the jacks, which are then tightened, and space around them is filled to the back with concrete. Such pillars have been built to height of 47 ft (127).

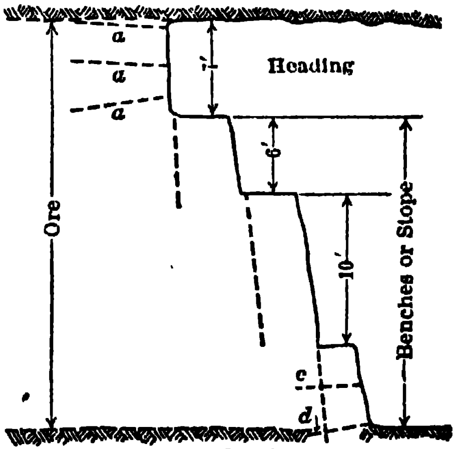
According to information from C. W. Nicolson in 1938, efforts to recover pillars in the TRI-STATE DISTRICT have been confined mainly to "gouging" by leasers. In recent years, some companies of the Okla-Kan section have trimmed and removed pillars quite extensively where ore reserves were exhausted. Many orebodies in this region are long and narrow, and the amount of ore originally left as pillars does not aver more than 10% of total (0-15%). Many original pillars were either unnecessary or too large; by removing or trimming them, the ore recovered, in individual mines, is probably $^1/_3$ of the original pillar tonnage. These ore pillars have not been replaced by other support, due to the high cost. Pillars 100 ft high have been successfully removed. When companies complete their own efforts, certain portions of the mine are usually turned over to leasers, who trim and remove pillars while retreating, recovering about 50% of the remaining pillar tonnage. Nicolson estimates that the combined work of company and leasers gives an ultimate recovery of about $^2/_3$ of the original pillar tonnage in leased areas, or about $^1/_2$ for the entire mine. Some falls of ground occur, but surface is unaffected, as deposits are overlain by strong beds of flint and limestone.

31. EXAMPLES OF PRACTICE, BREAST STOPING IN FLAT BEDDED DEPOSITS (S E Mo, Tri-State District, and Wis)

S E Missouri. Data from C. F. Jackson (155) in 1929. Disseminated galena occurs in dolomitic limestone. Formation, nearly horiz, has normal thickness of about 365 ft and outcrops in places; ore is chiefly in lower 100 ft. In the property described, thickness of individual ore beds is from 7 ft (min mining height) to over 200 ft, but stopes rarely exceed 40 ft high. Stoping widths are from a few to several hundred ft; some orebodies are 800 ft wide by 1 200 ft or more long. As a whole, the ore is in flat beds and the formation is self-supporting over wide spans. DEVELOPMENT. Property described covers a large area, containing numerous and sometimes widely separated orebodies. A number of vert shafts, sunk originally to develop the separate areas, were later connected by crosscuts, hoisting now being done through one vert shaft, with drifts, crosscuts, and raises as required. Main haulage drifts have min of 8 by 12-ft cross-sec. Other openings are usually 7.5 or 8 ft high. Raises, 6 by 9 ft, are commonly driven at an inclination of 45°, seldom vert. STOPING. Where ore is not over 9-10 ft thick it is breasted out to full height. In thicker ore a breast 7-8 ft high is driven at top of the ore; lower part is mined in one or more benches (Fig 182). Pillars of ore are left for roof support as required. Stope faces are kept close to face of heading. In breasting thin ore and driving headings, holes, *a*, 8-10 ft deep, are drilled in sets of 3, one above the other. Face of breast is purposely kept irregular, to provide free faces to break to. Burden on holes is 3-4 ft; middle hole in any set, having about 6 in less burden than others, is loaded more heavily, and fired first. Jackhammers, mounted on columns and with pneumatic feed, are used. Span between pillars in strong ground is 30 ft, decreasing to 16 ft in weaker. In turning pillars, holes are drilled tangentially to face of pillar (*b*, Fig 182) to avoid shattering it. Bench ore is broken by down holes drilled with hand-held jackhammers. Depth of top bench is limited by length of steel that can be handled in heading, usually 6 ft. Holes on lower benches are up to 10 ft deep. Bench or stope holes are drilled 3-4 ft back of face, and 6-8 ft apart. Lowest bench is mined with down holes if the ground breaks to a bedding plane with a resultant smooth bottom; otherwise, this bench is broken with "lifters" and "splitters," *c* and *d*, Fig 182. For lifters, drill rests on 2 parallel strips of wood laid on floor and connected on their underside by 2-in cross slats, with 2-in spaces. Driller uses a pinch bar, with a slat as a fulcrum to exert press on back end of drill; this device allows miner to stand while drilling. Several headings and stopes may be worked together in a given area. One man does the drilling for a heading and the stope behind it. The rock drills easily and 80–100 ft of hole is aver per shift. In a heading or in breasting thin ore, a miner breaks about 30 tons per shift; in bench or stope, 90–120 tons per machine-shift is common. Powder consumption varies: an aver of 0.459 lb of 40% ammonia gelatin per ton was used in mining 49 700 tons at this property in one month in 1929. Miners work on contract, based on ore broken; prices vary with height of stope and nature of ground. For data on breaking ground at Bonne Terre mine, S E Mo, see Ex 3, Table 29.



Plan of heading and stope



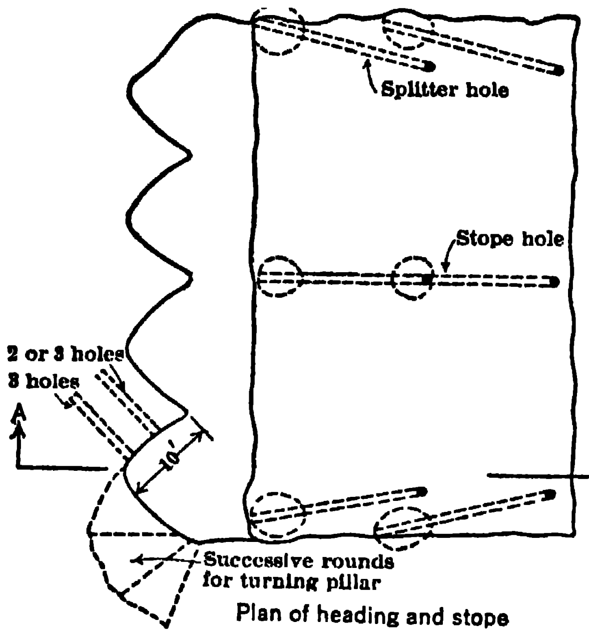
Vert Sec A-A

Fig 182. Breaking Ground by Breast Stoping, S E Mo

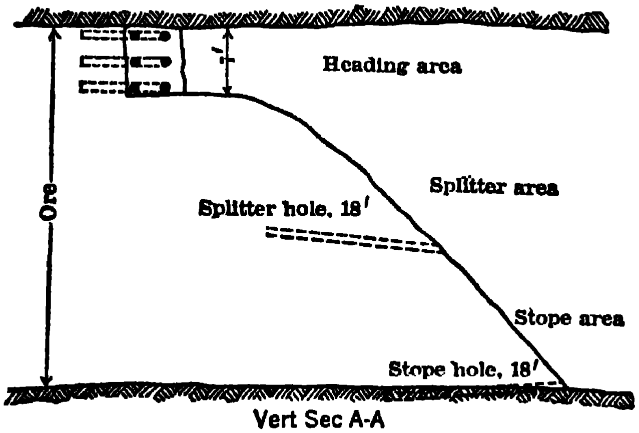
Tri-State District (S W Mo, S E Kan, and N E Okla). Breast stoping is used exclusively for flat bedded deposits of sphalerite and galena in flint and chert. Overlying rock is usually strong flint, standing well; sometimes, heavily fractured flint or limestone requiring close spacing of pillars. Main types of deposits: SHEET GROUND averages 7 ft thick, and is low-grade, crude ore assaying about 3.5% Zn and 0.5% Pb. It was mined extensively in S W Mo before 1918, at an aver depth of 150 ft, and since then locally, in Kan and Okla, at depth of about 350 ft. BRECCIATED GROUND occurs in beds, 6–30 ft thick, the most prolific being 20 ft thick; occasionally, in strong shear zones, mineralization extends through several beds, forming deposits 180 ft thick; aver grade of crude ore, 7.5% Zn and 1.0% Pb. This type of deposit has been mined largely in Kan and Okla from 1915 to 1938, at aver depth of 250 ft, and to some extent in Mo at shallow depths. For methods of exploring these deposits, see Art 10-b. DEVELOPMENT. Entry is by single-compt vert shafts, usually 6 by 6 ft inside timber, and sunk to lowest ore horizon. Most mines are opened on only 1 level. If shaft cuts ore, no lateral development is necessary in immediate ore area, but various "pull drifts" may be driven to isolated orebodies. Such drifts, rarely timbered, are 7 by 7 ft to 8 by 10 ft. STOPING. Breast stopes are carried with a single vert face in thinner deposits (6–12 ft), sometimes to 18 ft. In thicker deposits, a heading 7–8 ft high is driven at top of orebody; its face is kept 15–20 ft ahead of bench. Sometimes several benches 10–15 ft high are carried, making total height of excavation as much as 100 ft. Benches are broken with flat holes drilled from tripod or "stope boards" (Fig 185). According to C. W. Nicolson (191), hand loading into cans 32 in diam and 32 in deep, holding 1 400 lb, continues to be generally used. Aver shoveler loads about 25 tons per shift; under favorable conditions some men can load 50 tons per shift. Experiments with power shovels have not been generally successful. Recently, several of the larger companies have installed scrapers, with good results (see below for scraping at D. C. & E. mine). For further data on scraping practice in Tri-State district see Art 91 and Sec 27. Operating and cost data at 2 representative mines of Picher district are shown in Table 32.

No 1 mine, Picher, Okla. Data from W. F. Netzeband (115) in 1929. Fig 183 shows stoping in ore 25–40 ft thick; for faces about 40 ft high, a round of 6 splitters and 3 stope holes are used. Slope of bench is kept at about 45°. Holes are drilled with 20-ft steels: splitters, with a rise of 1 in per ft; stope holes downward, 1 in per ft. Bench holes were formerly squibbed, or chambered, before final charge was loaded, but this practice has been abandoned in recent years. Aver stope or splitter hole breaks about 250 tons; powder consumption, 0.75 lb per ton. Ordinarily, 30% ammonia dynamite is used, but for wet work or poor ventilation, gelatin powder of same strength is substituted. In headings, about 40 tons per machine-shift are broken; in benching, 60–75 tons. Pillars are 20–60 ft diam, depending on ground and height of roof; aver pillar diam, about 30 ft. Spacing varies, 40–100 ft c-c, aver 80 ft. Pillars represent about 15% of total area mined, but many are recoverable.

Hartley mine, Kan. Data from C. N. Anderson (323) in 1932. Sphalerite and galena occur in flat beds of chert about 300 ft below surface; sometimes in irregular masses. Mineable ore is 8–25 ft thick. Fig 184 shows methods of breaking ground. Pillars are 20–30 ft diam and spaced an aver of 40 ft edge to edge. Care is taken not to break a flint stratum overlying the ore, as roof may become slabby and dangerous. In low ground, mining is done by breast stopes with a single vert face; detail of work is similar to that for headings. Thicker ore is mined with headings and benches. Heading is 7 ft high; between pillars the face is in zig-zag form; drill round comprises 6–8 holes, 8–10 ft deep, by column-mounted drills. Midway between heading and floor, "splitters" are drilled 8–10 ft apart to depth of 12–14 ft, from tripod mountings. Floor or stope holes point slightly downward; they are 16–18 ft deep, drilled within a foot or two of mine floor; drills for these holes are mounted on either a tripod or "stope-board" (Fig 185). Aver tons broken per machine-shift in low ground, 71; in high ground, 72.5. In low headings with poorer ventilation, 35% gelatin is used; in high ground, 40% permissible explosive. Chambering of splitter and stope holes is rarely necessary. Over a 6-mo period, 180 212 tons were mined with powder consumption of 1.12 lb per ton.



Plan of heading and stope



Vert Sec A-A

Fig 183. Stope and Heading Rounds, Breast Stoping, Tri-State Distr

D. C. & E. mine, Oronogo, Mo. Data from C. W. Nicolson (173) in 1938. Orebodies lie in sheet-ground horizon, about 150 ft below surface. Deposits are of considerable extent laterally, but have an aver vert thickness of only 7 ft. Sphalerite and galena occur in horiz bands, or in vugs in a flint gangue; aver assay of crude ore, 3.5% Zn and 0.4% Pb. From 1920 to 1937, this district was idle, due to low metal prices. D. C. & E. mine was reopened to determine whether mechanization would make mining profitable. Scrapers used for loading, and belt conveyers for transport to shaft. Results were successful. Details. Mine is served by vert shaft (1) (Fig 186), formerly equipped with cage but refitted with 2-ton skips, loaded from a 50-ton storage hopper (2) at the shaft. Conveyer belt (3), 24-in wide, speed 350 ft per min, delivers to this hopper. Scraper (4) loads through a grizzly with 9-in openings to a reciprocating feeder and thence to belt (3). Other scrapers (8) load through grizzlies to cross-conveyers (7), which deliver at speed of 30 ft per min to belt (6) and thence to belt (3). Three-drum scraper hoists are driven by 25-hp motors. Scrapers are 48 in wide and hold 1 500 lb of ore; they have manganese-steel shoes 10 in wide, which handle about 11 000 tons and are then discarded. Pull-in cables are 0.5 in; pull-back cables, $^3/_8$ in. In a test run, one scraper delivered 162 tons 100 ft to the belt in 2 hr. Economical limit of scraping distance, 150 ft; scrapers at points

(8) thus handle all ore in a semi-circle of 150-ft radius. Drilling is by 3.5-in automatic-feed drifters, with long guide shells permitting steel changes of 36 in; mounted on hydraulic columns. Each machine ordinarily drills 12 10-ft holes per shift. Detachable bits are used, 2.5-in on hollow steel; aver life, 14 ft of hole. COSTS. Experimental work in mechanization showed a production rate of 19.4 tons per man-shift underground, as against 12 tons for other sheet-ground mines, and 7.65 tons for Tri-State district as a whole; also a cost reduction per ton from $1.23 for entire Tri-State district, or $1.08 for other sheet-ground mines, to $0.61 (see Table 31).

Fig 184. Breast Stoping, Hartley Mine, Kan

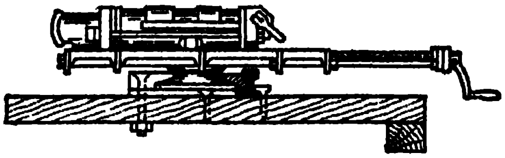

Fig 185. Drill Mounted on Stope Board

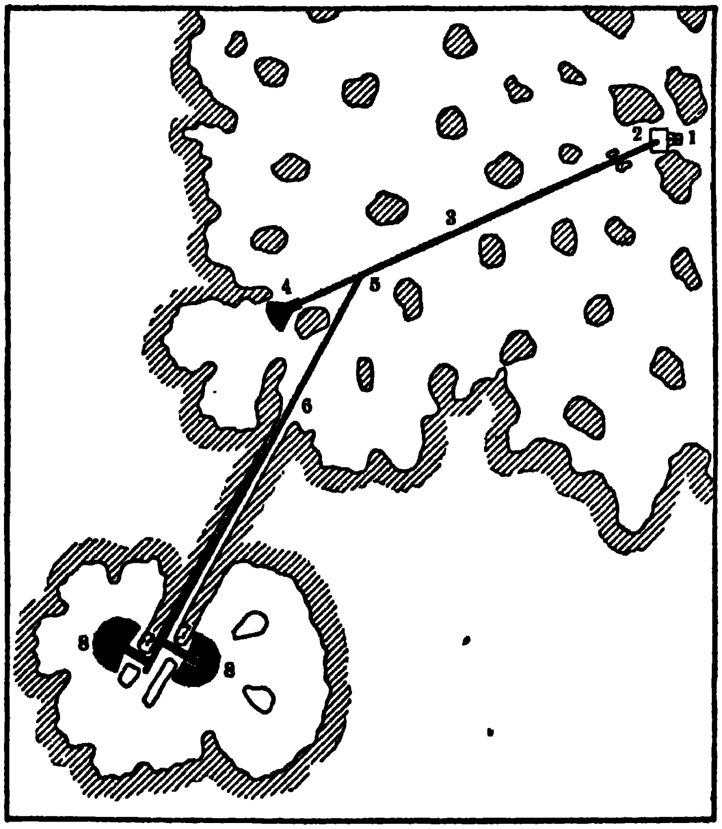

Fig 186. Part of D. C. & E. Mine, Oronogo, Mo, showing conveyer system and location of scrapers

Fig 187 shows a different method of breaking used at one mine in Joplin district (158); upper 12 ft of deposit was very tough, lower 12 ft broke easily. Heading was driven in softer ground on bottom of orebody by methods described above; drill holes, 12 ft deep. Upper stratum was broken with 12–14-ft holes, placed as shown; splitter holes were squibbed, roof holes being left as drilled, as squibbing would tend to loosen roof and make it dangerous; heading was carried 50–100 ft ahead of stope. This method proved cheaper in this mine than the usual plan. 5 drills broke an aver of 325 tons per 8 hr.

This plan resembles overhand stoping in wide veins; is not applicable to thick beds, due to difficulty of supporting men and drills; nor does it allow careful scaling of, and clean mining at roof. A variation of method shown in Fig 187 is described by Van Barneveld (482); flat roof holes and splitters replaced by uppers.

VERTICAL LONGITUDINAL SECTION

VERTICAL CROSS-SECTION

Fig 188. Breast Stoping, Wis Zinc Dist

Wisconsin zinc district. Deposits of ZnS and PbS occur in pitches and flats in limestone; some are so irregular that mining is practically gophering; larger deposits are commonly mined by breast stoping. Orebodies are from 5 to 70 ft high, 20 to 300 ft wide, and 500 to 7 000 ft long; roof is generally solid, thick-bedded limestone; deposits lie at depths of 75 to 200 ft. J. G. Trewartha, Gen Supt, Vinegar Hill Zinc Co, contributes following data on this district in 1938: Orebodies mined by breast stoping (Fig 188). Face of heading is kept not more than 8-10 ft ahead of stope. Wet jackhammers, weighing 45 lb and using 0.75-in hex steel, are used for all holes in heading and stope. A home-made mounting is used: a 2 by 6-in board with 2 steel points set in one end and a series of steel stirrups bolted at 8-in intervals to one face of board. Operator lays a 2 by 10 or 12-in "toe board" on the floor, stands the points of mounting board on this and hangs the drill handles in whichever stirrup happens to be at right height for the hole. While drilling, the operator leans against the mounting board. This device has greatly increased drilling speed; main objection is increased wear on front of the machine. Jackhammers are advantageous compared with piston or hammer drills on column; operator can place holes in best position and continue drilling while others are mucking

Shoveling cost per ton, scraper loading	0.132	0.139
Total cost (breaking, loading, tramming, pumping, hoisting, ventilation and maintenance) per ton	1.04	0.760

Note. These figures are from two typical mines under good management. SHEET-GROUND MINE: Gangue, hard and abrasive chert containing many vugs which force steel off line, breaking or binding steel. Explosive often breaks back into vugs, causing hole to fail. Bits forged on 1.25-in hollow round steel, lugs on shanks. Drifters, 4 in diam, hand-cranked, mounted on column. Explosive, 40% ammonia or gelatin. All loading by 3-drum scraper hoists on steel slides mounted on caterpillar treads. Tramming to shaft by rope haulage. Hand-loading cost given is cost prior to installing scrapers. BRECCIATED-GROUND MINE: Gangue, brecciated flint, better drilling than sheet ground. Mined heading and bench. 2.5-in detachable bits on 1.25-in hollow round lugged steel. Drifters 3 and 3.5-in. Explosives, 30% ammonia or gelatin. Loading, 80% by hand into cans, 20% by scraping into hoppers. Scraping cost includes drawing ore from hopper into cans and spotting on lay-bye. Tramming to shaft by rope haulage; some mules for gathering service.

32. BREAST STOPING IN DIPPING DEPOSITS (see also Art 33)

Park City, Utah. Fig 189 shows old workings of Silver King Coalition Co. J. Humes gives following data in 1915 (134) silver-lead orebodies occur largely as replacements in limestone; thickness, 1.5 to 25 ft; dip, 10° to 30°; oreshoots are irregular in outline and make off from fissures which gave access to mineralizing solutions.

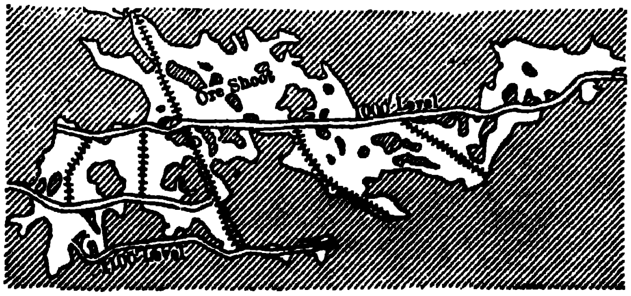

Fig 189. Part of Silver King Mine, Park City, Utah. (Aver dip, 18°; aver thickness of ore, 2.5 ft)

For mining THIN BEDS, exploratory drifts, in the ore bed, follow the fissures; when a drift cuts ore, stopes are started to the dip and carried as far as broken rock can be shoveled out. If ore continues, a small hoist is installed, track laid on floor and mine cars run to stope face. If deposit is thin, enough footwall is shot out to admit car. If the temporary inclines strike barren rock, tracks are turned and follow the ore. In orebodies of large lateral extent, small drifts (sub-levels) are run to right and left from main incline. Stoping proceeds up and down dip from sub-levels, in which run small cars dumping into cars on the incline. Many deposits are so flat and thin that machine drills can not be used with advantage. This method permits mining orebodies without excessive preliminary development, and is well adapted to handling broken ore on flat dips. More recent practice is described by M. J. Dailey in 1930 (159). Method is termed "overhand," as faces are advanced up the dip. In thicker portions, modified square-sets are used, with caps extending across 3 posts. Stopes are often back-filled as stoping advances, timber being recovered when possible. Weaker parts of deposit are mined in sections 50 ft wide. Around edges of orebodies, where ore is thin and less support required, 8 to 10-in round stulls, with headboards, are used.

Barton Hill mine, Mineville, N Y. Orebody is a bed of strong magnetite; thickness, 0 to 20 ft or more; aver dip, between 15° and 25°, rising to 35° or 40° in places. Hanging and footwalls are very strong tough gneiss, the former fairly smooth, the latter warped by 2 series of ridges, the axes of which are parallel and normal to strike; this complicates ore handling. Mining method. Deposit was first attacked at several points along outcrop by breast stoping to the dip. Mine cars were hoisted to surface on inclined tracks on footwall; Fig 190 shows 2 inclines, also pillars for roof support (note that inclines were swung to right or left as needed to follow ore); temporary horiz tracks were also laid to reach remote portions of stope faces, or for stoping along strike at points above bottom of inclines; these are typical dip workings. More recent practice, described by A. M. Cummings (495) in 1928, is shown in Fig 191. Deposit is opened by parallel shafts, 400–600 ft apart, following dip of orebody along footwall. At intervals of 1 000–1 500 ft on dip are haulage levels for transferring ore from auxiliary shafts to main hoisting shafts. Intermediate stoping levels extend from shafts on footwall at intervals of 30–100 ft, depending on width, dip, and faulted or folded conditions of orebody. Leaving 20-ft shaft pillars on each side of shaft, mining starts by cutting loading chutes on upper side of stoping levels every 50 ft. Ore is then breasted out as in Fig 191. Pillars, roughly circular and 20–60 ft diam, depending on height and character of roof, are spaced about 50 ft c–c. Where ore is more than 15 ft thick, a 7-ft heading is carried at top of ore; bottom ore broken by underhand benching. Ore is scraped to loading chutes, which deliver to cars (Fig 192). Pillars represent about 25% of total ore. Plans call for eventual recovery of much pillar ore by a retreating method.

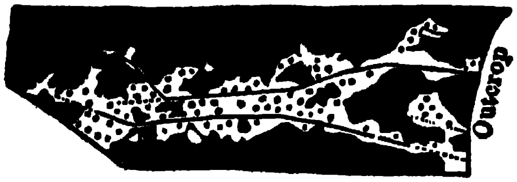

Fig 190. Part of Barton Hill Mine, Mineville, N Y

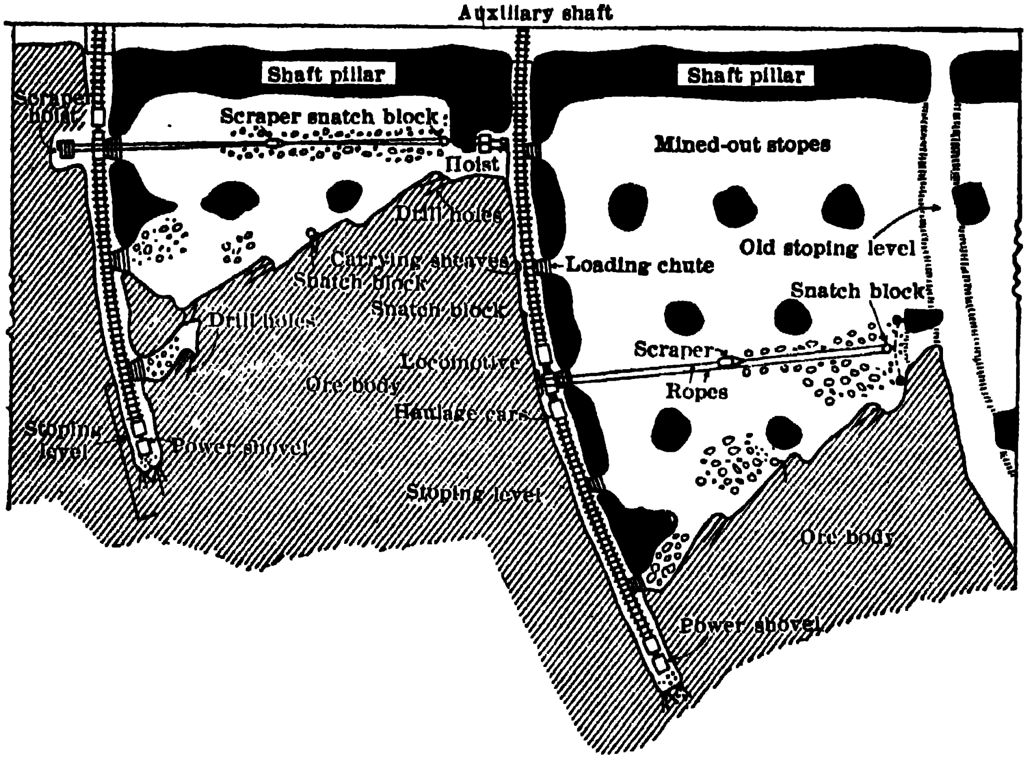

Fig 191. Breast Stoping, Mineville, N Y

Sherritt Gordon mine, Manitoba. Data from E. L. Brown, Gen Supt, in 1933 (162). Ore is coarse-grained mixture of pyrite, chalcopyrite, and sphalerite, with rock inclusions.

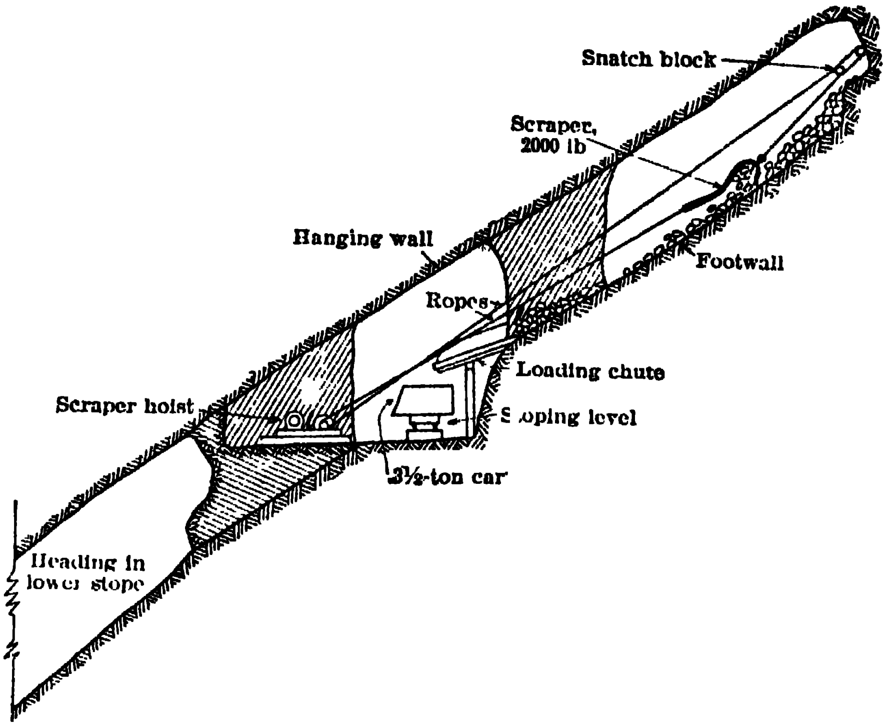

Fig 192. Handling Ore by Scraper, Mineville, N Y

Two lenses occur in shear zones along contact between massive gneiss on hanging wall and conglomerate and quartzite on footwall. Dips, 30° to vert. Aver width of ore 15.5 ft; sometimes exceeds 50 ft. Walls sharply defined. DEVELOPMENT (Fig 193). Main shaft is in footwall, inclined at 51°. Main haulage level, at depth of 500 ft on the incline, is along footwall contact, about $^{1}/_{3}$ of face being kept in ore; it is double-track, 7 ft high by 15 ft wide in central part of orebody, 7 by 8 ft toward ends. Above, at intervals of 150 ft, are two sublevels, 4 by 6.5 ft, in footwall, 10–15 ft from the ore. Raises, 5 by 5 ft, 120 ft apart along strike, extend from haulage level to bottom of pillar left to protect surface. STOPING. For method where dip exceeds 45°, see Art 36. In flatter dips breast stoping is used. Stope sections extend 50 ft each way from raises, making stopes 100 ft long, with 20-ft pillars between. Ore is breasted upward along dip to full thickness of lode unless thickness exceeds 8 ft, in which case a heading-cut, 6.5 ft high, is carried along hanging wall, and the bottom removed by underhand stoping with jackhammers. Ore is handled by scrapers. Raise to level above

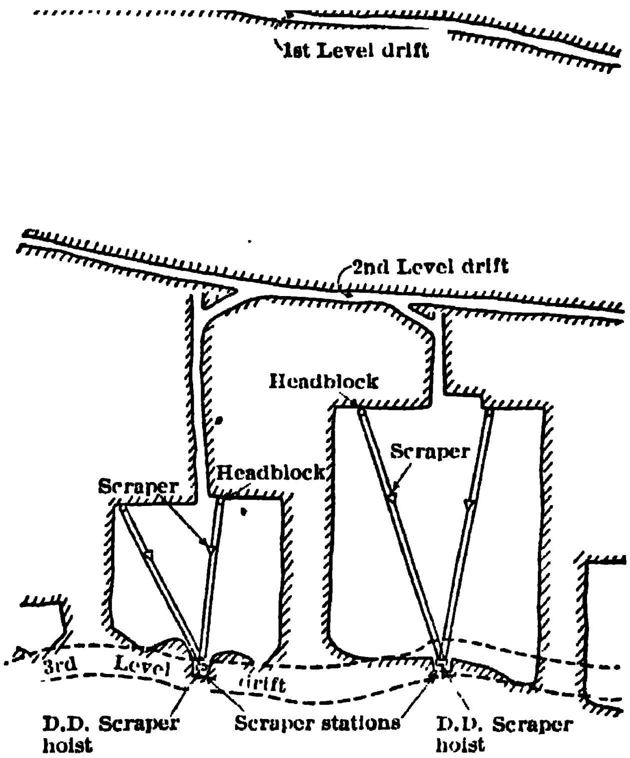

Fig 193. Breast Stoping in Flat-lying Section of Orebody, Sheritt Gordon Mine, Manitoba

serves as manway, and for air and water lines. Ore is handled on haulage level in 80-cu ft Granby cars, by storage-battery locos. STOPING COSTS, with above-described method during 6 first mo of 1932 were: labor, $0.302; explosives, $0.146; drill repairs and supplies, $0.066; steel and sharpening, $0.067; compressed air, $0.031; scraping, $0.054; general expense, $0.074; total, $0.740 per ton.

ART 33. EXAMPLES OF PRACTICE, EAST AND CENTRAL RAND, SO AFRICA

Following data are mainly from J. Thorlund in 1928 (568), C. L. Butlin, A. E. Payne, C. B. Brodigan, and others in 1930 (573), A. G. Boyden in 1931 (576), and R. S. G. Stokes in 1936 (195). For further details, see Bib (538, 556). For earlier practice, see 2nd edn of this book, and its Bib.

Orebodies comprise several gold-bearing silicified conglomerate beds (BANKETS or REEFS) interbedded with quartzite and slate, of which the Main Reef series is the most important. In Central Rand, extending 14 miles to both E and W of Johannesburg, 3 beds have been extensively mined: (*a*) Main Reef, aver width 6–7.5 ft; (*b*) Main Reef Leader, aver width 18 in, lies 1–10 ft above Main Reef; (*c*) South Reef, 8–12 in wide, is in places 80 ft above Main Reef Leader. Wide variations from above figures occur locally, and reefs are dislocated by dikes and faults; but their tenor and thickness are remarkably regular in individual mines. Dip in Central Rand averages 50° at outcrop, flattening to 31° in first row of deep-level mines, with flatter dips at greater depths; in East Rand, dips are as flat as 6°; in West Rand, dips are steep. Both hanging and footwalls are usually quartzite. For further details, see Bib (254).

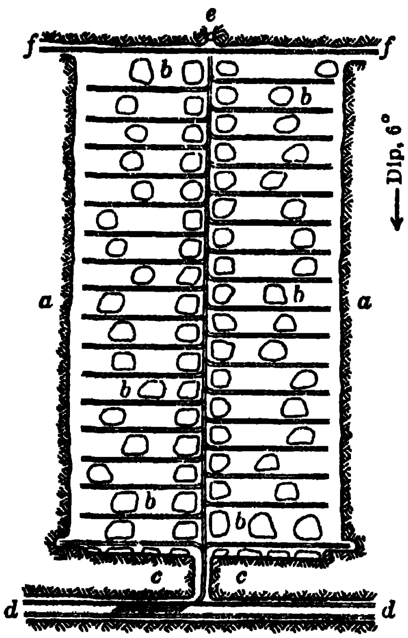

Fig 194. "Herringbone" Stope, East Rand. *a*, Stope faces *b*, Waste packs. *c*, Safety pillars. d, Haulage level. *e*, Winch. *f*, Drift

Development. For modes of entry, see Art 15. Workings tributary to inclined shafts from surface are nearly exhausted. Several vert hanging-wall shafts for hoisting from 5 000–6 300 ft in a single lift have recently been completed. Most of them are rectangular, 6 or 7 compartments, and are made larger than necessary for hoisting to aid ventilation. Such shafts may be 2 miles apart. Intervening areas are usually developed by "sub-inclines," delivering ore to haulage levels connecting with vert (or turned-vert) shafts. These inclines, of which 30–40 are constantly advancing on the Rand, are usually in footwall; some, designed to reach 8 000 ft (vert), are concreted. Three-compt inclines (17.5–22.5 ft wide) are 2 000–3 000 ft apart; those of 5 compts (35 ft wide) are spaced 3 000–4 000 ft; recent trend is towards the smaller inclines at closer intervals, to reduce hauling and ventilating distances at great depths. As precaution against crushing, common practice is to stope at least 1 reef, regardless of its gold value, as early as possible from a strip directly over an incline.

Lateral development, at intervals of about 140 ft vert, or as much as 1 000 ft horiz in flat-dipping reefs, includes drifts in reef and main haulage drifts in footwall. Former are 7–8 ft wide; latter are 15–18 ft wide in some mines, usually narrower. On deep levels, important haulageways are always in footwall; Robinson Deep (Central Rand) has a haulage drift on every level in its deep workings, 40–50 ft (normal to dip) in footwall, with crosscuts to reef drift every 500 ft; Crown Mines has footwall drift only at every 5th level. On Eastern Rand, drifts have commonly been driven in reefs, on straight lines and with varying grades, but nowhere exceeding 15%, to follow undulations of reef, requiring endless-rope haulage. More recently, footwall drifts on uniform 0.6% grade for loco haulage have been adopted, longest possible tangents being connected by such curves as will maintain reasonable proximity to reef. This system has incidental advantage of avoiding pumping from low spots in an undulating drift. With any system of footwall development, stoping areas are approached by crosscuts, raises, and ore-passes.

Stoping methods may be classed generally as breast stoping, but the nature of the reefs and problems arising from mining at great depth have resulted in unique practice. Press from hanging wall, with danger of rock bursts, demands special means of roof support, described hereafter. Experience with rock bursts has led to reversal of former practice respecting use of ore pillars for support; leaving of pillars is now generally avoided as a rock-burst menace. Present modes of support are based on principle that settlement is inevitable, subject only to control, not to avoidance. Backfilling, usually with sorted waste, is common method of control. Fig 194 shows the "HERRINGBONE SYSTEM" of breast stoping on the East Rand. Level interval is about 600 ft, along the dip. A raise, or winze, or a combination of the two, is driven between levels near middle of a stoping area, with a track connected with the tracks on each haulage level. A winch, with compressed air or elec drive, is installed at upper end, as at *c*. Stoping starts by widening the raise laterally on each side, by slabbing rounds drilled with jackhammers. Horiz and parallel branch tracks are then started at 30-ft intervals and advanced to keep within reach of the stoping face. Cars (1-ton) are loaded and trammed by hand to the incline, where they are hoisted or lowered to the haulage level above or below. In stopes 600 ft or more in dip length, a second winch may be installed at a mid-point for delivery of cars to the lower drift, while the winch at top hoists to the upper drift from upper half of stope. Roof support is by "waste packs" (backfilled).

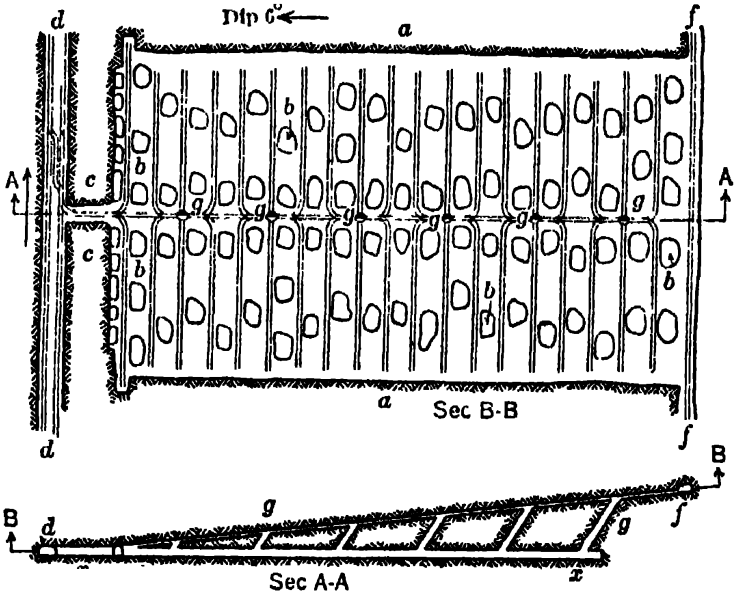

Fig 195. "Crosscut and Boxhole" Stope, East Rand. *a*, Stope faces. *b*, Waste packs. *c*, Safety pillars. *d*, Haulage level. *f*, Drift. *g*, Raises or "boxholes"

Fig 195 shows the "CROSSCUT AND BOXHOLE" method; it has been used on flat dips in E Rand, but has more recently given way to scraper methods. It is adaptable to widths of ore too small to permit use of main-haulage cars in stopes; in very narrow reefs, cars may have only 5-cu ft capac. Crosscut *x* is driven under a centrally located raise or winze, driven in reef between levels. Steeply inclined raises ("boxholes"), *g*, with chute pockets at bottom, are then driven 90 ft apart. Stope faces are advanced both ways from raise, in direction of the strike. Three parallel and nearly horiz tracks, about 30 ft apart, extend in both directions from top of each boxhole. Track is usually 20-lb rail, laid on 3 by 4-in hardwood ties; gage, 18–30 in. Ore is hand-trammed to boxholes, whence it is drawn into cars on main level. Waste packs are the roof support.

Fig 196 shows "SCATTER PILE" ("skeleton shrinkage") method, developed at Modder B mine, but also used elsewhere on E Rand and on steeper dips of Central Rand. According to C. L. Butlin (573), area between 2 main levels is divided by horiz openings, *o*, to form stoping blocks not longer than 200 ft on dip, extending both ways from a centrally located raise (or winze), *r*. A central, inclined track through raise *r* connects with haulage tracks on main levels, over which cars are hoisted or lowered by winch, *e*. Horiz branch tracks in openings *o* are depressed in footwall to allow scrapers to discharge into cars through loading chutes *l*. Stoping starts by breasting both ways from raise *r*. Broken ore is shoveled back 12–18 ft from face into a pile paralleling the face; it reaches the roof but gives no support to it, this being supplied by temporary timber packs, metal props, or other means described below. Purpose of pile is to prevent scattering of ore on blasting; hence the name "scatter pile." Ore from blasts is thrown back into the pile until the working space is too small for the drillers; scraper then removes enough to restore ample working space; ore thus removed from pile toward face is about 40% of total broken. At rear of pile, waste is sorted out for building waste packs. Sorted ore is scraped to cars on next lower horiz tracks; floors are then swept to recover fines. Scraper hoists, with air or elec (15–35 hp) motors, are moved from block to block. Stokes estimates (195) that scrapers, where suitable, save 6 pence per ton in cost of handling, as against hand loading. Saving in stope trackage, usually requiring footwall excavation, is also an

important economy in favor of scrapers, which are being widely used throughout the Rand for sundry mining methods. On Central Rand (dip 30°–50°), the "scatter pile" principle is widened, in that ore behind **the advancing face, aided by timber support,** maintains a safe working place. In such case the method is locally called "**SHRINKAGE**," since, as in "scatter pile" mining, about 40% **of the broken ore must be removed con**tinually from the side of pile toward the face to maintain working space for drilling; but stope faces advance laterally by breast stoping and miners stand on footwall rather than on broken ore; hence, the method is not "shrinkage" by usual definition (see Art 67). In Rand practice, sorting at rear of advancing pile precedes removal of ore from stope by means best suited to conditions, and waste is packed so as to allow roof to settle with minimum disturbance. A pile 10 ft wide usually suffices for roof support near face; unless ore is reclaimed from pile within 60 ft of face, crushing and compacting by roof press make sorting of ore difficult and inefficient. Cited advantages of so-called "shrinkage" system are: rapid advance of face; good roof support near working face; small loss of fines. Cited drawbacks: breaking and reclamation are separate operations, requiring divided attention of miner; ventilation less easily controlled; heat is generated from oxidation of pyrite in broken ore; ore pile may be diluted by waste from hanging or footwall during reclamation.

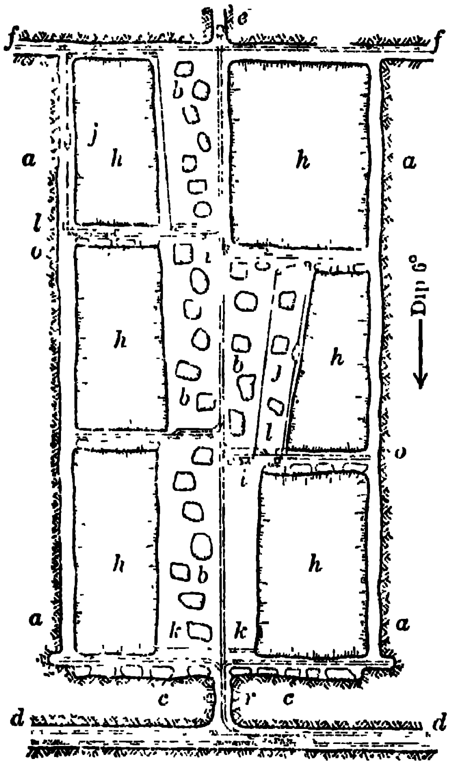

Fig 196. "Scatter-pile" Stope, Modder B Mine. *a*, Stope faces. *b*, Waste packs *c*, Safety pillars. *d*, Haulage level *e*, Winch. *f*, Drift *h*, Piles of broken ore *i*, Transportable scraper hoists *j*, Scrapers. *k*, Brattice *l*, Loading chutes *r*, Raise entry to stope

For thin reefs under heavy press, as in Central Rand, RESUING has shown its advantages, provided suitable partings exist; to 1936, City Deep had mined 4 000 000 tons by this method. According to A. G. Boyden (576) in 1931, advance of face begins by erecting a barricade of lagged 7-in stulls, 7 ft apart and 2 ft from face, leaving enough space under the roof for waste to be thrown over. Waste is then broken above the reef to a height that will give an ultimate width of about 42 in. At such width, for example, 25 in of waste, when broken, will fill final excavation completely; if the remaining 17 in contains sortable waste, it must be hoisted, or used for filling elsewhere. Waste face is advanced 8–10 ft, or until the pile reaches the barricade, the roof being supported on short props. Ore is then broken away from footwall, with light shots or air-driven gads, and discharged through chutes or moved by scrapers to the haulage level. As short props drop out, they are replaced by longer ones, keeping roof safe until next row of lagged stulls is set. The retreating edge of reef stops 1–2 ft from the waste face; after cleaning the floor, a new barricade is erected and operation repeated. At an individual face, waste stoping may take 12–16 days, extraction of reef, 6–8 days, extra shovelers working during latter period.

In all the above-described methods, stoping faces are maintained on nearly straight lines, usually parallel with dip, unless the prevailing direction of fractures makes it easier to control roof settlement behind a face advancing at some other angle. Faces are 200–400 ft long, on dips over 30°; 400–1 000 ft on flatter dips. When opening a stope from a drift, the tendency to abrupt falls of ground ("rock bursts") can be counteracted by stoping to a width of 8–10 ft on the dip side of drift, in advance of similar stoping to the rise, and packing the spaces with artificial support rigid enough to keep the drift open, but permitting enough settlement to relieve concentrated stresses in hanging wall. Control of roof settlement and avoiding of bursts are helped by rapid advance at face; for this reason (and also to provide more favorable conditions for use of scrapers, where applicable) drilling in some deep mines is concentrated at certain places almost to point of congestion, and at expense of drilling efficiency.

Breaking ground in stoping. Fig 197 shows the general shape of stope face, maintained to provide free faces, and the manner of placing holes. Usually, one hole will break or loosen whole width of reef. According to H. Simon (89), in a 40-in stope, a 42-in hole with about same burden, and loaded with 2.7 lb of 50% dynamite, will break about 7 sq ft of stope area, or 2 tons. Fig 197 also shows a "hole director," which, in various forms, is used widely on the Rand. The one shown (89) is of $^3/_4$ or $^7/_8$-in steel tubing, with welded joints, and weighs about 5 lb; it is made in different sizes for varying character and thickness of reef, on basis of records by efficiency engineers. With the instrument held in plane of reef, the inner end of arm *A* is placed at the point of the face where the hole is to be collared, and end of arm *B* is moved against the face. Arm *A* then indicates proper direction of the hole to give the burden for which the "director" is designed. Miner or foreman marks with chalk on the face and roof the direction which the hole is to take and its depth. Simon states that, in general, max effic is secured when area of rock in plane of "director" is 63% of area of rectangle indicated.

Until about 1920, drilling in thin or steep reefs was done by hand (p 582, 2nd edn), one 3-ft hole, breaking 0.5 ton, being a day's work for a native driller. In wider reefs, mounted drifters were used, drilling 4 holes per shift and breaking about 6 tons in a 4-ft stope. Nearly all drilling is now done with unmounted, 50-lb, wet jackhammers. These have been effective in reducing the minimum necessary stoping width, and the amount of waste broken and sorted in working a thin reef, and allowing production from reefs previously unprofitably narrow or low-grade. Table 33, from A. E. Payne (573), shows results in one mine before and after introducing jackhammers.

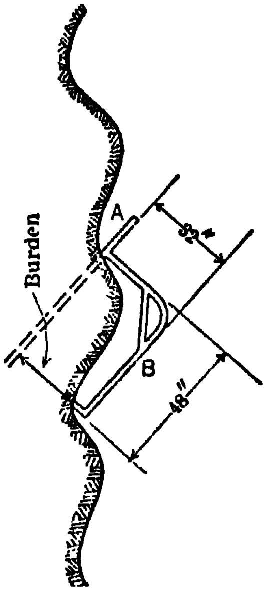

Fig 197. Hole Director

Table 33. Reef and Stoping Widths, Van Ryn Deep

Year	Fathoms stoped (*a*)	Reef width, in	Stope width, in	Waste width, in	Method
1919	8 771	36	66	30	By hand in Main Reef Leader
"	24 693	48	74	26	Mounted drill in same
1928	42 547	39	51	12	Jackhammer in same
"	26 402	20	37	17	Jackhammer in small leaders
"	68 949	32	46	14	Jackhammer in all reefs worked

(*a*) "Fathom" = 36 sq ft

Another advantage of the jackhammer as compared with reciprocating drill is that the smaller holes and lighter charges are less destructive to the brittle and fissured hanging wall. A third and most prominent effect has been a great increase in rate of drilling and breaking. In favorable ground, a jackhammer can drill 80 3-ft holes in a shift; aver over whole Rand, 75 ft of hole per drill-shift. Table 34, from A. E. Payne (573) shows stoping performance with jackhammers in 1928, in 6 mines under same management.

Table 34. Jackhammer Stoping in a Group of Rand Mines, 1928

Mine	Fathoms broken	Stoping width, in	Fathoms per drill-shift	Tons per drill-shift

* Calculated and interpolated by author

Stokes (195, p 216) gives the data in Table 35, on a representative group of mines, but states that variable conditions (such as the possible incomplete recovery of fine ore) render it difficult to compare stoping efficiencies.

Other factors contributing to improved effic of breaking in stopes: (*a*) increasing use of "hole directors"; (*b*) employment, in some mines, of a "cleaning shift," preceding drill

shift by about 1 hr and making faces ready for drillers; (*c*) increasing employment of shot-firing crews, holes being loaded by miners at end of their shift, as heretofore; since blasting must begin in stopes on the return air course, delayed firing may considerably increase the time applied to drilling in these stopes; (*d*) in deep mines, where roof press on an advancing face may be controlled as in longwall coal-mining, the natural crushing of reef may account for larger tonnage, recovered by hand pick or air-driven gads, than the blasting.

Types of roof support. ORE PILLARS, aided locally by stulls or other supports, were customary throughout the Rand to a vert depth of 1 000 ft. Local conditions govern as to depths at which pillars may be left without danger of rock bursts. In Central Rand, 2 000 ft was considered the max permissible depth for pillars in stopes; on Eastern Rand, with softer footwall, safe limit is considered to be 4 000 ft. As a rule, pillars at great depth have long been abandoned. Stokes (195) states an exception at Modderfontein East, where temporary pillars, 8 ft diam, are cut systematically to support the face. Each line of pillars is removed when the face has advanced enough to cut a new line and build the permanent stope supports. In some deep mines with wide reefs and large stopes, intrusive dikes, 50 ft thick or more, normally left standing as pillars, have caused trouble by bursting. Remnants at stope junctions present same objection as pillars; they are mined with special precaution, under written instructions to all concerned. PIGSTYES, or cribs filled with ore or waste, were long a common form of support, but have largely given way to other types. A disadvantage of the pigsty was its fire hazard and tendency to fail through rotting of timber (later reduced by use of timber preservative). CONCRETE "PANCAKE" COLUMNS (Fig 198) were introduced at Van Ryn Deep and soon nearly displaced pigstyes in that and some other mines of East Rand. A pancake is a circular reinforced-concrete disk, 30 in diam, 4 in or more thick, with a 4-in hole at center for handling. A level footing is concreted and allowed 1 day to set. Disks are then piled one on another, with a little sand between to cushion irregularities, to within 1 or 2 ft of roof, which space is packed with wooden blocks and wedges, providing some compressibility. A. E. Payne (573) shows that during one month in 1930, an East Rand mine used 2 409 columns (18 473 disks) in stoping 282 168 sq ft of area, stoping width averaging 52.5 in; area served by each column was thus 117 sq ft. Pancake columns are not effic on dips over 30°. At increasing depths their use has declined in favor of all-wood or waste packs, which permit better control of roof settlement. MONOLITHIC CONCRETE COLUMNS have been used in some mines of E Rand, but at increasing depths they are being displaced by more compressible supports. According to J. Richardson in 1926 (571), a steel-plate sectionalized form, 33-in diam, is filled with concrete to within 18 in of roof; reinforcement, wire-rope rings 30-in diam, 1 ring per in of height. One man can build a column 42 in high (for a 5-ft stope) in 3–5 hr. When concrete has set, space at top is packed with wood blocks and wedges. Where used, such columns serve mainly for protecting track-ways, reinforcing edges of pillars, and as corners for waste packs. RAIL PROPS, pieces of steel rail, each standing on a sole-plate in a sand box, are used for temporary support in "scatter pile" stoping (see above) in Crown deep-level mines of Central Rand. A single stope may require 400 such props, in 8 rows: 2 in working space at advancing face, 4 buried in broken ore, 2 holding open space for sorting. Last row is recovered and moved to front when replaced by packed waste. SAND FILLING (Art 92), according to Stokes (195), is no longer used on Central Rand, but is still common in

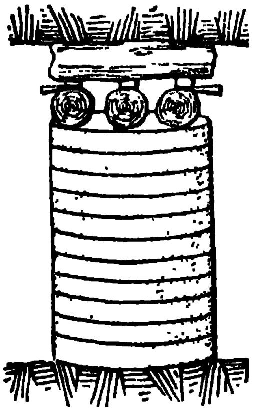

Fig 198. Concrete "Pancake" Column

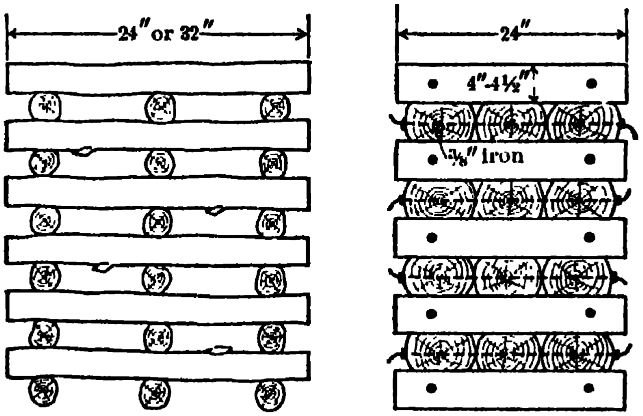

Duplex Pack. Three 3" sticks in each row. Also made of 4" sq sticks, 48" long

Fig 199. Two Types of All-timber Support, Rand

E Rand to support worked-out areas before extracting hanging-wall bands of ore. **Timber packs** and **chock mats** are favored for face support, having advantage of ready compressibility (after serving initial purpose) when weight comes on waste packing behind and around them, thus aiding control of roof settlement. "Duplex pack mat" (Fig 199) is of 3-in round or square pieces, 24–32 in long, piled 3 pcs on 3; or of 4-in squared pieces 48 in long. "Chock mats" (Fig 199) are of 6-in timbers, slabbed on 2 sides to give depth of 4–4.5 in: 3 pcs 24 in long, or 4 pcs 48 in long, are threaded on 2 $^3/_8$-in bolts and drawn together tightly. A chock of any height can thus be built. **Waste packs** consist of back filling with waste, usually from sorting. One type, **wire pack**, is made by enclosing an area, commonly a 6-ft circle, with woven fencing of 6-gage wire and 6 by 18-in rectangular mesh, attached to light wood props, and filling the enclosure with coarse waste or ore packed solidly to the roof. A 6-ft diam pack 4 ft high requires 9.3 sq yd of fencing. Ends of wire being joined, failure of props has no adverse effect. Such packs are used on dips to 50°. They are fire- and rot-proof.

Rand mine costs. According to Stokes (195) aver costs in 1935, excluding some old mines with diminishing development and capital charges, were roughly as in Table 36.

34. SYSTEMATIC ROOM AND PILLAR METHODS IN BEDS

Term "room and pillar" covers many different methods of cutting up a deposit by excavating rooms, in which sense it includes breast stoping (Art 30, 31). Methods described below differ from breast stoping mainly in being more systematic; rooms and pillars are generally rectangular and laid out with almost mathematical regularity; the pillars may be left for permanent support, or recovered by robbing operations. These are colliery methods applied to mining salt, iron ores, etc, but may generally be simplified in these deposits because of less rigid ventilation requirements. For details of coal-mining methods, see Art 102 *et seq.*

Suitable deposits for exploitation by room and pillar are flat or slightly dipping beds of uniform tenor and character, and of large area. Cheap, abundant, strong mineral, and a strong roof and floor are necessary if permanent pillars are left; where ore in pillars is recovered by robbing, a very strong roof may "hang" over large areas and cause trouble by dropping suddenly (Art 103).

Detroit Rock Salt Co, Mich. Data from H. D. Keiser (526) in 1930. Room and pillar mining (Fig 200) is applied to a horiz bed of rock salt 30 ft thick, 1 100 ft below surface. Overlying rocks, chiefly limestones, dolomites, sandstones and shales. Formation immediately above salt bed is of limestone, gypsum and salt; that beneath, shale and limestone. Entry is by 2 vert shafts. Haulageways are driven 40 ft wide and 300 ft apart. Bed is mined by rooms, 40 ft wide, 25.5 ft high, running parallel with and at right-angles to haulageways on 80-ft centers, leaving permanent pillars 40 ft square; extraction, about 75%. Bottom heading, 11 ft high and width of room, is advanced 20 ft in 3 to 3.5-ft rounds, of 32–36 holes arranged alternately as (*a*) 3 wedge cuts and (*b*) a wedge cut with 2 slabbing cuts (Fig 201 *A*). Upper bench is then broken to full height in 5 stages (Fig 201 *B*) by 14 holes in stages 2, 4, 5, and 24 holes in stages 3, 6. A 9-ft hole, 1.5 in diam, is bored by elec auger in about 1.5 min. Explosive, 60% ammonia dynamite. When 1 000 to 1 500 tons are broken in a room,

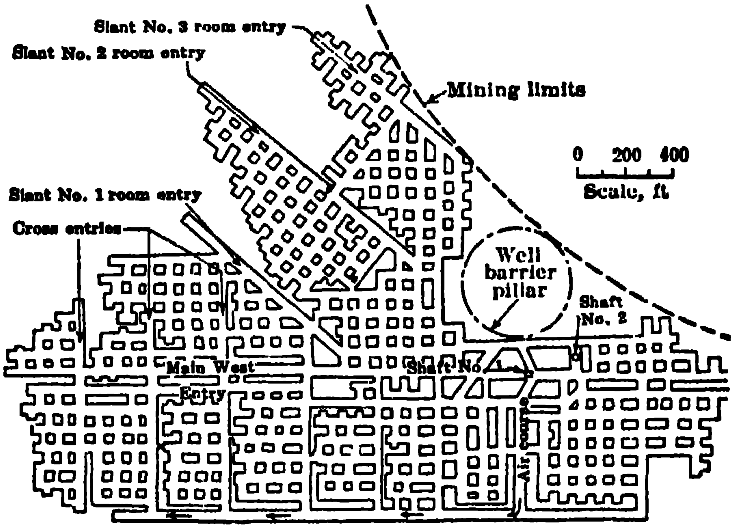

Fig 200. Plan of Workings, Detroit Rock Salt Co, Detroit, Mich

salt is loaded into 3-ton cars by elec shovel with 0.75-yd dipper, at about 600 tons per 9 hr. Large lumps broken by blockholing with augers or pneumatic picks, with air from a portable compressor.

Clinton iron ores, Birmingham, Ala. Orebodies are beds of hematite, interbedded in sandstones and shales. They extend many miles along the strike and have been opened over 2 000 ft on dip. Leaching has removed lime from upper parts, producing enriched soft ore for depths down to 400 ft on dip; below this, ore is hard. W. R. Crane (542) gives following data in 1924. Two seams have been mined, Big Seam and Irondale. Former is more important source of ore. It is 15-22 ft thick, divided by a slate band, from a knife edge to 30 in thick, into 2 parts: "upper bench," 10 ft aver thickness, "lower bench," aver 8 ft. Irondale seam is 3-8 ft thick, aver 6 ft. Due to folding, local dips are from 8° 50°, usually 16°-30°; hanging wall largely sandstone; footwall shale. METHODS OF MINING. Entry is by inclined shafts, 14-16 ft wide, in the deposit. Aver distance between slopes in various groups of mines, 1 333-2 475 ft. Level interval, 65-200 ft, present tendency being toward the higher figure. Manway raises, 12-15 ft wide, are driven 75 ft on each side of and parallel to the slope, leaving a shaft pillar. Headings 15 ft wide on each level are driven to manway raises. Beyond the raise the heading is widened to 20-45 ft, aver 35 ft, by breast stoping. In older workings, with smaller level interval, driving the headings with connecting raises at 100-ft intervals constituted the first mining. Pillars were then robbed, retreating from points midway between slopes, with estimated extraction of 80-90%. Present practice in mining upper bench of Big Seam is to use a "wide-stope" method, as follows. At intervals of 150-200 ft along the headings, preliminary raise stopes 25-30 ft wide are carried by overhand stoping to the heading above, leaving a pillar 125 ft long along strike. Successive slices are then taken off the pillars parallel to the raise stopes (Fig 202) until the stope is increased to 130-150 ft long, or such length as the back will stand. Rows of props paralleling side of pillar are put in to support back. Ore from both raise stope and slices is lowered to heading by gravity planes.

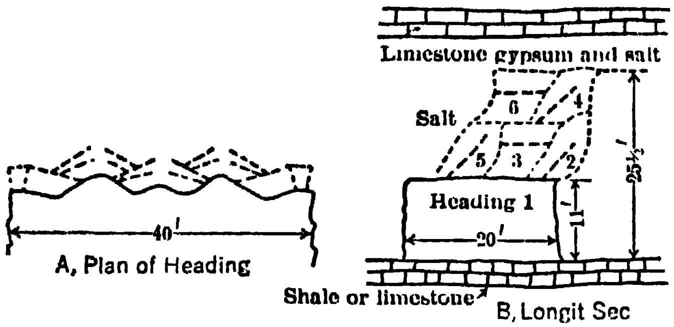

Fig 201. Breaking Ground in Detroit Rock Salt Mine

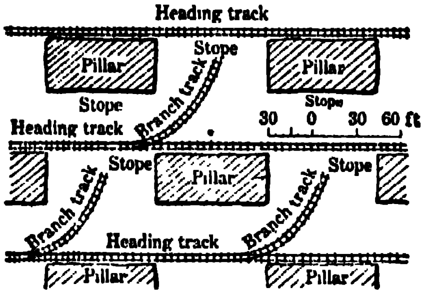

Fig 202. Branch Tracks for Working Wide Stopes

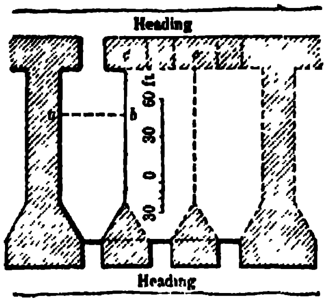

Fig 203. Stope Layout for Scraper Loading

Introduction of POWER SCRAPERS has permitted greater level interval and more extensive use of wide-stope method. A simple layout for scrapers is shown in Fig 203. Headings are 18-20 ft wide and 150 ft or more apart along dip. At intervals of 75 ft along headings, overhand stopes 20 ft wide are started, which, 20 ft up the dip, are widened to 50 ft and driven to heading above. Small pillars are left where required in stope and below heading above. These 50-ft stopes are later combined into one large stope, with a length depending upon strength of back. Ore hauled by scrapers to cars on lower heading tracks.

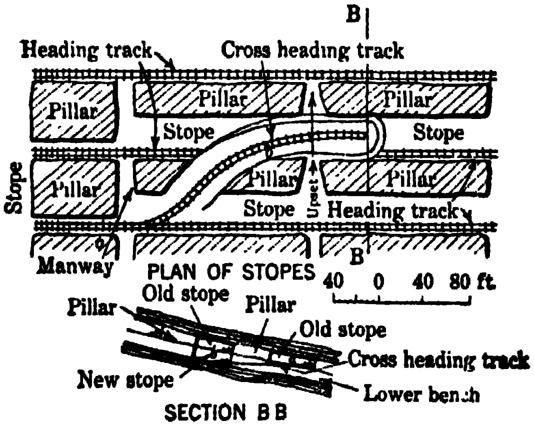

Fig 204. Working Lower Bench of Big Seam by Cross-heading

Mining the LOWER BENCH of Big Seam is done in older workings where conditions are favorable. It involves taking up the floors of the old pillar-supported stopes. Stopes 30-35 ft wide and several hundred ft long are mined. A branch track is turned off heading track, and extended diagonally across the stope through the cross-heading in the arch pillar to the middle or bottom of next stope

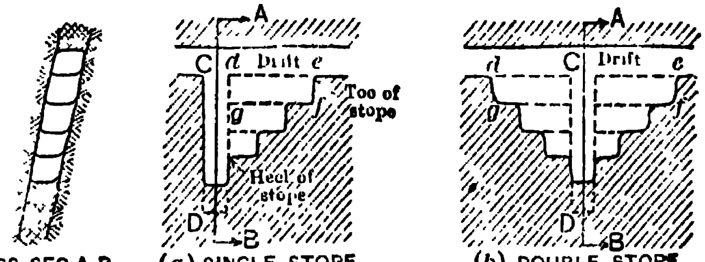
above, thence parallel to main heading track (Fig 204). Stope is then extended by underhand method full length of old heading. Pillar robbing, the final operation, is started in workings farthest away after stoping is completed, and carried back toward slope Pillars are mined by slicing parallel to the heading, and breaking through pillars up the dip until all possible ore is recovered.

Tennessee Coal, Iron & R R Co, Muscoda, Ala. Data from C. E. Abbott (167) in 1936. Company mines a high-grade limestone for its steel works from a bed 40–50 ft thick, dipping 17°, and lying 330 ft above and parallel with a bed of Clinton iron ore, also mined at same place. Limestone bed was entered from beneath by a rock slope from haulage drift of the iron mine, 2 500 ft inside of outcrop to avoid decomposed rock and watery strata; then opened by a slope with 12 by 20-ft entries on both sides, 200 ft apart. Rooms, turned up-dip at 70-ft centers, are 12 by 12 ft in sec for first 20 ft; then widened to 30 ft, and again narrowed to 8 ft when within 15 ft of next entry above, to which they break through near top of bed, for ventilation. Remaining 25–30 ft of good stone in roof is broken down in slices 8 ft thick, starting at lower end, with upper holes drilled normal to dip by 4-in wet hammer drills on tripods standing on broken rock; until room is finished, only enough rock is drawn, by scrapers discharging into cars in entries, to make room for drillers. Explosive is 42%, water resistant ammonia dynamite. Practically no timber is required. Resemblance to coal mining is emphasized by occurrence of CH_4, probably from an overlying bed of bituminous shale, requiring circulation of 25 000 cu ft air per min, and the precautions observed in gaseous coal mines.

Blue Diamond mine, Arden, Nev. Data from W. G. Bradley (193) in 1932. A gypsum deposit is worked as a side-hill quarry until capping becomes excessive; then by room and pillar underground. Bed is 12–20 ft thick, nearly horiz; capping rarely exceeds 100 ft of soft sedimentaries, roof is a firm, 2-ft bed of clay and gypsum. Headings 10–25 ft wide enter from wall of quarry at intervals of about 25 ft. Crosscuts of same width, 20 ft apart, form pillars about 20 by 25 ft, containing 25% of original volume. Pillars are robbed by slabbing, until only 8% of original volume remains. Caving of ground above mined-out area is then induced, as a safety precaution, by blasting out the pillar remnants; gypsum thus broken is not recovered. Jackhammers drill 50 ft of 1.25-in hole per hr. In a 14 by 25-ft heading a round requires 17 10–13-ft holes, arranged for center draw-cut, loaded with Hercomite No 6 powder (25% strength) and 1 stick of 30% gelatin in middle of each hole; little secondary blasting is needed to reduce to size for hand loading. Aver advance, 8.5 ft per round, breaking 1.14 ton per ft of hole, with 0.5 lb powder per ton broken.

35. OPEN UNDERHAND STOPES, NARROW VEINS

Applicability is to narrow veins at any dip, but best suited to steep dips. Strong walls are desirable for any dip, and are usually essential in steep veins from standpoints of safety and ore dilution. In steep veins, the method is usually limited to orebodies requiring no sorting (see "Handling waste," below). Strength of ore is rarely a determining factor in applicability of method to narrow veins.



CROSS-SEC A B (a) SINGLE STOPE (LONGIT SEC) (b) DOUBLE STOPE (LONGIT SEC)

Fig 205. Simple Underhand Stopes

General plans of mining by underhand stoping are shown in Fig 205, 206.

Details vary with modes of breaking ground and handling ore and waste. In simplest case, (*a*) and (*b*) Fig 205, floor of level is broken into with a winze as at *C*, from which a horiz slice *defg* is excavated from wall to wall; as face *ef* advances, the winze is deepened and another slice started. Process is repeated by advancing successive slices, forming step-like faces, converging toward bottom of stope, as is characteristic of underhand work. Stopes like (*a*) Fig 205 are SINGLE STOPES; those like (*b*), DOUBLE STOPES. Terms TOE and HEEL sometimes designate top and bottom of stope. Fig 206 shows a better plan, known as the

Cornish method. Stope is worked around a raise or winze between 2 levels. Where work is carried on as in Fig 205, all ore except that from first slice is shoveled into buckets and hoisted out to the level above. In Cornish method, broken ore falls through raise to level below, and is loaded by a chute into cars; such stopes are self draining. This method is used instead of that in Fig 205 wherever possible.

Underhand stoping as in Fig 205 is convenient for mining ore below a level without preliminary development, but its use increases cost of mining by the cost of hoisting ore out of the stope. Though such stoping is not used for systematic mining on a large scale, it is useful: (*a*) for mining small, irregular oreshoots with spotted values; often such deposits can be explored only by stoping them; this work approaches gophering (Art 29); (*b*) for mining isolated or faulted portions of orebodies, as *XY*, Fig 207, where development openings required to get underneath them would be too costly or difficult to maintain; (*c*) for small-scale work, lacking funds for preliminary development.

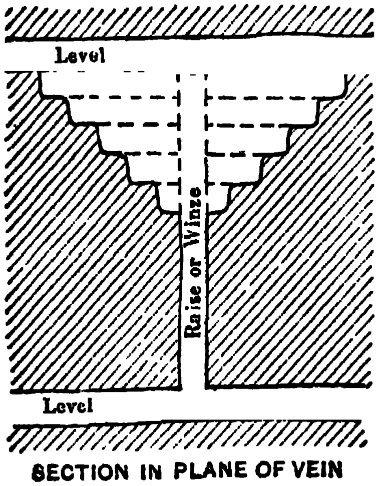


Fig 206. Underhand Stope, Cornish Method

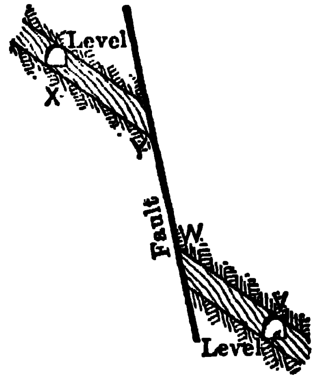

Fig 207. Cross-sec

Fig 208, P. B. Scotland (178), shows underhand stoping in a narrow vein with firm walls by Arizona Copper Co. Stoping began near top of untimbered raises, put up in the oreshoot 25 to 50 ft apart. An arch pillar was left; working floor was kept cone-shaped to reduce shoveling; a grizzly of logs, over top of chute, prevented large pieces of ore from entering and clogging it.

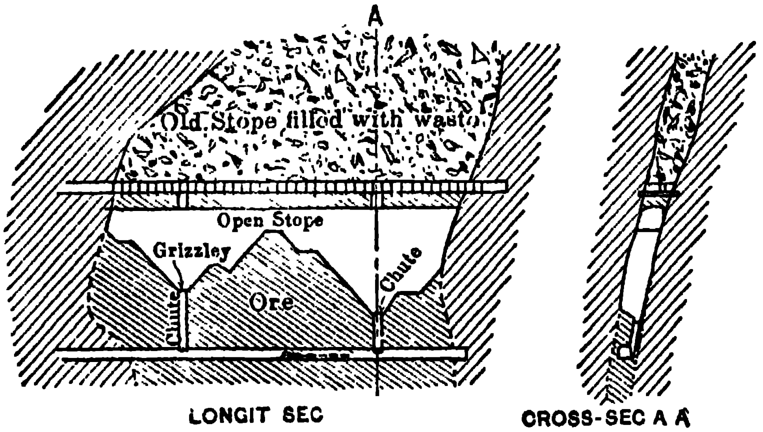

Fig 208. Underhand Stoping, Morenci, Ariz

Development. Drifts are usually driven in veins. On steep dips, level interval may be limited by safety factor (Art 14–19).

Breaking ground (see Art 26 to 28).

Support of levels. Underhand stoping, carried on as in Fig 205, 206, destroys the drift floor over a stope. Communication with parts of level beyond stope can be maintained by: (*a*) A row of stulls placed as at *S* (Fig 209) and lagged, and tracks laid on them; with this plan there is always a break *ef* at end of the stope, which is bridged temporarily with timber. Where vein is much flatter than in Fig 209, stulls are set nearly normal to hanging wall; waste may be placed on the lagging to support car tracks. (*b*) A LEVEL-PILLAR (or ARCH PILLAR), left over back of stope, as at *P*, Fig 209; it is formed by driving a drift *G* from the raise and stoping below it. Opening *G* is a STOPE-DRIFT (Cornish, STOPE-DRIVE) or SUB-DRIFT. Choice between (*a*) and (*b*) depends largely on grade of ore. A level-pillar may also be required to support stope walls, in which case, depth of pillar depends on degree of support deemed necessary.

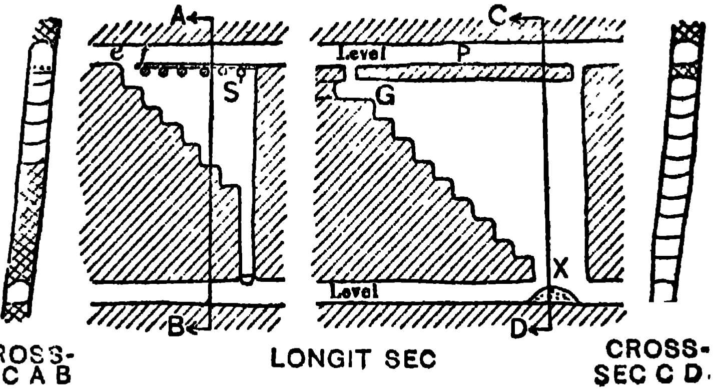

Fig 209. Simple Underhand Stopes

Handling ore. All broken ore must be moved along face to heel of stope; amount of shoveling required depends on: (*a*) general slope of stope face, which may be varied by changing the proportionate length and height of the benches; (*b*) dip of vein, which, together with slope of stope face, determines the pitch of the footwall corner of the stope, and amount of broken ore which will "hang" and require shoveling. These factors are less important where conditions allow use of scrapers (Sec 27).

For economical handling, benches should be high and close together; higher benches are possible in wide than in narrow veins (Fig 214 shows extreme case). Very high benches reduce number of points of attack in a stope, which, for a given tonnage in a narrow orebody, requires more stopes kept open simultaneously. Heel of an underhand stope eventually reaches the level below. If ore in the back of the level is mined as at *x*, Fig 209, the advantage of loading from a chute is lost, unless back of drift is replaced by lagged stulls, as is often done. Sometimes pillars of ore are left over the level.

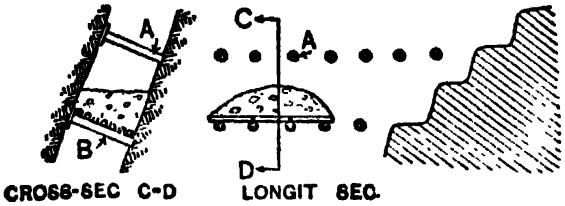

Fig 210

Handling waste. In steep veins, sorting of waste is rarely practicable in underhand stoping, and all the vein matter is usually sent to level below. In narrow veins, where general slope of stope face is kept sufficiently flat, waste may be sorted and stored on stulls (Fig 210). On flat dips, regardless of vein width, waste may be stored on footwall.

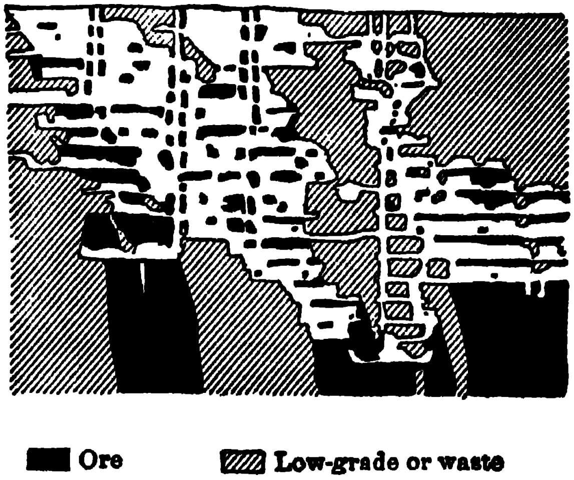

Fig 211. Underhand Stoping (Sec in plane of vein)

Support of walls. In a steep vein the area of unsupported and inaccessible walls overhanging a stope constantly increases. This makes an open underhand stope dangerous in weak ground, and is a serious disadvantage. Both foot and hanging walls must be carefully examined, and all loose stuff barred down before the stope faces leave them. In narrow veins, slabs may be supported by STULLS (*A*, Fig 210); larger areas of walls, by ARTIFICIAL PILLARS of waste piled on rows of stulls (*B*, Fig 210). Stulls are placed roughly opposite benches; their diam varies, with width of vein and local conditions, from 8 to 14 in or more; distance between stulls, 3 to 6 ft; round 4 to 6-in poles make good lagging. For details of hitches, blocking and placing stulls, see Art 38. PILLARS OF ORE may be left where desired. As a whole, working by underhand stoping depends on pillars of ore for supporting walls.

Fig 211 shows actual underhand stopes covering a large area of vein. Mine was opened by inclined shafts in the vein (note SHAFT PILLARS on each side of shafts). As in other methods involving pillar support, an attempt is made to reduce loss of ore in pillars by leaving them, where possible, in low-grade or narrow parts of vein.

Pilgrim mine, Chloride, Ariz. Data from E. F. Hastings (540) in 1937. This mine offers an example of underhand stoping where hanging wall is weak. Gold-bearing veins occur along both hanging and footwall sides of a well defined shear zone in a series of volcanic flows, intruded by rhyolitic and basic dikes. Shear zone dips about 30°, with aver width of 60 ft. Width of commercial ore, 3–18 ft. Hanging-wall vein, to which the method described below applies, dips 32°, and is of hard vein matter or a breccia. Above it is a layer of clay, over which is soft gouge; soft rhyolitic flows and latite predominate behind the gouge. Levels are at 100-ft intervals along dip, connected by raises 60 ft apart along strike. Stoping starts at top of a raise by slabbing downward with jackhammers, producing a V-shaped opening (Fig 212). Slabbing holes rarely have burden greater than 2 ft and are usually 4 ft deep. Broken ore is conveyed to chutes by scrapers, or loaded by hand into shaking chutes of 12-in split fan pipe. Stope faces are kept straight to facilitate scraping. Back is supported by 8 by 8-in stulls, with headboards. Light burden on drill holes avoids opening much unsupported ground. Timbering is carried to within 4 ft of face. Drill holes are blasted lightly, with only 1 or 2 sticks; hence timber is rarely broken by blasting. After ground has remained open for a few weeks, back begins to weather and slough, and starts to cave. Thus, filling the mined-out area with caved material follows advancement of stope faces. Under the protection of the stulls, the ground near the face remains open long enough to complete the stoping. In effect, the method is one of retreat.

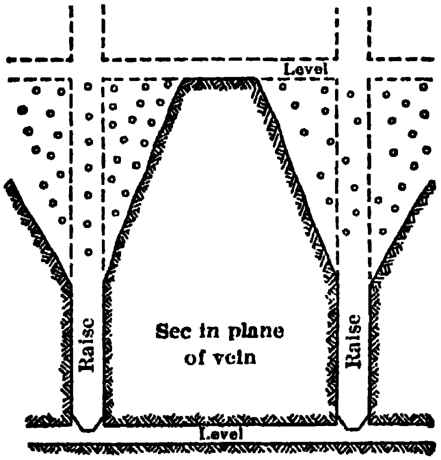

Fig 212. Underhand Stoping, Pilgrim Mine, Chloride, Ariz

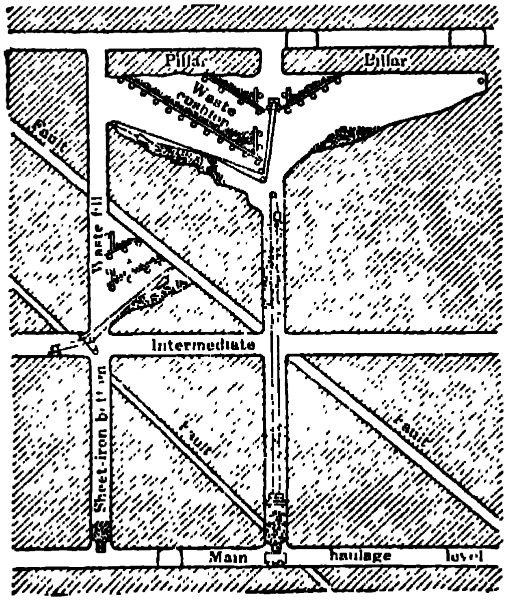

Fig 213. Underhand Stoping, Golden Messenger Mine, York, Mont. (Longit sec in plane of vein)

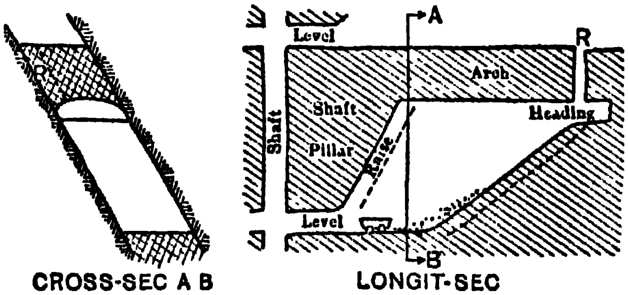
Golden Messenger mine, York, Mont. Data from S. H. Lorain (69) in 1937. For geol features, development, and mining by overhand stoping, see Art 40. Usual width of ore, 4–10 ft; aver dip, 40°. In 1937, underhand stoping seemed to be successful in one stope, and its adoption as standard was anticipated. Fig 213 shows general procedure. Vert distance between main levels, 150 ft. Intermediate level shown has no special significance as to mining method. Raises, 10 by 5 or 6 ft in sec, are spaced irregularly as convenient. Ore is benched downward in slices, and delivered to and down a central raise by scrapers. Stope face is kept at a low inclination to afford secure footing for miners, drilling with jackhammers. Protection for miners is by rows of 8-in stulls 7 ft apart, lagged with 3-in sawed or 5-in round lagging, and covered with a thin layer of waste. Rows of stulls are 15–20 ft apart along the dip, depending on the ground.

36. OPEN UNDERHAND STOPES, WIDE VEINS

General. Narrow-vein methods (Art 35) can sometimes be extended for use in wide deposits. In veins over 15 to 18 ft wide, the usual economic limit for stulls (Art 38), pillars of ore must be left to support walls and slabs. These methods are therefore limited to orebodies with strong walls and strong ore where dip is steep, or with at least a strong hanging wall where dip is flat.

Candelaria Mining Co, Chihuahua, Mex, has mined a vert oreshoot (length over 100 ft, aver thickness, 33 ft, crumbly porphyry footwall) by underhand stoping. Horiz timber trusses placed across stope supported the walls at intervals of 4 to 6 ft vertically and 5 to 8 ft horizontally. This was tried because ground was very wet, and the water level was lowered so slowly that it was inadvisable to delay production until the orebody could be attacked from below (179). Some stopes were timbered with square-sets (see Art 45), but elaborate timbering in wide underhand stopes is not generally feasible.

Heading method has a limited application to wide, steep-dipping veins or lenses. Fig 214 shows its simplest form. A shaft is sunk in orebody, and levels started at 50 to 100-ft intervals along dip. Drifts are run out 15 to 50 ft; then a vertical or inclined raise is put up to within 20 or 30 ft of level above. From top of raise a drift, or HEADING, is started and widened to walls of deposit. Ore below the floor of heading is broken down into the raise. When stope is well opened it has appearance shown in Fig 214; heading is kept only a short distance in advance of bench; auxiliary raises *R* may be made for access to stope; pillars of ore may be left irregularly as required. (Note similarity between shape of stope face and method of breaking ground here and in breast stoping, Fig 183, 184.) Bench may be broken in vertical steps, or in slices parallel to the face, as shown by dotted line (Fig 214); deep holes and heavy charges may be used for blasting.



CROSS-SEC A B LONGIT-SEC

Fig 214

Above method is simple and requires little dead work; it leaves a high inaccessible back over stope, and over floor on which trammers work; breaking ground is cheap, but all broken ore must be handled by hand shoveling or mechanical loaders (Sec 27) and much blockholing and sledging may be necessary. From 20% to 50% of the ore is left in pillars, some of which may be recovered at considerable expense by first filling stopes with waste rock. It is sometimes possible to break the arch pillars into the open stope below, beginning at boundary and retreating toward shaft; in old workings this is apt to be dangerous.

Fierro, N M. Data from L. M. Kniffin (168) in 1930. Irregular, lenticular replacement bodies of hard magnetite, aver 40 ft thick (200 ft max), dip 50°–60°; ore and walls strong, though fractured by minor faults with small displacement. Developed by adit and haulage drift along footwall, 350 ft below outcrop, with chute raises *A* 150 ft apart and manway raises *B* midway between them (Fig 215). At 25 ft above level, each chute raise is enlarged to a grizzly chamber (bars with 16-in openings), above which 2 diverging 7 by 10-ft inclined raises *C* with min slope of 38° are driven to intersect similar raises from adjoining chutes. Raises are connected by an intermediate level 175 ft above haulage drift, and by a subdrift *E* 25 ft below the intermediate, leaving a 15-ft floor pillar. Underhand stoping begins from this subdrift, and proceeds downward by benching with jackhammers until the triangular block between 2 raises is reduced to a small protective pillar above the grizzly chamber. Manways between main chutes are then converted to chutes, as at *D*, with grizzly chambers for mining, in similar manner, the triangular blocks above them. Low-grade patches usually afford the necessary pillars; where good ore must be

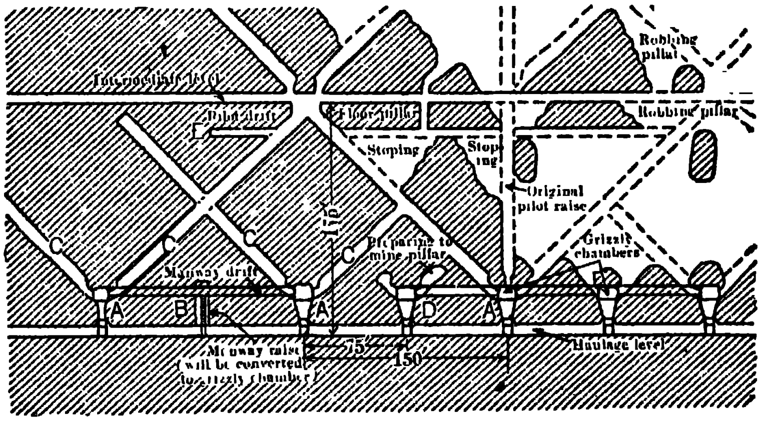


Fig 215. Underhand Stoping, Fierro, N M (168). (Longit sec in plane of orebody)

thus sacrificed, most of it is recovered later, with estimated loss of 10% of marketable ore. No timber is required in stopes except for temporary bulkheads and manways; most of it is used repeatedly. Output averaged 10.1 long tons per man-shift underground in 1929. Explosive (50% gelatin) per long ton, 0.355 lb for stoping, 0.096 lb for secondary breaking, and 0.580 lb for all purposes, including drifting and raising.

Sherritt Gordon mine, Manitoba. Data from E. L. Brown (162) in 1933. Two lenses of ore, 4 200 and 5 800 ft long, occur in shear zones along contact between gneiss band on hanging wall and highly squeezed conglomerate and quartzite on footwall. Ore is a coarse-grained mixture of pyrite, chalcopyrite, and sphalerite, with rock inclusions. Width of ore, from few inches to over 50 ft; aver, 15.5 ft; dips, 30° to vert. Walls are strong and sharply defined. DEVELOPMENT. Main shaft is in footwall, on incline of 51°. Main haulage drift *H*, Fig 216, at depth of 500 ft on incline, was driven along footwall, about one-third of face being kept in ore. In central portion of orebody, drift is 7 by 15 ft, for double track; near ends, it is 7 by 8 ft, single track. "Second" and "first" level drifts, respectively 150 and 300 ft above haulage level, measured on inclination of shaft, are in footwall, 10-15 ft from the ore, and are 4 by 6.5 ft in sec. Raises, 5 by 5 ft, 120 ft apart along strike, extend along footwall, in ore, from haulage level to surface, or to uppermost mining limit. Crosscuts connect raises with drifts on the 2 upper levels. STOPING. For method used in flat dips, see Art 34; underhand mining is used where dip exceeds 45°. Along footwall side of haulage drift, at 30-ft intervals, "boxholes" (chute raises) are driven. A "stope floor" (Fig 216) is first cut out above haulage level by slabbing around tops of boxholes, until both walls are exposed, and by funnelling the boxholes until they connect with each other. At elev of "second" level, a breast-stope cut (Art 30) is started by slabbing around a raise until both walls are exposed. Retreating in one direction from the raise, ore is then mined in 8-ft vert slices, each slice being mined by benching downward in successive 10-ft cuts until the "stope floor" below is reached. Bench next to raise includes whatever ore exists on hanging-wall side of raise. Drilling is with jackhammers, holes 10 ft deep. On first bench, holes are at the corners of 2-ft squares, close-spaced to avoid hang-ups in the raise; otherwise, bench holes are 3 ft apart. A "goat path," 3–4 ft wide, is cut into and along the footwall at top of stope for access to benches. Crosscuts to this path are driven from footwall drift ("second" level) to reduce traveling distance along the path. Ladderway and pipe lines are carried along footwall from path to bench. While working on benches, miners wear safety belts. Stope faces are usually carried back 50–55 ft from center line of raise, thus leaving rib pillars 10–20 ft thick, depending on width of ore. If a lean or narrow section of ore occurs before stope face has retreated to the regular pillar location, such section is left as a pillar, and the regular pillar stoped out. After the benches of first lift above haulage level have retreated 30–40 ft back from center-line of raise, a similar stope is started at the elev of the "first" level. Later, a third series of benches is started from a sub-level above the "first" level. Broken ore falls through the open stope to the boxholes below, and is drawn off at the haulage level. All stoping is done on contract; rates in 1932, covering labor and explosives, were 30¢ per ton on widths over 15 ft, to 50¢ per ton on widths less than 6 ft. In 1931 and first half of 1932, STOPING COSTS per ton were: labor, $0.298; explosives, $0.21; drill repairs and supplies, $0.055; steel and sharpening, $0.067; comp air, $0.028; misc and general, $0.089; total, $0.747. Underground base-wage scale per shift: motormen, $4.25; machine-men, pipe fitters, trackmen, cagers, $4; helpers, loaders, muckers, nippers, $3.50. Powder cost, $9.05 per case 40% gelatin dynamite.

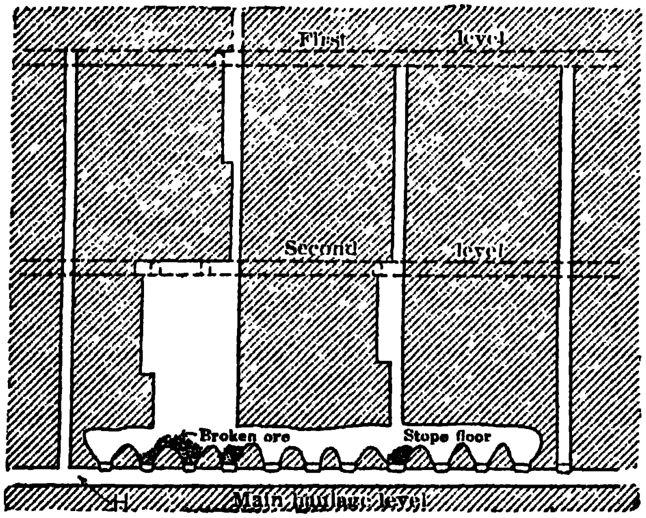

Fig 216. Underhand Stoping, Sherritt Gordon Mine, Manitoba. (Longit sec in plane of orebody)

Above method might be classed as sub-level stoping (Art 43), but underhand mining is the dominant feature. Differences from ordinary sub-level stoping are that sub-levels are much farther apart, and sub-level drifts are not driven in the ore.

37. UNDERGROUND GLORY-HOLE METHOD

This method, also known as UNDERGROUND MILLING, is an adaptation of opencut methods of same name. The top of a raise is widened in all directions, making a funnel opening (GLORY, or MILL HOLE), widened and deepened by underhand stoping. Face of hole usually carried in benches, forming in plan rough concentric circles or ellipses around the raise (Fig 218). Slope of face must be steep enough for broken ore to slide to the raise.

Often, before underground milling begins, sub-levels are run through the orebody to connect raises at vert intervals of 25–50 ft. Sperr states that, for economical work, raise interval on each sub-level should not exceed 25 ft. This condition can be met by inclined raises branching from main vert raises. Economic interval between raises and sub-levels depends also on hardness of ore. (Full discussion of branched-raise method in Bib 182.)

Applicability. Method is limited to large orebodies, as masses or wide veins, with strong walls and ore. Glory-hole walls become inaccessible as stoping progresses, with great danger from falling slabs in any but strong ground. Application of method to narrow inclined deposits is limited to those having dips steep enough for the footwall to clear itself by gravity. Ore breaking and handling are cheap, high benches being carried with deep holes. Since no sorting is possible in stopes, orebodies must be uniform.

Fayal mine, Minn (183). Hematite, underlying a cover of 65–90 ft glacial drift, was formerly mined by underground milling in rooms 24 ft wide, 60 ft high, and up to 100 ft long. A drift was run under center of proposed room, with raises to top of ore about 50 ft apart. A wide drift was then run over top of room and timbered with saddle-back stulls (Art 38) and heavy lagging, under which ore was milled into raises. Pillar widths, 23 ft. When a room was mined out it was filled, intervening pillars being mined by top slicing (Art 70). Timbering backs of glory holes is rarely feasible.

Section 21 mine, Marquette Range, Mich (153, 184). Fig 217, 218, show method of mining a steep-dipping lens of medium hard hematite; footwall, diorite, hanging, jaspilite. Shaft was in footwall. To open a level a crosscut was driven from foot to hanging; walls were then followed until drifts connected (see plan, Fig 217); crosscuts were driven between foot and hanging-wall drifts at intervals of 50 to 60 ft. Footwall raises were put up to level above for ventilation, when development had advanced far enough for a chute to be operated without interfering with other work on level; other raises were as shown, all vert or nearly so, excepting a few next to hanging. Ideal cross-sec (Fig 217) shows stages of work; on 820-ft level, development is partly completed; milling has started in raises above 760-ft level; between 700 and 640 ft, a more advanced stage is shown; work on 640-ft level has reached final stage of removing pillars. To explain the method 4 operating levels are shown; in practice, all stages of work occur simultaneously in different parts of a lift. Fig 218 shows detail of milling. Breast stopes *S* are started near top of each raise, leaving a 6 to 10-ft chain pillar under level above, which supports the level until ore above has been removed. Ore below breast stope is milled into raise, and milling continues downward to lines *abcef*, where ore will no longer slide on face of stope. Robbing the V-shaped pillars over level above then begins from raises *r*, the pillars being thinned down until they will just support caved material above. Ore is dumped into open stopes below. Holes are then drilled in remaining pillars and in level-pillars *L*. all being fired together in sections, beginning at boundary and retreating. Broken ore from pillars is drawn through chutes *b* and *e*; some ore is lost by mixing with waste, which falls when pillars are broken. At this mine a rigid geometrical plan could not be followed, because

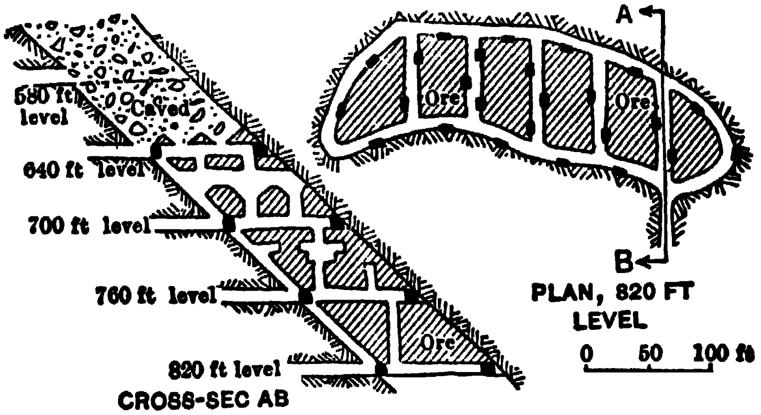

Fig 217. Glory-hole Mining, Marquette Range, Mich

of numerous intersecting dikes. An attempt was made to locate development raises to reach thickest portion of pillars on level above. This method proved economical and safe; no timber was required except for chutes, and ventilation was good. It is stated that the percentage loss of ore through contamination with waste was low.

El Potosí mine, Chihuahua, Mex. Data from H. A. Walker (174) in 1934. Highly irregular lead-zinc-iron sulphide replacements in limestone have been worked to depths of 2 800 ft. Orebodies are in 2 typical forms: chimneys, of which a large one may have a horiz area of 10 000 sq ft and depth of 1 000 ft or more; and "mantos," long, ramifying, nearly horiz channels, 30–150 ft wide, 8 or 10–20 ft (rarely 60 ft) high. There are 3 vert shafts, one for ventilation only. Level interval, 165 ft. Fig 219 shows method of mining chimneys. A 5 by 7-ft raise, centrally located, is driven from one level to next above, and near the bottom has a bulldozing chamber. Mining begins by breasting around the raise on upper level; benches are then started by drilling, with jackhammers, 2 concentric circles of down holes around top of raise. Holes, 6–8 ft deep, have a burden of 3 ft, and are inclined toward the raise. Explosive, 30% gelatin. Benches usually 6 ft high and 6 ft wide. After making the initial bench, a grizzly, with 10–12-in openings, built across the raise, prevents boulders from entering and blocking the raise, and is a safety measure. The grizzly is moved downward for successive benches. It is of old rails supported by wooden stringers. Grizzly in bulldozing chamber below is of crossed rails, with 10-in square openings. Access to benches is from level above by wire-rope ladders. Pathways along benches have cable handholds. Men are guarded from slipping down glory hole by ropes around their waists. In an unusually wide chimney an intermediate level is driven about half way between main levels, and the block between main levels is mined in 2 stages. A 10–15-ft shell of ore is always left directly above a level, whether main or intermediate, as a protection until stope below is finished.

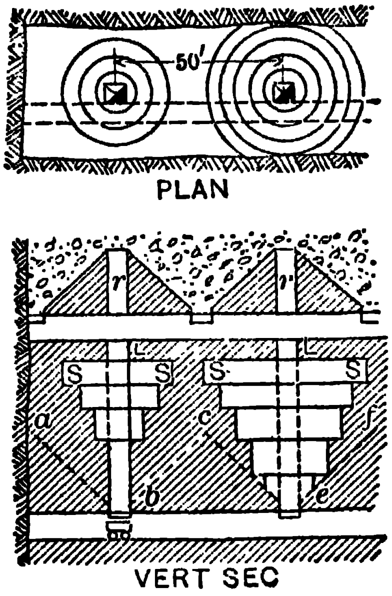

Fig 218

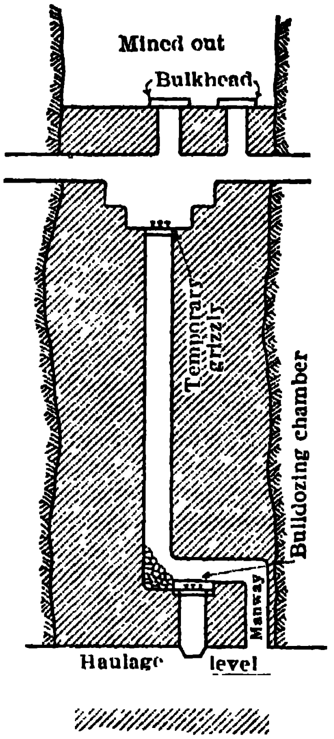

Fig 219. Glory-hole Stope in Chimney Deposit, El Potosí Mine Chihuahua, Mex. (Vert sec)

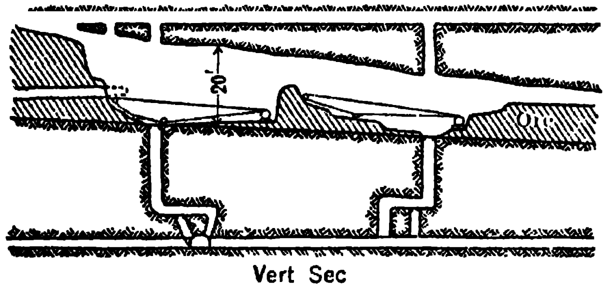

Fig 220. Glory-hole Stoping in a Thick Manto, El Potosí Mine, Chihuahua, Mex

Wide mantos are mined as shown in Fig 220. From a haulage level beneath the manto, raises, 150–200 ft apart, are driven to level above, or to top of the manto. Mining procedure is same as in chimneys until ore will no longer run into raises by gravity; then scrapers are used, with triple-drum hoists and 15-hp elec motors (Art 91 and Sec 27).

Mascot mine, Mascot, Tenn. Data from H. A. Coy (175) in 1930. Veinlets and seams of sphalerite occur in dolomitic limestone beds dipping 18°–22°. Thickness of ore varies to max of about 100 ft. The strong dolomite hanging wall will stand indefinitely over unsupported widths of 100 ft; mineralized dolomite does not stand well without support.

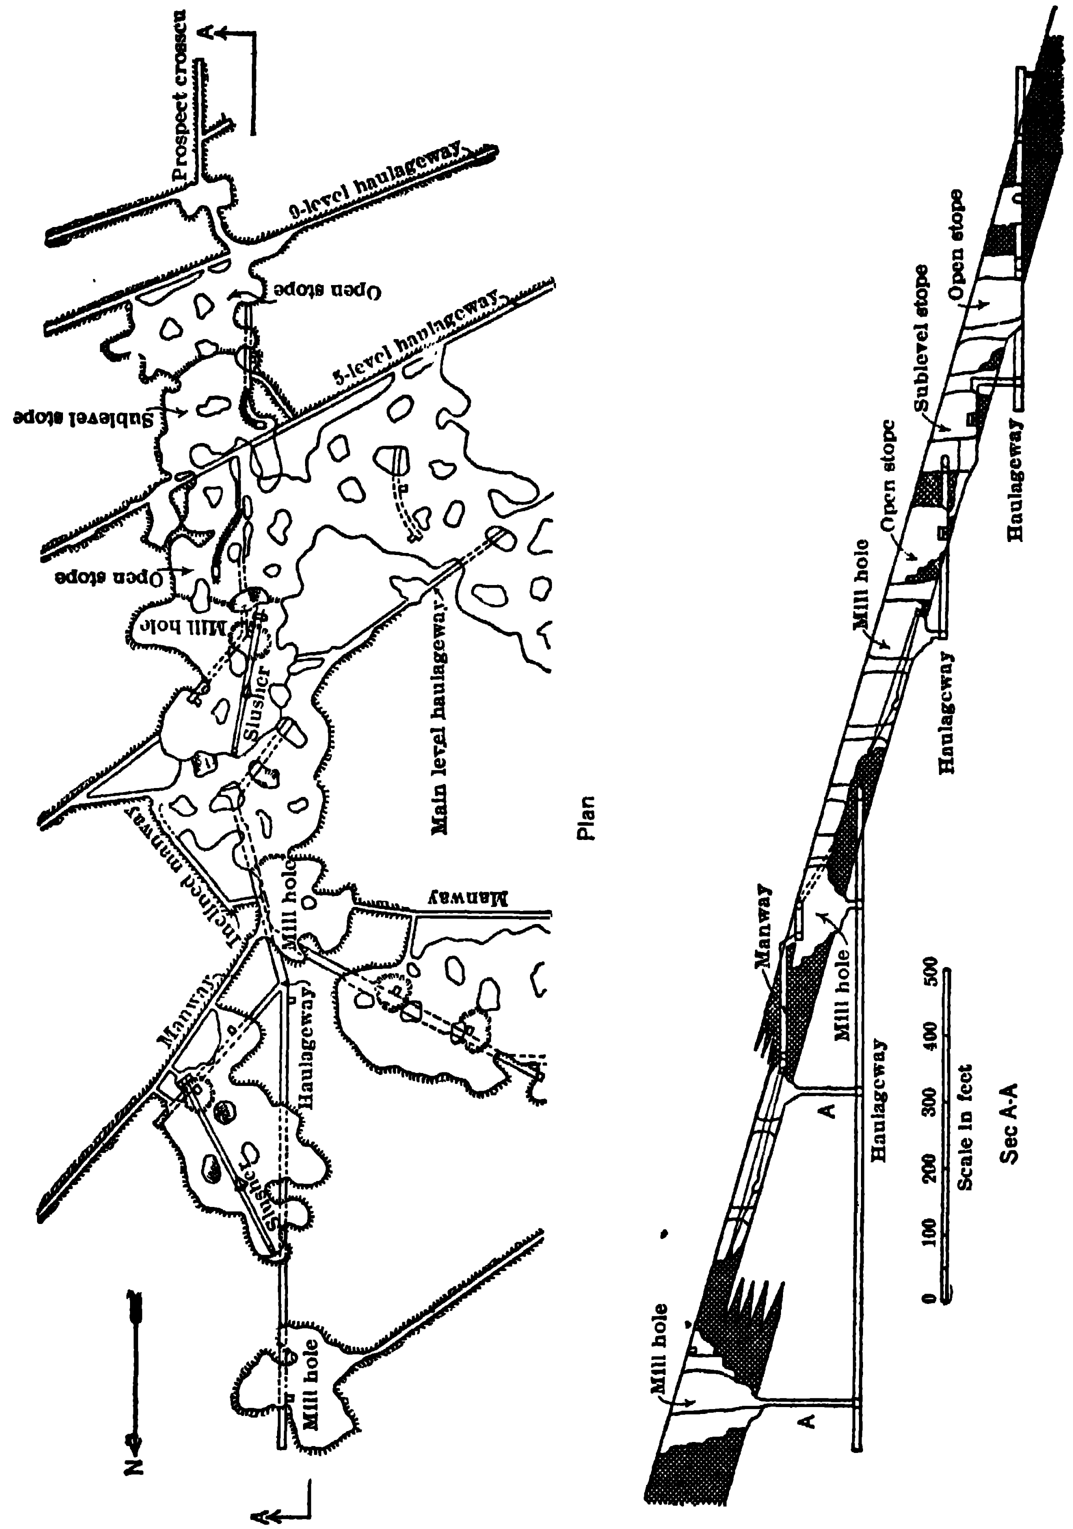

Fig 221. Part of Mascot Mine, Mascot, Tenn (175)

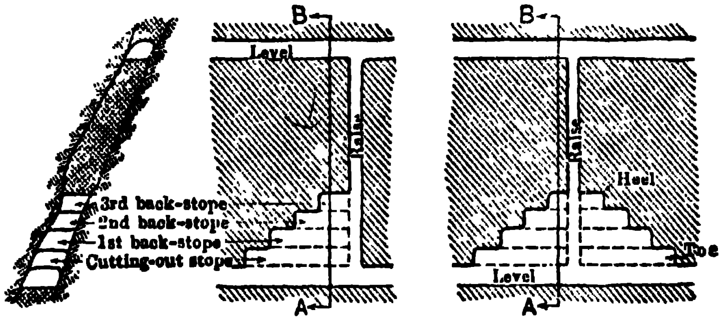
A vert shaft is started in hanging wall. From a main haulage level, at depth of 520 ft, 2 inclines extend up and down the dip, and from these, working levels are driven in ore at varying intervals (Fig 221). From some of the levels, crosscuts into the footwall allow the mineralized beds to be attacked from below through 5 by 5-ft vert chute raises *A*, which are later reamed to 10 by 10 ft. In such case, mining is by glory-holing; where development within the footwall is not warranted, ore is mined by breast and bench (Art 31), shoveling or scraping of ore being necessary. In either case, a raise is driven to top of ore and a heading, about 8 ft high, is advanced under the roof. Ore below is mined in benches 4 ft wide by 10 ft high, drilled with single row of vert holes and blasted with 30% gelatin dynamite. Ore broken in glory-holing falls through chute raises into cars in haulageways. Breast and bench stopes start as glory holes and so continue until ore will no longer run to raises by gravity; then scraping begins and in this sense only does the method change from ordinary glory-holing. Pillars are of varying size and spaced at irregular intervals, depending on ground conditions. On basis of 528 626 tons produced in 10 mo of 1929, output averaged 10.83 tons per man-shift (9-hr) of underground labor. Explosive used, 0.502 lb per ton.

Granby Consol Co, Phoenix, B C. A novel and modified glory-hole method is described by R. Dunn and L. R. Clapp in 1923 and 1924 (185). Spiral raises, started from top of a chute raise, are carried up on grade flat enough to permit men to walk up. Diam of spiral is increased as raises advance, the interior cone being mined as they are driven. Result is a funnel opening above each chute raise, extending to top of ore. Spiral raise with inner side open climbs sides of funnel, and is connected at extremities of its swings with manway raises in pillars at each end of stope. If necessary, more than one spiral raise is driven in a stope. Subsequent work consists in widening the spiral and breaking down the benches between its turns. All ore falls to central opening, which is drawn empty daily, the long fall into empty glory hole tending to break up slabs. Where required to support heavy ground, a rib of the spiral is left as a strut across stope, being drilled before passing it and later blasted. L. R. Clapp points out advantages of method over ordinary glory-hole work: men always work close under back; access to working place is easy and safe; method is flexible, since lean ore or dikes can usually be left as pillars and taken down later, and work can readily be changed to any part of stope to adjust type of ore mined to smelter demands. Chute raises are equipped with bulldozing chambers. Ore is very hard and breaks in slabs; cost of blockholing is almost as great as primary blasting. Output per miner-shift varies from 20 tons in newly opened stope raises to 150 tons in older stopes. For later modifications of this method, see Bib (596).

38. OPEN OVERHAND STOPES, NARROW VEINS

General plans of mining are shown in Fig 222 to 225. Overhand stopes are practically inverted underhand stopes (Art 35), miners working upward underneath the ore to be broken. Details vary with modes of breaking ground, handling ore, and supporting walls and men; dip of vein and distribution of ore are the principal factors causing variations Open stopes are limited in general to deposits having strong walls and ore strong enough to stand unsupported over back of stope. Stopes are preferably started from bottom of a raise, successive horiz slices being taken (Fig 222). First slice, directly over level, is the CUTTING-OUT STOPE; succeeding slices are 1st, 2nd, 3rd, etc, BACK-STOPES. Stopes may be SINGLE (*a*), or DOUBLE STOPES (*b*) (Fig 222). Terms TOE and HEEL sometimes designate bottom and top corners of stope face. The drift and cutting-out stope may be excavated together making a DRIFT STOPE (Art 41). RILL STOPES have a longit sec like an inverted V (*b*, Fig 222); inclined faces may be produced by keeping the faces of successive back-stopes close together, or by using inclined slices (Fig 223). Stoping with inclined slices is more useful in filled than in open stopes. In FLAT-BACK STOPES (horiz or longwall stopes),



CROSS-SEC A B (*a*) Single stope (*b*) Double stope

SECTIONS IN PLANE OF VEIN

Fig 222. Open Overhand Stopes

the face is advanced in a general line parallel to the level, by keeping faces of successive back-stopes far apart (Fig 224). Many combinations between rill and flat-back stopes are found. The number of back-stopes advanced simultaneously determines number of points of attack, and this, in combination with width of vein, determines daily output obtainable from a stope. If back-stopes are too close together, miners working on adjacent faces interfere with each other. General term STEPPED-FACE OVERHAND STOPE denotes stopes like Fig 222, or intermediate forms between this and Fig 224. All these terms describe overhand stopes of same form in wide orebodies.

Local conditions may require stopes to be opened in the back of a drift without first driving a raise, as in mining portion *WV* of vein in Fig 207, or in case of small irregular oreshoots with problematical extent above the level. Raises insure natural ventilation, furnish points of attack for starting stopes, and provide entry and facilities for lowering timber, etc, into the stope.

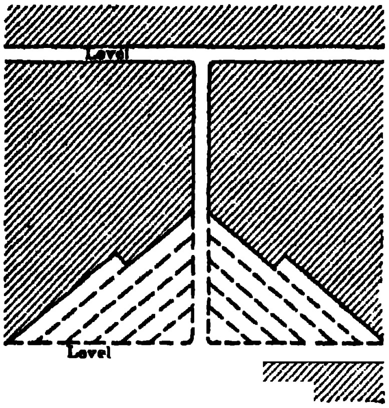


Fig 223. Inclined Slice (Sec in

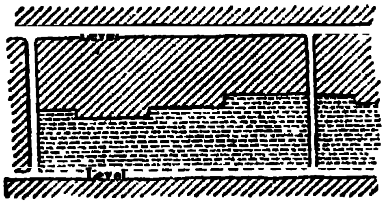

Fig 224. Flat-back Stope (Sec in plane of vein)

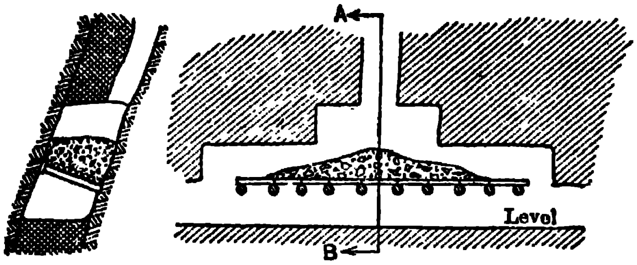
Development. Fig 107 shows typical development in a vein, providing requisite openings for overhand stoping.

Breaking ground (see Art 26 to 28).

Support and protection of levels. Broken ore from an open overhand stope slides or falls to level below; hence a barrier is necessary between level and stope to protect men and keep broken ore off haulage tracks. Protecting the back of level also allows broken ore to be loaded through chutes (Art 90) and avoids shoveling. Practice varies with dip and width of deposit, character of walls, and local custom. STULLS usually protect back of level in narrow veins having walls strong enough to support them; Fig 225 shows common arrangement; a cutting-out stope is taken before the stulls are placed; distance between stulls and back of cutting-out stope, 7 to 10 ft.



CROSS-SEC A B

SEC IN PLANE OF VEIN

Fig 225. Overhand Stope, Stull Timbering

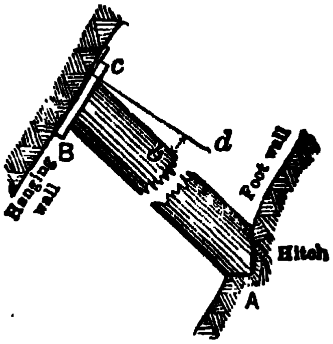


Fig 226. Stull Timbering

Stulls are of round timbers, diam, 8 to 24 in or more; usual spacing, 3 to 5 ft, rarely exceeding 6 ft; occasionally, they are close together (Quincy mine, Art 41). LAGGING poles, 4 to 6-in diam, or slabs or planks (see Timbering drifts, Art 21) are laid on the stulls. In open stopes, a 3 to 4-ft layer of broken ore is left on lagging to protect it from blasts and falling ore; this is removed when stope is finished. A pocket called a HITCH is cut in footwall with a moil or plugger-drill to receive foot of stull, which is flattened as at *A*, Fig 226, to prevent it from rolling. Hitch may be only 1 or 2 in deep in strong rock; a weak footwall may require hitches 6 or 8 in deep or more; loose ground must be removed before cutting hitch. Head of stull is square and to distribute pressure rests against HEADBOARD *B* (sometimes called a cap) of 2 to 4-in plank; where necessary, wedges are used between headboard and hanging. Headboards and blocking are compressed by initial creep of ground and protect stull from splitting. Stulls are set at a steeper angle than the normal to the hanging wall. In Fig 226, line *cd* is normal to hanging wall; angle *dcb* is ANGLE OF UNDERLIE. Setting of stulls varies. W. E. Sanders states angle of underlie should be about 0.25 × angle of dip of vein (186); T. Johnson favors a max underlie of 10° for dips of 60° or over, and a ratio of about $^1/_8$ between angle of underlie and angle of dip on flatter dips (187); usual practice in U S is between these limits. Object of setting stulls with an underlie is to prevent their falling under weight of ore or waste, and to cause them to tighten under small settlement of hanging wall. Foregoing detail applies to placing stulls in both overhand and underhand stopes, as well as to stulls over levels. If footwall is weak a FALSE STULL may be set underneath main stull (Fig 227). In steep-dipping or vertical veins with poor walls, stulls over levels may be reinforced, Fig 228 (186).

Max economic length of stulls, placed as in Fig 226, is 12–20 ft, depending on timber supply, facilities and room for handling timber underground, lateral pressure from walls, and relative cost of alternative methods. Usual max width of vein in which single stulls are used to protect levels (also for supporting slabs and men in open stopes) is about 15 ft. SADDLE-BACK STULLS (Fig 229) may be used in veins up to about 25 ft wide. They lack lateral rigidity, and are apt to fail by buckling sidewise; they will support vertical wt of broken ore or waste, but do not resist wall pressure; joint at apex must be carefully framed and fitted. They have a limited application, and many engineers object to them under any conditions.

Advantage of stull timbering for levels is that the stope from below can be readily broken through to level above, and without disturbing the waste and debris which accumulate on stulls under exhausted stopes.

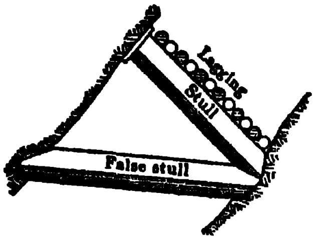

Fig 227. Stull Timbering

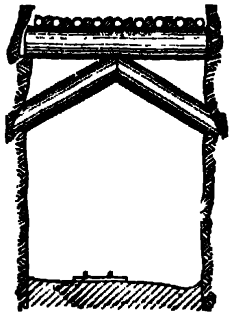

Fig 228. Reinforced Stull

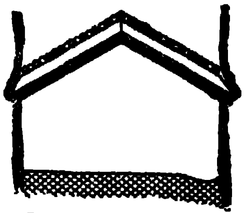

Fig 229. Saddle-back Stull

Stulls and posts may be used in steep-dipping veins, 12 to 20 ft wide, with weak walls. The stull is set with a flat underlie (generally in hitches), with posts under both ends, and at intermediate points if required.

Drift sets (Art 20) are common for protecting backs of levels under stopes in narrow veins with weak walls; like stulls, they are placed and lagged after the cutting-out stope is broken. HALF-SETS are used where one wall is weak; THREE-QUARTER SETS, where both are weak.

Pillars of ore (level-pillars) may be left over level at bottom of overhand stopes; Fig 230. In this case, stopes are opened from a sub-level (stope-drift) *A*, and connected with it by short raises *B*, in which chutes are built; wedge-shaped piles of ore, collecting between chutes on top of level pillars, are cleaned off by shoveling when stope is finished. Pillars may sometimes be recovered prior to abandonment of level. In open stopes, choice usually depends on comparative cost of timbering, extra cost of the sub-level, and net value of ore left in pillars (20).

Packwalls may be built above level on flat dips and holes left in them at intervals for chutes (for detail, see below under Support of walls). Need for protecting the level diminishes as dip of vein decreases; no protection is necessary where dip is less than 20°; for varying practice on dips of 30° to 40°, see Art 39 to 41.

Support of level above stope. Pillars of ore are left where it is necessary to keep the upper level open (Fig 252). Such pillars may be also required to support walls. See below and also Mohawk mine, Art 41.

Support of men. On dips less than about 40°, men can stand on and work from footwall, no provision for their support being necessary; on steeper dips, timber staging is required. Stulls in rows 6 to 12 ft apart vertically are used in veins where width does not exceed max economic stull length; interval between stulls is 4 to 6 ft (Fig 231); men stand on temporary platforms of plank, slabs or lagging laid on stulls; temporary stulls may be put wherever required to keep miners up to the face. Stopes thus timbered are STULLED STOPES (for examples, see Art 39). Square-sets and other timbering are used in open stopes in steep-dipping veins, too wide for stulls (Art 45 to 54).

Support of walls in individual stopes, in veins worked by open overhand stope methods, is limited by definition of open stope to timbering, pillars of ore or waste, and artificial pillars. Stulls are commonest timber support in narrow veins (see above, under Protection of levels, for economic limits of length). When placed as in Fig 231, they support loose slabs. Stulls do not adequately support very shelly walls, or those which slough off on exposure to air; for such cases square-sets or other timber (Art 45 *et seq*), with lagging along walls, may be employed. Open stopes are not adapted to veins with weak walls; filling systems (Art 59 to 66) usually preferable. Timbering in general is to support slabs or to hold walls temporarily until the stope can be abandoned and allowed to cave; it will not permanently support the weight of rock overlying a deposit. For examples of stulled stopes, see Art 39.

Artificial pillars. Usually, in narrow veins, waste is piled on stulls (Fig 210). Fig 232 shows an overhand stope thus supported. H. C. Hoover states (20): " This system implies a strong roof which does not demand continuous support; it effects economy in stulls by using waste which accumulates underground; artificial pillars also apply to cases where stulls alone are not sufficient support, and yet where complete filling or square-setting is unnecessary; under propitious conditions they have the comparative advantage over timber systems of saving timber and over filling systems of saving imported filling." Inverted V shape of pillars (Fig 232) allows broken ore to slide to the level without especially built passes; when this system is employed, more special staging must be provided for miners than in square-set or filling systems.

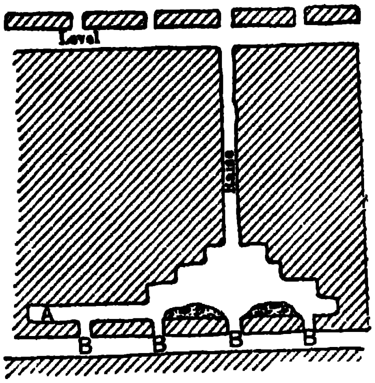

Fig 230. Level-pillars, Overhand Stope (Sec in plane of vein)

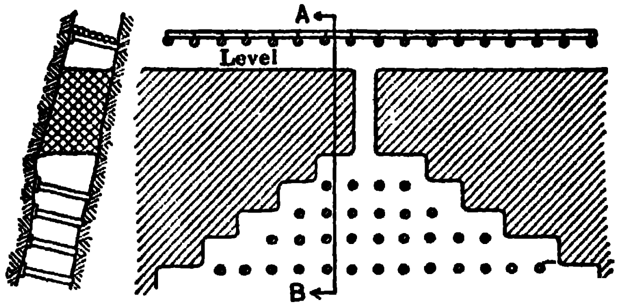

CROSS-SEC AB

SEC IN PLANE OF VEIN

Fig 231. Stulled Stope

Cribs or cogs are used for roof support in flat deposits; examples, Art 33. They are adapted to temporary support, prior to abandoning a stope or filling it with waste. For similar use of CONCRETE PILLARS, see Fig 181, 198, and text.

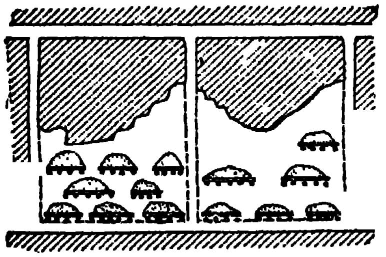

Fig 232. Artificial Pillars (After Hoover)

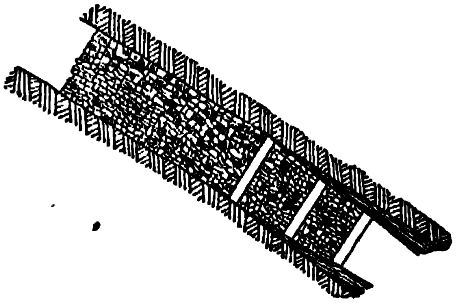

Fig 233. Packwall (After Johnson)

Packwalls (Fig 233) are sometimes built on the upper side of levels in veins dipping 30° or less, to protect them and to support the hanging wall when ore is completely removed; they may also be employed as artificial pillars in stopes. T. Johnson (187) comments on Rand practice as follows: packwalls should be built nearly at right angles to plane of deposit, and not with vertical end walls, which may fail by slumping " upbrow " (up the dip); in long packs, middle portions of walls bulge and eventually fail. Stulls are placed as in Fig 233, with or without lagging to steady the walling until weight comes on; small timbers serve this purpose. Small waste should be thrown in while walls are being built, to form bedding for large boulders and give solidity. It is advisable to bind walls to inside of pack with pieces of old pipe, rails, rope or boards, particularly at corners. For wire-bound packs on Rand, see Art 33.

Pillars of ore may be left in an overhand stope, where the hanging wall will stand unsupported between them, and where net value of ore in pillars will not pay for alternative modes of support.

Low-grade or waste portions of an ore-shoot are usually left as pillars; temporary pillars of ore (as level-pillars) are common; use of pillars for permanent support is confined to low-grade orebodies, usually to extensive deposits lying on flat dips. For examples see Art 40, 41.

Control of hanging wall over entire mine, in veins worked by open overhand stoping: (*a*) In veins where ore is in shoots, the barren areas often serve as pillars; support in individual stopes is obtainable by one of the above methods, depending on size of stope and character of walls, and stopes will remain open indefinitely or cave after they have been abandoned. For permanent support to protect shafts, surface buildings, etc, exhausted stopes may be filled. (*b*) Where ore is continuous over long distances, the hanging wall may be supported on permanent pillars of ore. Flat-dipping, low-grade amygdaloid copper deposits (Mich) furnish an example of this practice (Art 41). (*c*) In continuous orebodies, stoping on each level may be carried to property line or to limit of ore, leaving temporary pillars, often of large size, to support roof. As much as possible of the pillar ore is then mined, retreating from boundary toward shaft, and the hanging wall caves over robbed areas (see Clinton iron ores, Art 40). (*d*) In continuous orebodies of good grade, or at great depth causing heavy pressures, levels may be driven to boundaries before stopes are begun above them. Ore is stoped in blocks, starting at boundary, each being mined before work begins in next one toward the shaft. Size of block is adjusted to pressure, kind of roof, and speed of work, so that the stope can be kept open with timber until finished; the hanging wall is then allowed to cave and work repeated in adjacent block (see Calumet & Hecla, Art 39). The foregoing remarks apply to open stopes; for support of walls by filling, see Filled stopes, Art 59–66.

Handling ore. In STEEP-DIPPING VEINS, ore broken in open overhand stopes goes by gravity to level below. Loading chutes are built in openings in level timbering or pillars at intervals of 15 to 30 ft (for details, see Art 90). Minimum angle on which ore will slide depends on character of ore and footwall; soft ores often slide less easily than hard (see Birmingham, Ala, Art 40). Angle of friction varies with ore; an irregular footwall causes ore to hang; minimum angle, usually about 40°; varying from 35° to 45°. In open, overhand work, no ore is stored in the stope except the small amount left on level-pillars or to protect level timbering. WING STULLS (Fig 234) (winged stulls or wing chutes) are sometimes used to facilitate handling ore in steep-dipping veins, where all the vein matter is sent to surface. They permit wider chute spacing and eliminate shoveling into chutes ore that otherwise forms cones or pyramids between chutes.

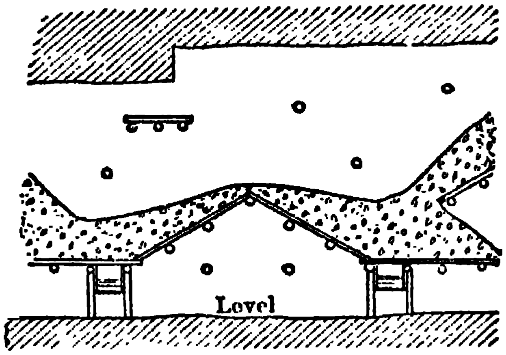

Fig 234. Wing Stulls (Sec in plane of vein)

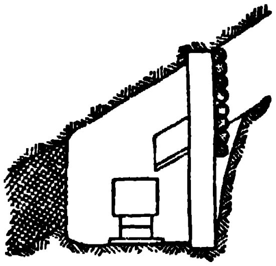

Fig 235

On dips between 35° and 40°, movement of ore from stope face to level must generally be aided by shoveling. In some districts no level timbering is used on these dips. The ore runs into the level and is shoveled into cars, or slides onto platforms at foot of stope, high enough for ore to be shoved off into cars or shoveled with a low lift (see Mich copper mines, Art 39 and 41). In West Australia, levels are timbered on flat dips, as in Fig 235, drifts being far enough in the footwall to give room for cars below lip of chute; this kind of timbering is used in filled stopes also (83). In flat deposits (less than 35°), scrapers and other mechanical devices are used to reduce shoveling and cheapen stope transport (see Art 91; also Sec 27).

Handling waste. Sole means of storing waste sorted from ore in open overhand stopes on steep dips is by piling it on stulls (Fig 232). Since this provides limited storage, these stopes are not suited to ores containing much waste which it is desired to sort out underground. In flat stopes, some waste may be utilized for packwalls or filling cribs, or it may be left on floor in middle of stope, but the cost of shoveling much waste to this point is usually prohibitive, and if it is left promiscuously on stope floor it interferes with transport to the level and is mixed again with ore.

39. EXAMPLES OF PRACTICE, OPEN OVERHAND STOPES (Stulled)

Cripple Creek, Colo. During days of great activity in this district, open overhand stoping with stulls was widely practiced. Veins mined with stulled stopes were narrow and nearly vertical, with sound walls of andesite, tuff, breccia, etc, and strong, often high-grade ore, in irregular shoots. Wolcott gave following data in 1908 (142). Fig 236 shows method of stoping and timbering in veins up to 8 or 10 ft wide, where back-stopes were broken with uppers. A flat-back stope was carried, with stulls 5 to 7 ft below back, and enough lagging on top row for a working platform.

Formerly (1906) 2.25-in piston-drills were used and height of slice taken in one back-stope was 4 ft. Permanent stulls were say 7 to 8 ft apart vert and 5 to 7 ft horiz; 2 slices were taken across a stope before setting second row of stulls. Part of the broken ore was left on lagging, or temporary stulls (sprags) were put in to keep men up to the back while mining the second slice. In later practice, stope-drills were used, making deeper holes, and 6 to 8-ft slices were broken in one operation. Manways *M* were often formed at ends of stope by lagging a vert row of stulls.

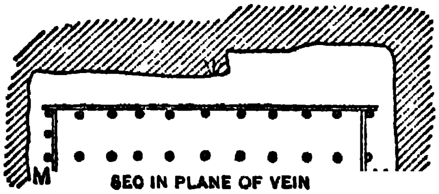

Fig 236

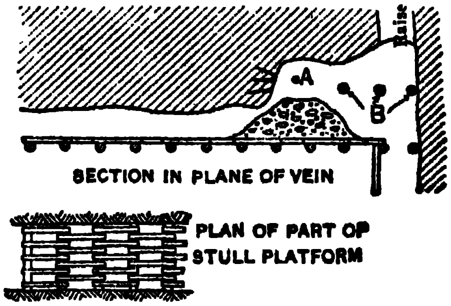

Fig 237

Portland mine (in 1907). Some stopes were carried, as in Fig 237, with stulls 4 or 5 ft below back of stope. Small piston-drills were mounted on a bar at *A*, in stopes less than 8 ft wide, or in wider stopes on a column set between the back and a muck pile on lagging. Stulls were spaced 5 ft horiz and 7 or 8 ft vert, with lagging poles, 6.3 ft long, as shown. The lagging supported broken ore, provided a place for machine men to stand without staging, and prevented large pieces from falling and injuring stulls below. A flat-back stope was carried in 8-ft slices. As face advanced, lagging at the rear was removed and muck dropped down, large boulders being broken before they were allowed to fall. Lagging was reused on higher rows of stulls (*B*, Fig 237).

Wright-Hargreaves mine, Ontario. Data from L. B. Smith (176) in 1934. Gold ore occurs in fissure veins in porphyry. Metallic minerals are chiefly pyrite, tellurides, chalcopyrite, free gold, and molybdenite. Veins range in width to 15–18 ft, but are usually narrower. Three main veins: (*a*) " North " vein is a well defined fracture, bordered by brecciated porphyry which is penetrated by quartz veinlets; walls are indefinite and determined by values, close sampling being necessary; dip, nearly vert; (*b*) " South " vein is of crushed and silicified porphyry, penetrated by stringers and bunches of quartz; usually there are 2 smooth, well defined walls which are weak and shatter easily; dip, nearly vert; (*c*) " Inclined " vein is a narrow quartz band accompanying a calcite-filled fracture; walls, highly altered porphyry and hanging wall is very weak. Development. Level interval, 150 ft, with drifts in ore. Stoping methods. Shrinkage stoping (Art 68) is used in some cases where ore is over 6 ft wide and walls are good. Filled rill stopes (Art 65) are used in some parts. Open stoping with square-sets (Art 46) is used where ore is over 10 ft wide and walls are bad. Open stoping with stulls is commonest method and is suitable for widths to 10 ft, where walls are too weak for shrinkage stoping, but not weak enough to warrant square-setting; advantages, flexibility, continuity of operation, and safety to men. Open stoping with stulls (Fig 238). Back of drift is first raised

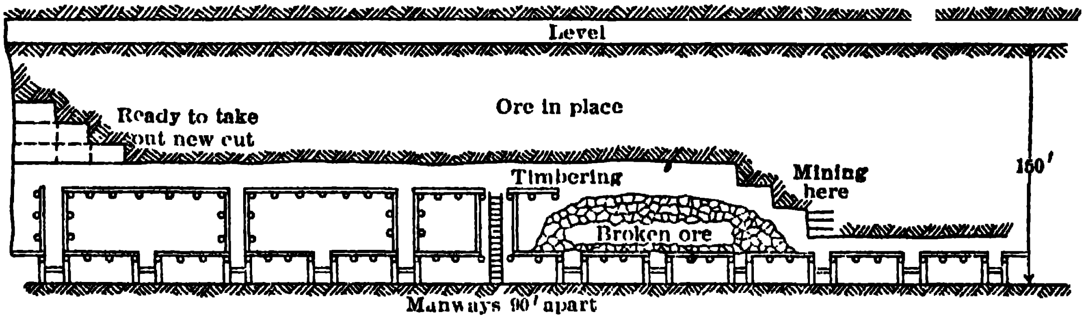

Fig 238. Open Overhand Stope, Wright-Hargreaves Mine, Ont. (Longit sec in plane of vein)

to height of 15–16 ft above rail. Stulls are then placed over the drift at 6-ft centers except for chute sets, which are at 5-ft centers. Stulled manways are carried up 90–100 ft apart. Stope breasts are 8 ft high; usually 3 are advanced simultaneously in a given section, and lagged-stull floors are placed under each 24-ft cut. Chutes are raised by carrying two lines of stulls 8 ft apart vert, lined with 8-ft half-round timber. Mat of broken ore on floors prevents timber breakage and affords footing for miners. As the cuts advance, ore is drawn through chutes as in shrinkage mining. As rock is drawn, loose walls are stulled. Stoping routine eventually consists of advancing mining, followed by drawing of ore and mucking; muckers are followed by timbermen, who set stulls, raise, chutes, and place floor stulls and lagging. Flooring is of 6 to 8-in round timber, split down center and laid alternately round and flat side up. When stopes reach height of 40 ft, tugger hoists are used to hoist timber up manways.

Liberty Bell mine, Telluride, Colo (131). Quartz vein, aver width, 4.3 ft; aver dip, 57°; wall rocks, andesite, tuff and breccia; pay ore occurred in shoots of variable size. Much mining was done in stulled overhand stopes, stoping practice and details varying with dip and strength of hanging wall. C. A. Chase gave following data in 1911. Ore was broken with vertical or highly pitched holes, drilled with stope-drills or hand augers, miners working on a partial floor near back of stope. Wing stulls (Art 36) deflected broken ore to chutes at 25 to 35-ft intervals. Stulls, 8-in diam up, were placed 5 ft apart in floors 7 ft apart. Working floor was chiefly of 6-in round timber; stoping floors, of round or split lagging, 10.5 ft long.

Tonopah Mining Co, Nev. Much mining in early history of the camp was done in stulled stopes. Ore occurs in quartz veins carrying gold and silver. Fig 239 is a cross-sec, showing method used in upper part of Mizpah vein; width, 5–30 ft; dip, about 70°; wall rock is dry andesite, which will stand for a long time. Ore as broken averaged $15–$25 per ton; no sorting done under ground. Entry was by vert shaft; level interval, 100 ft. First row of stulls was horiz, 8 or 9 ft above level, and supported by 2 or more posts on sills wedged between walls on floor of drift. Succeeding rows were set as usual at vertical intervals of 6 to 15 ft. Plank lagging was used for platforms and to protect stulls at level; wing stulls (Art 36) were often employed. Stulls were 8 in or less in diam, braced in wider parts of the vein by struts to stulls above and below (Fig 239). When a stope broke through to level above, the sills there were blocked up from the stulls below.

Fig 240. Handling Ore in North Star Mine, Calif (578)

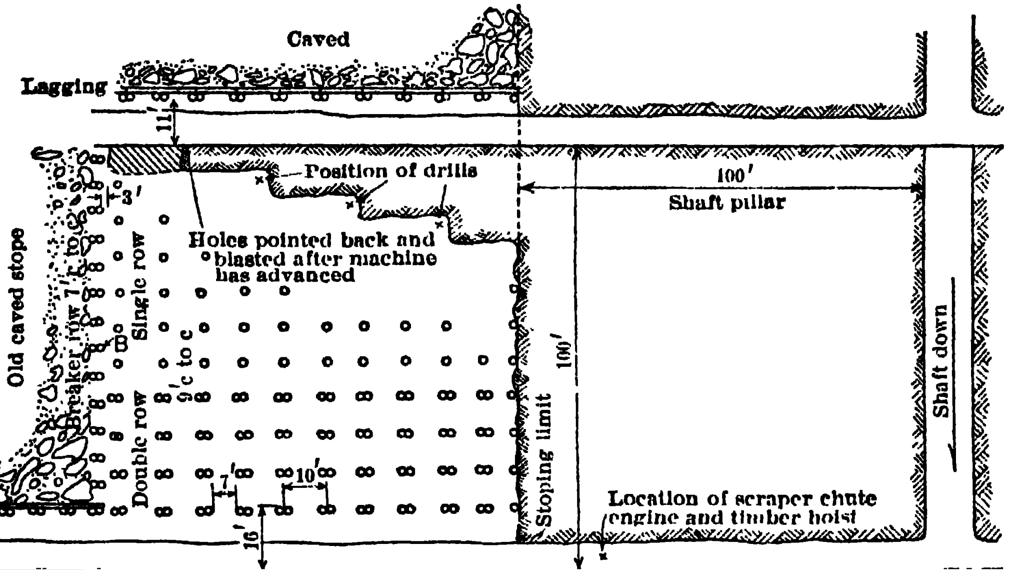
North Star mine, Grass Valley, Calif. Data from J. A. Fulton and A. B. Foote in 1926 (578). Gold quartz veins, 1 in to 6 ft thick and averaging 16 in, occur in hard granodiorite. Portions of vein as narrow as 4 in are sometimes mined; aver stoping width, 42 in. Dip is flat, averaging 26°.

Main levels, 5 by 7 ft, are run on vein at 300-ft intervals. Stopes are carried up overhand, with stull support as shown in Fig 240. Sub-level tracks are laid at 60-ft intervals for scraping and 30-ft for shoveling, being moved up as stope face recedes. Broken ore is shoveled or scraped into cars of 1 500-lb capac on the sub-levels, and handled to main level by a go-devil plane (Art 91). About half the waste broken is sorted out in stopes. Stulls are used for temporary support and to keep blasted ore from being blown down stope. Production is 0.95 ton per miner-hr and 0.9 ton per shoveler-hr, which includes stowing waste, or 0.47 ton per man-hr in stope; ore recovery, probably over 90%. Footwall is swept with brooms before stope is abandoned.

Calumet & Hecla mine, Mich (67, 482, 489). Following paragraphs describe practice on the CALUMET CONGLOMERATE LODE, which has been worked about 2 miles along strike and to depth of over 8 000 ft down dip. Recent annual reports indicate that work in deeper parts of mine has been stopped and recent work confined to extraction of pillars, retreating toward the surface. For practice in amygdaloid lodes, see Art 41.

Physical characteristics of ore and wall rocks. Calumet conglomerate lode is 12–20 ft thick and dips 36°–38°. Lode consists of pebbles of felsite and quartz porphyry, cemented by a mixture of rock and native copper. Tenor of ore mined is about 2% copper. Ore is tough and abrasive. Hanging wall is shelly diabase. Footwall is a fragmental amygdaloidal layer of diabase, relatively weak and with tendency to burst upward into openings when subjected to concentrated pressure, as from caving hanging wall. This condition was an important factor in selecting a retreating system of mining.

General plan of mining in the conglomerate bed differs from amygdaloid practice (Art 41), because of the weak hanging wall and great depth of mine; a retreating system is required by these conditions and also by high temperatures at depth, which necessitate good ventilation at working face; in advancing systems, much of the air current is apt to short-circuit through old stopes close to shaft. Stoping is begun either at the boundary or midway between adjacent shafts, retreating toward shaft; small blocks are stoped rapidly, held open temporarily by stulls and then allowed to cave; the only pillars left are the shaft pillars, extending 100 ft along strike on each side of shaft; these are robbed after hanging wall has settled around them, beginning at bottom and retreating up the dip.



Longit Sec in Plane of Lode

Fig 241. Open Stope, Conglomerate Lode, Calumet, Mich (489)

Development. There are numerous inclined shafts in the lode and several vert shafts which cut through lode at depth. Level interval is about 100 ft; higher stopes can not be worked out quickly enough to allow control of hanging wall in lower portions of stopes. Drifts are 8 by 8 ft, and follow the footwall to take advantage of better ground and a well marked slip; double-track drifts in Red Jacket workings are 7 by 11 ft; drift-stopes (Art 41), where tried, have proved difficult and costly to maintain. A 7 by 7-ft raise is put up between levels at boundary or in the end stope on the level, for ventilation and to furnish points of attack for stoping; as stoping progresses there is enough open space between solid and caved ground for these purposes.

Stoping. Data from Henry Vivian, Ch Engineer (489) in 1931. Successive overhand back-stopes are about 6 ft high. Hanging wall supported by stulls during active life of stope, but caves later. Length of stope standardized at 100 ft; height limited to 100 ft. These dimensions permit mining entire stope before caving starts. An advancing system was used to depth of 6 000 ft, leaving floor pillars 8–15 ft thick under each level; these were later crushed by the caving of mined-out areas above and below, but were recovered profitably. Since 1909, and below 6 000 ft, a retreating system has been used exclusively; no floor pillars are left, so that all the lode material is mined.

Details. Length of block stoped in one operation depends on speed of work and length of time that hanging wall can be held with timber; therefore on thickness of ore and character of roof. **Length of stopes** has been consistently shortened as depth increased. At first, stulls were used entirely for timbering stopes; later, due to increase in lode thickness, square-set timbering (Art 46) was standard and stopes were 200 ft long. Below 5 500 ft on dip, the lode was generally less than 20 ft thick and stulls were again used, length of stope then being reduced to 100 ft. **Spacing of stulls** in lower part of stope has become standardized, but spacing in upper part depends on foreman's judgment. Present practice (1931) calls for 4 rows of 18–24-in stulls, set in pairs with about 7-ft clear space between timbers in horiz rows and about 9 ft c-c between rows measured down dip (Fig 241). These double stulls ("batteries") cover about 40% of height of entire stope. Above this height, stulls are placed singly, with a variable increase in spacing, depending on appearance and behavior of hanging wall; the top 20–25 ft of the stope may need no timber. Experience shows that a stope should be completed in approx 100 days. **Drilling** is by mounted drifters, usually 3 machines, sometimes 4, in a stope; slices are about 6 ft high. Depth and spacing of holes are left to judgment of miner, but, for a 12-ft width of ore, an aver round for a slice consists of 4 rows of 8 to 9-ft horiz holes, 3 holes per row, with burden of 2.5–3 ft. **Procedure.** First or "cutting out" slice starts at end nearest shaft and advances toward previously completed stope, which is usually well caved when first slice reaches it. Successive slices then extend from the caved stope toward the shaft, thus avoiding raise rounds to start each slice, and also the dangerous projection which would exist at the caved end if a slice were approaching it. Just before completing a stope to the level above, a row of doubled 2-ft or larger stulls ("breaker row" *B*, Fig 241) is placed 3 ft back from the face of solid ore in the block next to be stoped; pairs of stulls are spaced 3 ft apart on the dip. This maintains a safe space from which the successive

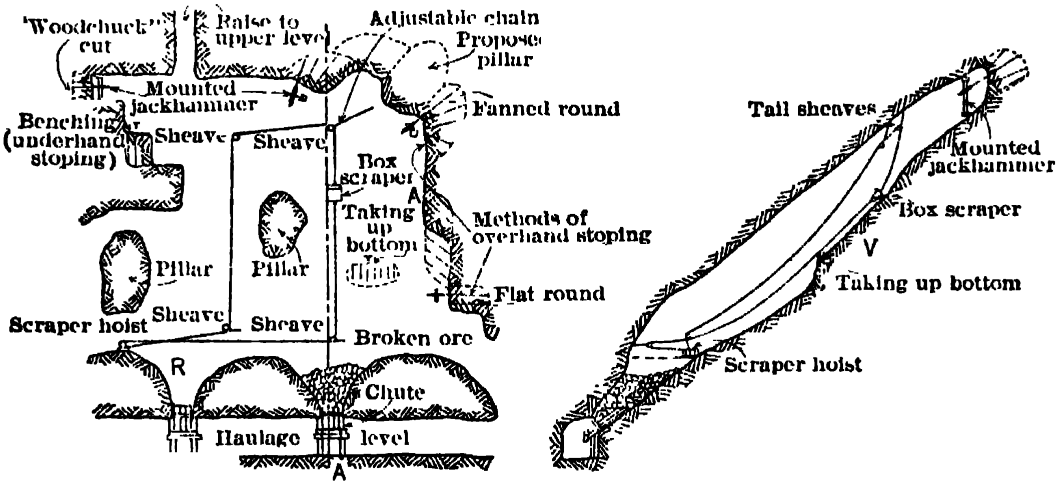
back-stopes can be started. As the top slice of each stope is cut, the floor arch of level above is drilled, but actual breaking of the arch is deferred until slice has advanced enough to leave a short length of protecting arch above the driller (Fig 241, 242). Last timbering in stope is to place heavy lagging along upper side of the lowest row of stulls; this facilitates recovery of floor arch from below. A complete mining operation on either side of a shaft is a series of 4 retreating stopes on 4 successive levels, the top stope leading the next below by approx 150 ft, and so on down (Fig 243). No attempt is made to hasten caving of hanging wall in stopes by removing timbers. Regulation of time of caving, if necessary, is by increasing or decreasing number of stulls placed during active stoping. Handling stoped ore. Tendency is for ore to break into slabs, so that, in spite of the relatively flat dip, most of the broken ore runs to drift below. For retreating stopes, chutes are rarely built, the ore being scraped from the floor up a portable scraper incline high enough for cars to run underneath. About 15% of the ore from upper faces is scraped down to level by same scraper used to fill cars. Mine cars are of 3.75-ton capac and are end-dump; gage, 4 ft. Haulage is by storage-battery loco. Duty of labor. In 1930, production by above method was 6.33 tons per man-shift charged to stoping; for all underground labor, 3.06 tons per man-shift.

40. EXAMPLES OF PRACTICE, OPEN OVERHAND STOPES

(Support by Pillars of Ore)

Edwards mine, St Lawrence County, N Y. Data from J. B. Knaebel (253) in 1932. Lenticular masses of zinc ore (pyrite and marmatite), aver about 17% Zn, occur as replacements in silicified dolomite. Lenses are 5–25 ft thick, 100–200 ft long on the strike, and may extend down dip to vert depth of 1 700 ft. Aver dip, 40°–45°, with local variations from 0 to 90°. Ore drills easily, but is tough and difficult to break. Both walls generally strong, but sometimes slab badly. Large horses of waste are infrequent; sorting in stopes has not been feasible. Development. Main shaft is vert; in hanging wall to 1 100 ft; thereafter in footwall. Level interval was at first 100 ft; now (1932), 200 ft. Lateral development is by drifts, crosscuts, and raises, irregularly spaced according to requirements of stoping and ventilation. Stoping. Formerly some shrinkage stoping was done, but with flattening of dip in depth, reworking of old stopes, and for flexibility, open stopes with pillars superseded old methods. Stoping is overhand or underhand, or a combination. Overhand stoping. Chute raises *R* (Fig 244) are driven up dip on footwall, 30–40 ft apart, to height of 15–30 ft above drift; raises are connected at top and then belled to funnel shape. Fig 244 shows methods of advancing faces and of placing holes. Thicker parts of deposit are mined in 2 parts: first an overhand stope at least 6 ft high is driven under the hanging wall; later the bottom is taken out in benches; this work resembles breast and bench stoping (Art 30). Drilling is chiefly by mounted wet jackhammers, occasionally with stopers for cutting around pillars on steep dips. Rounds in overhand stoping, as at *A* (Fig 244), are of 9 8-ft holes. Pillars are left in lean or barren material where possible, their size and spacing depending chiefly on extent to which hanging is fissured or seamed; usually spans of 40 ft or more will stand during life of stope. Pillars are oval in outline, not more than 25 ft long; long dimension parallel to dip. Vert holes take up the bottom. Handling broken ore. Where dips exceed 42°, ore runs to chutes with a little hand-shoveling. In stopes flatter than 42°, mechanical scrapers have lowered costs. Duty of labor. During 1930, output per man-shift of all underground labor and surface labor chargeable to underground operations was 5.06 tons.

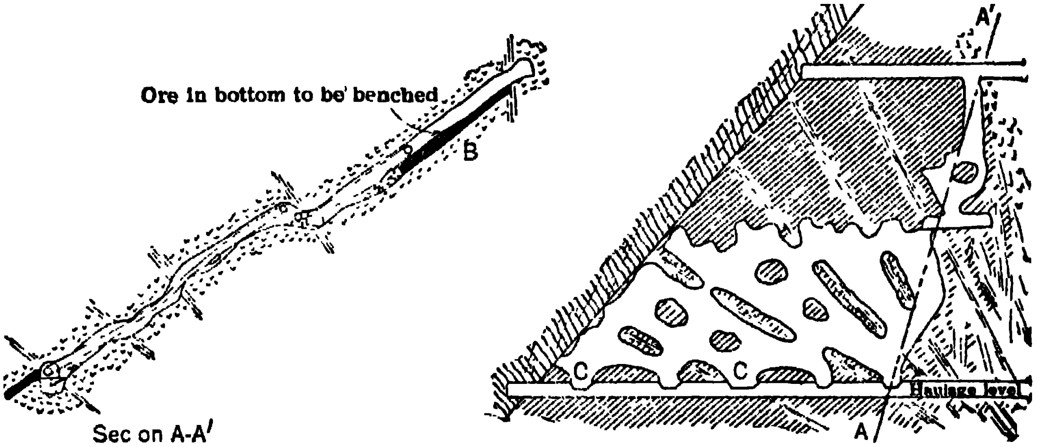


Vert Longit Sec

Cross Sec A-A

Fig 244. Breaking and Handling Ore in Open Stopes, Edwards Mine, St Lawrence Co, N Y (253)

Golden Messenger mine, York, Mont. Data from S. H. Lorain (69) in 1937. Gold-bearing veins are quartz and sulphide replacements along fractures in diorite; the gold associated chiefly with pyrite, sometimes galena and sphalerite. Values are generally uniform, with some enriched pockets. Usual width of workable lode, 4–10 ft. Dips vary from 30° to 60°; usually about 40°. Veins are cut by numerous post-mineral faults, mostly of small displacement. Ground drills and breaks easily. Hanging wall is blocky, requiring occasional support. DEVELOPMENT is by 2 tunnels (haulage levels), 150 ft apart vert, from which the orebodies are reached by raises and sublevels. Extraction drifts are driven in the veins. STOPING. Main output has come from overhand stoping; a novel underhand method has also been used (Art 35). For overhand stoping, chutes (*C*, Fig 245) are installed along the drift under the stope, 15–30 ft apart, depending on location of faults and dip of vein, closer spacing used on the flatter dips. Pillars are left over the drifts, between the chutes. Chutes at intervals of 60–75 ft are equipped with scraper hoists. Drilling in stopes is by jackhammers or stopers. Where vein is over 6 ft wide, a cut is first taken next to hanging wall, and ore in the bottom is mined later by bench *B*. Elongated pillars along fault lines divide stopes into segments, slightly offset above or below each other by faulting (Fig 245). These pillars are holed through only when necessary for scraping. Within the sections between faults, hanging wall is supported by ore pillars about 10 ft diam, and 15 ft apart. It is planned ultimately to recover much of these pillars.



Sec on A-A'

Sec in Plane of Vein

Fig 245. Overhand Stoping Method, Golden Messenger Mine, York, Mont (69)

Clinton iron-ore mines, Ala. T. C. DeSollar (177) describes mining of upper bench of the Big Seam in Woodward Iron Co's mines, Bessemer, Ala, in 1933. Entry is by slopes, following the ore. At No 3 mine (Fig 246) the " top " slope met a fault at 3 636 ft along the incline, requiring a second or " bottom " slope, the two being connected by a 2 300-ton storage pocket. " Top " slope has 20 by 10-ft cross-sec, and hoisting is done in balance with 2 10-ton self-dumping skips. Ore is handled on " bottom " slope in 2 25-ton wooden or 5-ton steel cars, hauled by elec hoist; a rotary car dump is installed above the storage pocket. Drifts from slopes are 9 ft wide, if broken ore is loaded by hand, or 12 ft wide, if mechanical (ramp and scraper) loading is employed; they are driven rapidly to property lines, and opening of rooms, starting 25 ft inside of line, retreats towards main slope. Room necks, 12 ft wide and 75 ft apart, are driven 25 ft up the dip, and an all-steel ramp, mainly of 16-ft lengths of 12-in, 25-lb channel-iron, is installed at each one (see Sec 27). A double-drum, 55-hp hoist, mounted on a self-propelling truck on track parallel with haulage track, and operating a 3 100-lb box-type scraper, serves 3–5 stopes on a level. Inside the neck, a room is widened to 30 ft and carried up to next level, usually

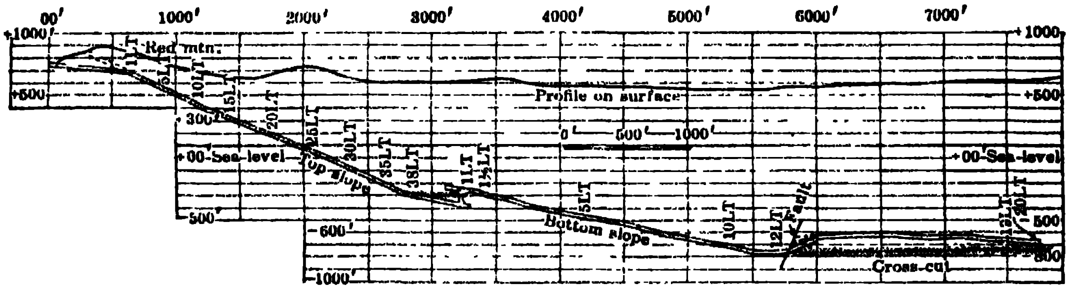


Fig 246. Sec through Slope of No 3 Mine, Woodward Iron Co, Bessemer, Ala

220 ft, occasionally 300 ft. A slab 10 ft wide is then taken from each side, making rooms 50 ft and pillars 25 ft wide. When a group of stopes is finished, a slab is taken from side of drift, from which track and pipes are removed. Recovery from first mining is about 65%; further recovery of 10% is expected from splitting of pillars. Ore drills and breaks easily. With drill on tripod, 2 men make 14–18 holes, finishing at 2-in diam and 8 ft deep, per shift; a blast breaks 100–125 tons. Two or 3 drills work at once in a stope, accumulating broken ore in 2 stopes while a third one is being scraped and 2 others started. This permits the hoist to work for several days from same position; scraper is not removed from stope until completed. Full stope crew includes 4–6 drill men, 1 hoist engr, 1 motorman, 3 muckers. Drill steel is 1.25-in hollow round, with star bits. Explosive, low-density ammonia dynamite in 5.75 by 1.5-in cartridges, received daily from manufacturer and immediately transferred to underground magazine; detonated with No 6 tetryl caps. Aver daily output (2 8-hr shifts) at this mine is 3 000–3 300 long tons.

Avg cover, 1500' Extraction, 40.3%

Avg cover, 1600' Extraction, 36.8%

Fig 247. Pillar Spacing, Muscoda, Ala

Tennessee Coal, Iron & R R Co mines the Big Seam at Muscoda, Ala, under conditions similar to those at the Woodward mine (above). As described by E. M. Ball and A. W. Beck (507) in 1937, the main slope had reached bottom of the basin at 6 260 ft from outcrop and under 1 600 ft of cover. From this slope or its branches, haulage levels 20 ft wide, 10.5 ft high, are turned at right angles at 230-ft intervals, and laid with standard-gage double track; grade not to exceed 8%. Each room, up the dip, is entered by 2 or 3 necks 20 ft long; in former case, room is 110 ft wide and yields 16 000 tons of ore (210 lb per cu ft solid) in its length of 190 ft; a 3-neck room is 160 ft wide and yields 24 000 tons. Small (20-ft) circular pillars are staggered over stope areas, usually 5 in a 110-ft stope; 8-in posts used as required. Width of pillar between adjoining rooms is adjusted to depth of cover, as shown in Fig 247. It is planned to extract pillars on retreat. Two drifters on tripods are used in each stope, making V-cuts and slabbing rounds; no secondary blasting required. Explosive is ammonia dynamite, equivalent to 45% gelatin. Ore is scraped from rooms and haulage headings by 50-hp, double-drum hoist, mounted on self-propelling truck on a parallel track, scraper discharging its 2-ton load over a steel ramp into 5-ton cars. Data on first 6 months of 1937: tons per man-shift in actual production, 16.5; per man-shift underground, 7.11; tons per lb explosive, 1.5; bd ft timber per ton, 0.873; kw-hr per ton for scraping, 1; for air compression, 4.65.

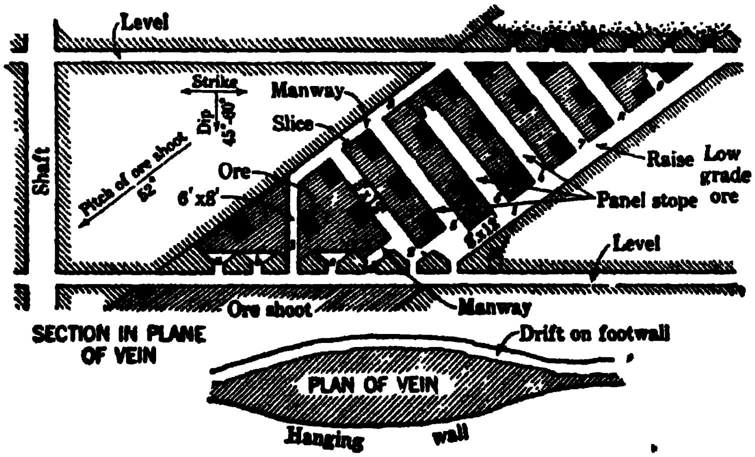

Fig 248. Panel System of the Herman Mine

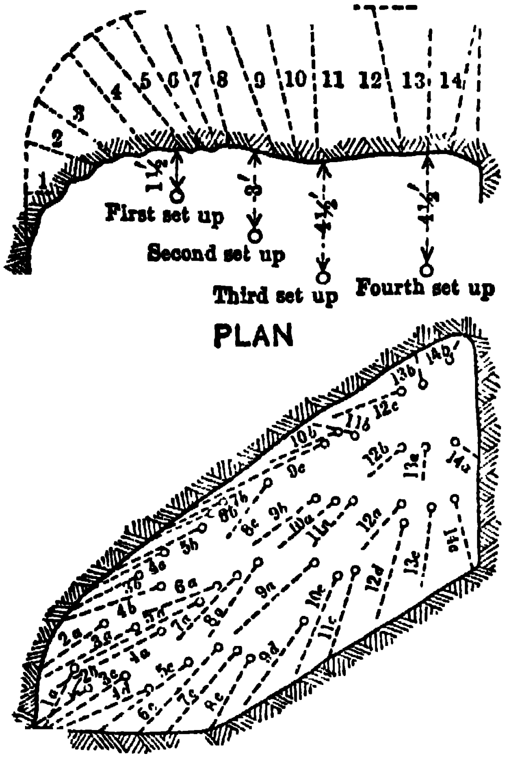
Herman mine, Placer Co, Calif. Quartz vein, 8–12 ft thick, dipping 45°–60°, occurs in schist. Country rock is blocky, with cross fractures; on the hanging wall is a layer of soft slate. Ore is in shoots, about 200 ft long, pitching about 52°. Level interval, 150 ft. Underhand square-setting was tried and abandoned, due to its danger and expense. Open stoping with pillar support (Fig 248) was used. Stope was opened by driving raises 1 along the bottom of oreshoot and on the footwall; also the manway 3 and the chute raises *a* to *d*. Panel stopes, 2 to 9, were then carried up. Chute *E* was cut when necessary. Pole bulkheads were constructed between pillars if required to divert ore. When the panel stopes were fully opened, the pillars on both sides were sliced and finally cut through, leaving small pillars shown in solid black. All these stope pillars were then drilled and blasted. Finally, the pillars under the level above were blasted, allowing caved material from the stope above to follow down until it rested on the pillars above the lower level. Data from S. H. Brockunier in 1919 (570).

41. EXAMPLES OF PRACTICE, MICH AMYGDALOID MINES

(Support by Pillars of Ore) (67, 153, 170, 486)

Michigan amygdaloid copper deposits, Keweenaw Peninsula, carry native copper in volcanic flows of vesicular basalt (amygdaloid), interbedded with flows of compact diabase, the whole series tilted on dips from 35° at the north to 73° at south end of Range. All beds tend to flatten slightly at depth, which has reached over 9 000 ft (on incline) in some workings. Profitable beds occur at 5 out of 17 recognized copper-bearing amygdaloidal horizons. Distribution of copper is irregular; average tenor of all ore, less than 1%. Hanging wall is diabase, usually strong, but often rough and irregular. Footwalls of some lodes may contain offshoot orebodies, and copper-bearing cross-fractures are fairly common throughout the Range.



PLAN

VERT SEC

Fig 249. Drift-stope

General plan of mining. Open overhand stopes are used for beds on dips of 35° to 45°, pillars being left for roof support. For mining steep-dipping beds with weaker walls, see Baltic mine, Art 63. For practice in the Calumet conglomerate, see Art 39.

Development. For modes of entry and development, see Art 15 to 17. Early level intervals of 100 ft or less (on dip) have now been enlarged to 160 ft in some mines; aver about 125 ft, though 150 ft is common. In irregular Osceola lode, 120 ft proved better than larger or smaller interval. Inclined-shaft pillars, formerly 50 ft wide, are now 200 ft on each side of shaft, to insure support at 5 000 ft vert depth. Crosscuts, when required, are 7 ft high, 8-12 ft wide.

Drifts. Strong hanging wall permits lateral development openings of large cross-sec without excessive cost for maintenance. Hence, the development drift and the cutting-out stope, when advancing through profitable ore, are often excavated together in openings called DRIFT-STOPES (Fig 249). In passing through barren or low-grade zones, width of drift may be reduced to 7–8 ft. Drifts maintain uniform haulage grade and are mostly in lode; hence, apt to be crooked.

Details. Size of drift-stope depends on behavior of hanging wall under existing press; at medium depths in Osceola and Kearsarge lodes it was about 9 by 19 ft; at Allouez, where hanging was shattered in many places, size was 9 by 18 ft; at Wolverine, where hanging was strong and lode wide, 11 by 25 ft; at North Kearsarge, 10 by 16 ft. At increasing depths, tendency is to reduce drift-stopes to 8 or 9 by 14 ft. Fig 249 shows an earlier typical stope, 9 by 19 ft, on OSCEOLA lode. The cut, towards hanging wall, where a well defined slip and also the most persistent copper usually appear in this lode, is drilled and blasted first. Complete round in recent 8 by 14-ft heading takes about 30 holes, loaded with 40% gelatin, to break 4.75 ft. Osceola lode drills easier than Kearsarge, but is harder to break. Two contract miners, working on opposite shifts with 108-lb column-mounted jackhammers, advance a round per day, mucking being done by others. In deeper levels of KEARSARGE, former practice of pointing cut towards hanging wall (where good parting occurred) has been abandoned, due to falls induced by breaking of roof rock. The cut in 9 by 14-ft stope-drift is now taken 5 ft into footwall (Fig 250), leaving lode matter across whole width of roof. Two contract miners on opposite shifts drill 35 holes to break 5.5–6 ft per day, using mainly semi-bulk powder with 2–3 sticks of 50% gelatin at bottom of each hole. Other men muck by hand. At AHMEEK mine, in Kearsarge lode, a 9 by 14-ft drift-stope is advanced 5 ft per day of 2 shifts (aver 100 ft per mo), drills and supplies being brought down between shifts, and hand mucking proceeding while 1 man drills with 154-lb, hand-fed, column-mounted drifter. A round requires 32 holes averaging 6.25 ft deep, each loaded with 2.1 lb of 66% low-density ammonia dynamite and 2 sticks of 40% gelatin at bottom. There is no standard round; holes left to judgment of miner.

Stoping (67). Stope widths between walls vary from 8 to 20 ft. General plans of work: (*a*) A stope of profitable width, usually 8 to 12 ft, is first opened along hanging wall; later, any ore occurring below the arbitrary footwall of first stope is broken in benches; this method is followed in Osceola workings of C & H Co, Fig 251 (486). (*b*) Stope follows footwall. Ore less than 12 ft thick is broken in one operation; where thicker, a stope 10 to 12 ft high is advanced a short distance on footwall, then ore on back is blasted down. Opinions differ as to better method: under plan (*b*) it is difficult to reach and trim the hanging wall in stopes 16 to 18 ft wide; under plan (*a*) the mining of footwall ore starts at top of stope, for breaking ore onto the fairly smooth floor of first stope; this leaves less ore to be shoveled out when stope is finished than when floor is mined up the dip.

Drilling and blasting. Presence of coarse copper reduces drilling speed and may cause abandonment of holes. Drills are mounted on columns, which in places must be 10–13 ft long. With 1-man machines it is usual to work 2 drills close together for mutual aid in setting-up. Contract drilling, with bonus, is the rule in amygdaloid stopes; in Osceola lode, bonus base is 50 ft of hole per drill-shift; in Kearsarge lode, 40 ft; holes are inspected and measured by shift-boss, and an improperly placed hole is not counted towards bonus. At Ahmeek mine, on Kearsarge lode, advancing a stope face 37 ft wide by 7 ft high, up a 38° slope, 30 7-ft holes in 3 horiz rows are drilled by 154-lb, column-mounted, hand-fed drifters, at 60 ft per drill-shift. The 2 vert rows at center make a V-cut. Explosive (66% low-density ammonia dynamite), 0.9 lb per ton broken; output, about 22 tons per drill-shift. In Osceola lode, aver output is 25 tons, with explosive of same grade.

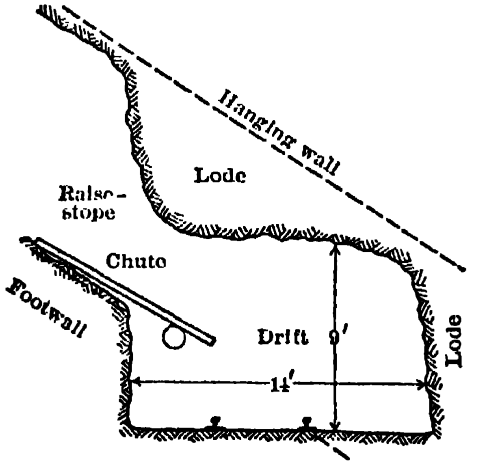


Fig 250. Section at Bottom of Stope, Kearsarge Lode

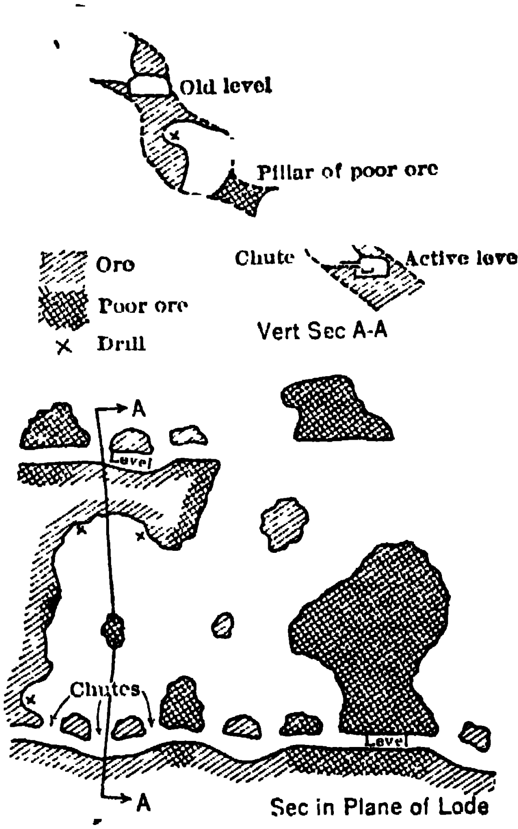

Fig 251. Open Stope, Osceola Lode

Pillars of ore support hanging wall in stopes; their size and spacing depend on same factors as in breast-stoping (Art 30). Wherever possible, areas of low-grade ore have been utilized for pillars, leading to irregularity. Recent practice on deeper levels aims at more systematic use of relatively small pillars for temporary support; roof ultimately allowed to cave. Aver spacing has been about 40 ft along strike, less along dip; interval ranges in different mines from 25–60 ft. Axis of pillars is at right-angles to dip. Pillars flare slightly at top and bottom, with upper sides shaped to shed broken ore falling from above; diam varies from 8–15 ft or more. Little timber is used in stopes; a stull or two may be put under a slab, or to hold up broken ore for supporting men and drills.

Handling ore in stopes. Dip of amygdaloid lodes is great enough (generally 38°–54°) for most of the ore to fall to level below; fine ore clings to footwall and irregularities in the latter make some shoveling or scraping necessary.

Formerly all ore slid from stope onto a plank platform (SOLLAR), alongside track in the level, and was shoveled thence into cars. Since chutes were not used, fine breaking in stopes was unnecessary; about 60% was over 4-in size; large pieces lifted into cars by hand; trammers used short D-handled shovels. Later practice generally adopts scrapers, discharging through hardwood plank chutes, which are dismounted and used repeatedly. Footwall at Quincy mine is so rough that practically all ore must be shoveled to drift (see Fig 254 and text). STOPE FLOORS ARE CLEANED before stope is abandoned, sometimes by scraper. At Mohawk mine, ore remaining on stope floors has been shoveled into semicircular steel chutes, 32-in radius, laid on the broken ore, and supported on wooden horses at the level for dumping into cars; they were moved along the stope floor as it was cleaned up; 4 shovelers and 2 trammers handled 42 tons per shift.

Stoping generally begins at a RAISE-STOPE, say 24 ft on strike by full width of lode, put up between levels as far as possible from the shaft.

Examples of stoping. WOLVERINE MINE is on an amygdaloid lode with strong hanging wall; dip, 41°; aver width, 14 ft; Fig 252 shows stoping method; level interval, 100 ft; levels were opened as drift-stopes. Gound was mined in blocks 75 ft long, running from level to level; 2 pillars *A*, say 15 ft diam, were left at top of drift-stope in each 75-ft block, with an 8 to 10-ft chain pillar along the back to support level above. A raise *R* was put through chain pillar in each stope for ventilation. MOHAWK MINE. Aver width of lode, 20 ft; aver dip, 38°; level interval, 100 ft. Stopes were 100 ft long, separated by pillars (locally, " dead ends "); chain pillars were also left, and a pillar about 13 ft diam above drift-stope in middle of each stope (Fig 253). A flat-back stope was carried, a cut being broken out of back for each slice. Ventilation was poor in upper parts of stope. NORTH KEARSARGE MINE. Aver width of lode, 18 ft; dip, 38°; level interval, 125 ft. Lode was stoped in blocks 20 ft along strike and half the level interval on dip, ore being broken in slices parallel to dip. Upper 62 ft was similarly mined; several lower stopes were usually finished before the upper were begun. Pillars were usually left in alternate stopes at top of drift-stope and at bottom of upper stope, but their spacing along strike depended on hanging wall. An 8 to 10-ft chain pillar was left, except where levels above were stoped out. ALLOUEZ MINE. Width of lode, 16 ft; dip, 38°; level interval, 125 ft. Lifts were mined in 3 series of stopes, each say 40 ft high, with pillars at bottom of each stope; poor hanging wall often required pillars as close as 25 ft along strike. HANCOCK MINE. Width of lode, 8–10 ft; dip, about 45°; level interval, 100 ft. Drifts, 6 by 7 ft, were enlarged by a cutting-out stope to 24 ft. Back of level was timbered with stulls 4–6 ft apart, lagged with 4–6-in poles. A 2 by 4-ft hole was left in lagging at 25-ft intervals, with a sollar under it about 4 ft above track. Some broken ore remained in stope to protect lagging and aid in setting up drills; the rest was drawn onto sollars, sorted and loaded. Ground was good, requiring no stope timber. Pillars were left where ore was poor, also a chain pillar, 6–10 ft thick. QUINCY MINE. A lode about 10 ft thick, dipping 38° to 54°, has been worked at great depth (9 150 ft on dip). Stopes at Quincy were at first 100 ft wide, alternating with pillars of same width. As depth increased, these dimensions had to be changed to 50-ft rooms and 50-ft pillars; this made workings safer, percentage of extraction greater, and tenor of copper rock stamped increased. Fig 254 (482) shows layout for use of light reversible hoe scraper.

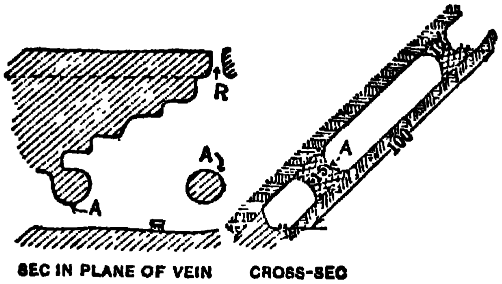

Fig 252. Stoping, Wolverine Mine

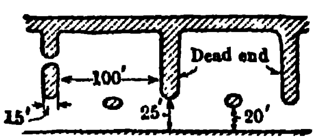

Fig 253. Stoping, Mohawk Mine (Sec in plane of lode)

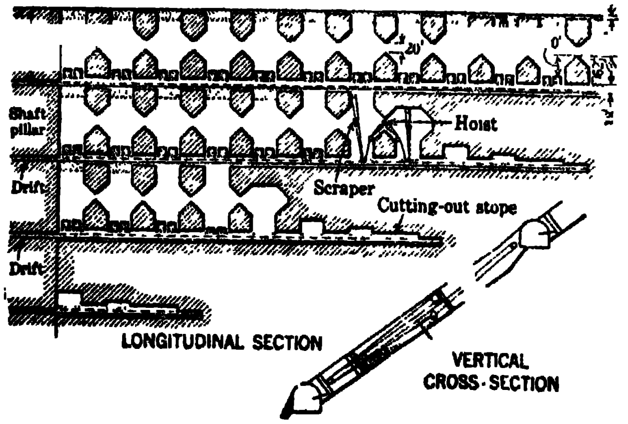

Fig 254. Stoping Method Quincy Mine, Showing Use of Light Scraper and Portable Hoist

Osceola lode is erratic as to shape and mineralisation of oreshoots (486); aver dip 37°; no systematic arrangement of pillars is feasible. Occasional rich pockets in footwall are discovered by minute examination of floor as stoping proceeds; if isolated by more than 4–5 ft of barren footwall, such pockets may be mined by special stopes from crosscuts; if within that distance, they are mined by underhand jackhammer work from main stope. Levels at 120-ft (slope) intervals are opened as drift-stopes (see above); in workable ore, chute raises, 9 ft wide by 5 ft high, are opened on 25-ft centers (Fig 251); latter equipped with nearly level chutes of hardwood plank and old rails, delivering about 4 ft above track. Scraper, when required, is 4 ft wide and operated by double-drum air or elec hoist with 0.5-in rope.

Retreating systems are attempted in most amygdaloid mines, especially as depth and pressure increase. Hence, drifts or drift-stopes must reach the boundary before stoping begins above them. This reduces cost of drift maintenance and avoids the following disadvantages of the advancing system: (*a*) blasting in stopes injures tracks on level; (*b*) mucking in stope and in drift or drift-stope interfere; (*c*) small pieces of ore rolling from stope onto rails often derail cars; (*d*) danger from slabs falling from stope into drift; (*e*) sometimes a stope caves, and ore from points beyond must then be run to level below; this is troublesome and costly, especially on flat dips.

Kearsarge lode has been mined for a strike distance of 6 miles within C & H ground, and to depths of 4 000–5 000 ft (on 38° dip). To 3 000 ft, usual method was open stopes with pillars of barren rock or poor ore. Later modifications adapted to heavier press, described by O. Potter in 1931 (486), include stoping on retreat and use of "rib pillars," latter to control roof settlement without attempting to prevent it. Levels at 150-ft (slope) intervals are advanced as 9 by 14-ft stope-drifts to boundary. Starting there, chute raises (*R*, Fig 255) 5 ft high and 21 ft c–c are driven about 10 ft up the footwall and enlarged at upper ends to full profitable width of lode, leaving a brow over the chute (Fig 250). From top of last raise on drift, a "cutting-over" drift (*D*, Fig 255) starts back towards the shaft, breaking into tops of successive raises and funneling them. When 4 such chutes have been completed, a stope 37 ft wide and full height of lode is started over chutes No 2, 3, leaving No 1, 4 open for ventilation. As the "cutting-over" drift advances, more 37-ft stopes are started, each centered over 2 chutes, leaving a 5-ft "rib pillar" between every 2 stopes; this pillar is holed through, at about 25-ft intervals, for access and ventilation (Fig 255). Width of pillar is varied according to experience; no timber is required except an occasional prop under a slab that can not be barred down. Four 1-man drills in 2 adjoining stopes can about keep pace with 1 drill in "cutting-over" drift, combined output of the 5 drills being 220–250 tons per 2-shift day. When a stope is finished and all ore withdrawn, pillars of better-grade ore are blasted down; under strong roof, a whole row can sometimes be recovered; those that remain are expected to crush so as to allow gradual subsidence; total recovery from stoping area, 95% of pay ore. About 85% of broken ore can be loaded (into 5- and 8-ton cars) by gravity, with a little help from trammers. For the rest, and always when extracting pillars or working under bad roof, 4-ft scrapers operated by 2-drum air hoists with 0.5-in rope are used. Storage-battery, 7-ton loco hauls 2 to 4 8-ton cars; 3-ton loco for 5-ton cars; max haul, 5 000 ft; usually not over 2 500 ft. Advantages of this system: (*a*) all holes are drilled upward and parallel to dip; hence more easily directed to avoid breaking either wall. (*b*) When roof falls in old stopes, caving stops at first solid line of pillars. (*c*) Small expense for timbering. Chief drawback is that all mining is substantially the advancement of a heading, with adverse effect on powder consumption and output per shift.

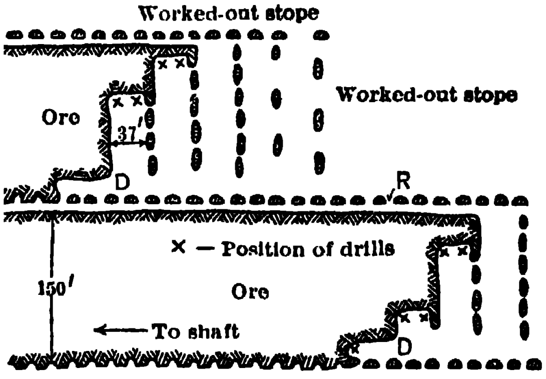

Fig 255. Open Overhand Stopes with Rib Pillars, Kearsarge Lode. (Projection on plane of lode dipping 38°)

42. PILLAR AND CHAMBER WORKINGS

The term denotes methods of mining in which large chambers are excavated, leaving pillars of ore for permanent support. Chambers may be mined as underhand stopes, glory holes, or overhand stopes. Support for men in overhand stopes is afforded by accumulation of broken ore (Shrinkage stopes, Art 67), or by square-sets (Art 45 *et seq*); chambers are rarely filled with waste to support men (see Rimogne quarry, below).

The method is a development of room and pillar work in beds (Art 32), for mining masses or wide veins. In typical cases, workings are a series of large open stopes, separated by a network of vertical and horiz pillars of ore. Synonymous terms are CHAMBER WORK-

INGS, PILLAR WORKINGS, ROOM AND PILLAR, PILLAR AND STALL, ROOMING (see index for other use of same terms; also Art 104–6).

Chamber workings are a very old form of mining, obsolete for metalliferous deposits, except in rare cases; they are useful for exploiting cheap and abundant minerals, as salt or slate, where much of the deposit (40% to 70%) can be sacrificed in pillars for securing cheap support and low mining cost. Recovery of pillars is generally costly, often impossible, and workings are left in such shape that a change to other methods is difficult.

Requirements of method: (*a*) large deposits, as masses, wide veins or thick beds; (*b*) deposits of strong mineral or rock, with strong walls, which will stand unsupported over back and on walls of chambers; (*c*) cheap minerals, which will not pay cost of installing other methods; (*d*) deposits of uniform value, as no sorting is done in chambers.

Examples of practice which follow, while old, well illustrate principles, variations and applications of the method.

Tilly Foster mine, N Y. Orebody was a steep, lenticular mass of strong magnetite, embedded in gneiss; in horiz sec, it was about 200 ft wide by 300 ft long; dip, about 60°. Fig 256 shows method of mining part of the deposit. An inclined shaft was sunk in footwall, with wide drifts at 100-ft intervals along footwall to ends of orebody. From drifts, rooms 24 ft wide, with 20-ft pillars, were carried across to the hanging wall. They were excavated overhand as shrinkage stopes (Art 67). A timbered crosscut in middle of each room connected with footwall drift for access and transport. Rooms were raised to within 15 or 20 ft of level above, leaving a floor of that thickness extending over whole area of orebody. When a room was finished, all broken ore was drawn, and the room abandoned. More than half of the orebody was left in pillars. Attempts to fill old rooms with concrete and to mine pillars under this support failed; many pillars were eventually recovered by open-cut (200, 201).

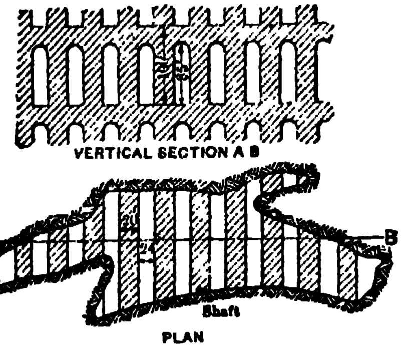

Fig 256. Tilly Foster Mine

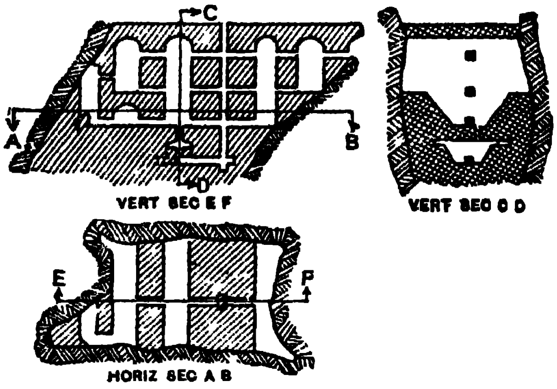

Fig 257. Republic Iron Mine

Republic mine, Marquette Range, Mich. Fig 257 shows former method for mining wide portions of a hard hematite deposit, having in places a horiz sec exceeding 150 by 400 ft (202). A vert shaft was sunk in the deposit, with a 70-ft pillar to protect it; drifts were driven at intervals of 30 to 50 ft and connected by winzes about 60 ft apart; from winzes, chambers 30 ft wide were opened from wall to wall, leaving 30-ft pillars. Top of chamber was a breast stope, with arched back, ore being mined underhand, starting at top of a winze. At places, the glory-hole method (Art 37) was used. Where a level-pillar was left, the heading method (Art 36) was employed (Fig 257, vert sec *CD*), the chambers being 50 to 150 ft high. At other places, 2 series of 30-ft rooms were driven at right-angles to each other, leaving 30-ft square pillars. About half of orebody was left in pillars; some of this ore has since been recovered after filling old stopes with waste. For hard ore, shrinkage stopes are now used, with subsequent filling (Art 68).

Rio Tinto mine, Spain. Orebodies are lenses of pyrite, with enough chalcopyrite to carry an aver of about 3% Cu. Length of deposits, 1 200–6 500 ft; width, generally proportional to length, max 250 ft; depth, 500–1 800 ft. Deposits usually occur along contacts between porphyries and clay slates, or along other lines of weakness in either rock. Nearly all have at some period been exploited by pillar and chamber (locally, pillar and stall). J. Allan gives following details (203). Lode was divided into horiz slices, alternate slices being worked by series of galleries at right-angles to each other; between every 2 networks of galleries was left a solid floor of ore of varying thickness, depending on strength of ground. Ordinarily, galleries were 13 by 13 ft; 16.5 by 20-ft and 20 by 20-ft sections were also tried, but proved unsafe in weaker parts of deposit; smaller openings were preferable, which could be made larger on entering good ground and smaller in weak ground. Face of galleries was attacked by a small top heading, leaving a bench about 8 ft high (compare Heading method, Art 36). Fig 258, from Foster (10), shows work in one deposit; entry was by vert shaft in footwall, with levels 41 ft apart, connected by vert raises. Alternate levels were used as main haulageways. Drifts and crosscuts, 10 to 11.5 ft square, were driven at right-angles on each level, at 33-ft centers, with pillars 21 to 23 ft square, the pillars being superposed in successive lifts. Chambers were then made by heightening and widening spaces between pillars. In firm ore, pillars were about 10 ft square and chambers 30 to 33 ft high; under aver conditions, pillars were 15 to 20 ft square, chambers 20 to 25 ft high. Vert sec (Fig 258) would be the same, whether taken parallel or at right-angles to strike; it shows successive stages of work in different levels. At many mines in the district, only 33% of the total ore was won by this method; in case shown, extraction averaged 50%; in firm ore, it might reach 73%. Chamber workings were adopted because they offered a cheap and ready method of obtaining large tonnages; ore was so plentiful that recovery of pillars was neglected. Many mines have stripped the overburden and mined old pillars by open-cut. Orebodies once worked in this manner have been reworked by a modified crosscut method (Art 64). Virgin ground at Rio Tinto is now worked by filled, flat-back stopes (Art 60) (549).

Underground slate quarries are typical of correct use of chamber workings. Following examples illustrate methods; further detail in Bib (10, 169, 204, 205).

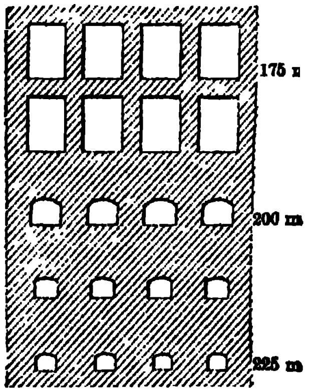

Fig 258. Rio Tinto Copper Mine, Spain. (Vert sec)

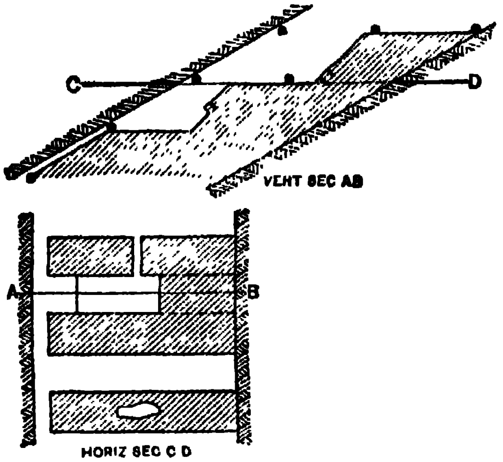

Fig 259. Underground Slate Quarry, Wales

Festiniog District, N Wales. Slate beds, 30-120 ft thick, dipping 20° to 35°, are opened by inclined shafts or by adits; levels are about 50 ft apart. Transverse chambers are opened 30 to 50 ft wide along strike (Fig 259), with pillars of about same size. With hand drilling, sides of pillars follow planes of weakness at right-angles to cleavage; these are askew to dip and deviate a little from perpendicular. Where channelers are used, pillars are vert and normal to dip. A chamber is started by a 4 by 4 or 4 by 6-ft raise along hanging wall at center or corner of proposed chamber; the raise is then widened to full width of chamber, widening and raising usually proceeding simultaneously. Floor of widened raise is carried back toward hanging wall by cutting off slices parallel to cleavage. A bottom cut is first made across width of chamber by a bar channeler drilling close-set 2-in holes; ribs between holes are broken with a chisel bit. Other cuts are made higher up and also along chamber walls, and blocks blasted down with small charges. Chambers and pillars on successive levels are under and connect with each other. Vert distance between floor of chamber and hanging wall may reach 120 ft. Main drifts are destroyed by work in the lift below, communication being maintained by run-around drifts in hanging, or by bridges; intermediate drifts are also run. Slate from development is all lost, and about half of the total is left in pillars. Further loss in splitting reduces net yield to about 13% of the deposit. L. Mayer states that in 1908 the Oakley quarry, with 1 500 men, produced 6 000 tons of slate per mo (169). One chamber may provide work for a small crew for 10 or 15 years. Elsewhere in the district, conditions allow chambers to be 100-150 ft and pillars 24-50 ft wide. No means have been devised for mining pillars. Men work under high unsupported roofs, but, though pillars often collapse, fatal accidents are rare. Backs are examined and trimmed from ladders erected in 30-ft sections, and held by guy ropes; 3-6 men take 1 week to build up a 100-ft ladder. In 1922 a hand-held hammer drill and a hydraulic rotating drill were being introduced (550).

Rimogne quarry, French Ardennes. Principal slate bed dips 22° to 45°; thickness, 0-200 ft. Long chambers (30-50 ft wide) are excavated along the strike, instead of across it, as at Festiniog. They reach from foot to hanging, with pillars about 13 ft wide along dip, sides of pillars being normal to dip. Chambers are mined as overhand filled stopes (Art 60); much of the waste is used as filling (205).

Anjou, France. Slate beds 130-500 ft thick stand almost vert. Outcrops are generally covered by a considerable thickness of worthless slate. They were formerly worked in large isolated chambers, each with its own entry from surface. A vert shaft was sunk to good slate, and an arched room excavated over top of proposed chamber by breast stoping. Floor was mined underhand in 10–13-ft benches. Slate blocks were handled in a stone skip attached to a trolley on a cable brought down the shaft and fastened to an eye-bolt in floor of chamber. Horiz sec of chamber was a circle or a rectangle, with maximum area of 21 500 to 27 000 sq ft; some chambers were 360 ft deep. Similar methods have been used for mining rock salt at Marmoras, Hungary (205).

Avery Island salt mine, La. Deposit is a dome-shaped mass, in places over 2 000 ft thick, overlain by 16–25 ft of soil, and has been worked on 2 levels at 90 and 160 ft depth. A. G. Wolf (551) describes methods in 1921. Deposit is opened by a 500-ft shaft. Parallel 7 by 7-ft drifts, put in on 120-ft centers, are widened by breast stoping till they form rooms 60 ft wide, leaving 60-ft pillars. Pillars are broken through in both directions, so that a series of regularly spaced pillars 60 ft square is left. Rooms and breakthroughs are then mined overhand by men working on ladders or on broken salt. Rooms are carried to a height of 60 ft at center. Drilling is done with air-driven augers, sometimes making 100 ft of hole per hr. All shoveling done by hand on contract.

43. SUB-LEVEL STOPING

This method, also known as sub-stoping, was developed in Michigan iron mines about 1902. It is an open-stope method and distinct from sub-level caving (Art 75, 76).

Applicability. Sub-level stoping is a relatively low-cost method, in terms of cost per ton of ore extracted. It does not permit very effective sorting, and is therefore applied where values are fairly uniform and sorting is not essential. Ore should be strong enough to stand well after trimming, and permit benches to stand under their own weight. Method may not be advantageous in very hard ore, due to high cost of driving sub-levels. Walls must be firm, or they will cave prematurely and dilute ore. Method is best adapted to steep dips, but has been successful on flat dips at Roan Antelope mine (see below).

Michigan practice. Following data and drawings are from F. W. Sperr, P. B. McDonald, and F. C. Roberts (208). TYPE OF DEPOSIT mined by sub-level stoping in Mich includes "pockets" and narrow ends of large lenses; in general, steep-dipping, tabular deposits, 12 to 100 ft wide. Ore should be free from slips, and strong enough for backs to stand after trimming and benches to stand under their own weight (very hard ore increases cost of driving sub-levels and is a disadvantage). Walls must be firm, or they will cave and mix with ore, and overlying capping should be strong, so as to permit stoping of large panels or blocks.

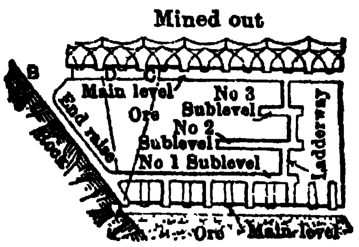

Fig 260

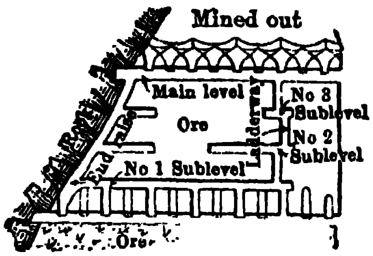

Fig 261

Shafts or other DEVELOPMENT entries should be outside of the orebody, as mining eventually causes walls to cave. Level interval, 100 to 150 ft vert, each level having a main haulage-drift from which crosscuts are run to the walls to outline the deposit. Chute-raises are put up from drift and crosscuts to about 25 ft above level floor. Drift and crosscuts are planned so that centers of raises are 15 to 30 ft apart; in 25 to 40-ft orebodies, raises alternate on opposite sides of haulage drift; some wider bodies have 2 parallel haulage drifts, connected at intervals by crosscuts, to facilitate motor haulage. At end of deposit (or at end of panel to be stoped) a raise is put through to level above. Fig 260 shows procedure when end of orebody slopes forward. The triangular block *ABC* is broken by underhand stoping and handled to the level through the end raise; and ladderway and sub-levels 1, 2, and 3 are driven. If end of deposit slopes backward or is vert, sub-levels are started from end raise as well as from ladderways (Fig 261). Lowest sub-level (No 1) is at tops of chute-raises; vert interval between sub-levels, 20 to 25 ft; they are closer in soft than in hard ore. STOPING. A sub-level usually consists of a single drift in middle of the deposit. Where ore is less than 40 ft wide, sub-level No 1 (Fig 261) is first widened to the deposit walls, a breast stope about 12 ft wide and of same height as sub-level is then carried across end of deposit, and worked back toward ladderway. Down holes are drilled around tops of chute-raises, and uppers in back of breast stope, the former being blasted first, to give a funnel shape to tops of raises (Fig 262). One round of back holes breaks a block 8 or 10 ft high across width of deposit and about 12 ft along strike, broken ore falling into finished raises and to chute gates in main level. After this work has proceeded 20 or 30 ft toward ladderway, sub-level No 2 is similarly opened Holes are drilled in floor and back of breast stope and fired together, breaking off the bench of ore over sub-level No 1, and an 8 or 10-ft slice off back over No 2, broken ore falling into the open stope below. This procedure is repeated on each sub-level. Fig 262 shows appearance of work after stope is well opened; faces of sub-stopes retreat uniformly, being kept 20 to 30 ft apart. Each main level in turn forms the top sub-level of the series. When the ladderway is reached, a new ladderway and set of sub-levels will have been opened to the rear. Thus, men on each sub-level work under solid ore, and far enough back from open stope to be safe from falling slabs. Fig 263, 264 show application to orebodies 50 to 100 ft wide. A stope about $^1/_3$ the width of the ore is first carried back through middle of deposit, leaving a pillar on each side. After central stope has advanced 60 to 100 ft, crosscuts *K* and drifts *M* (Fig 263) are driven on each sub-level; drifts *M* are extended and form benches along face of pillars (Fig 264) and benches *B* (Fig 263) are carried across ends of pillars to walls. Pillars are then mined by holes drilled from benches *B*, as in the central stope; each bench is kept a safe distance in advance of the one above. A vert sec through *DJ* or *D''J''* (Fig 263) would be like Fig 262; vert sec through *D'J'* would show the central stope worked back to a vert face.

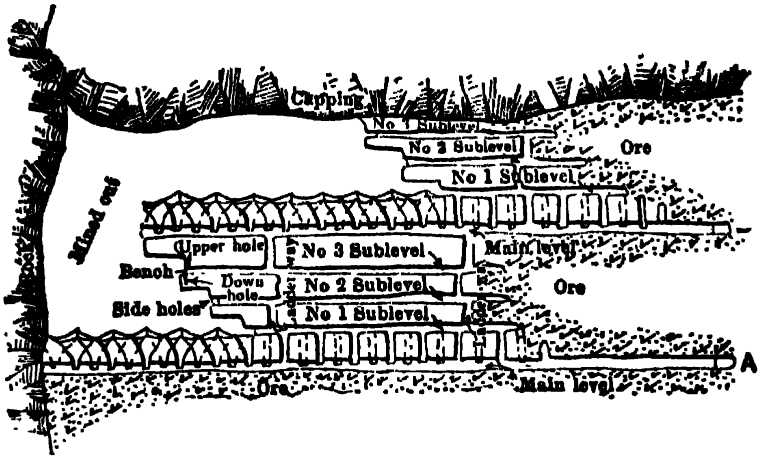

Fig 262

In long orebodies, stopes in Mich are about 250 ft long, separated by pillars containing ladderways. Length of stope is adjusted to prevent premature caving of walls; horiz pillars can also be left underneath main levels. Ore in pillars may be mined later by tip-slicing (Art 70), or by sub-level caving (Art 75, 76), if stopes are first filled. Filling for stopes between 2 levels may be drawn down and reused in lift below, allowing walls above to cave. Bib (545) gives examples of sub-level stoping, but no costs. Advantages of method are its safety and small timber consumption in suitable orebodies. Due to numerous points of attack, large tonnage can be broken in a small stope, most of it being immediately available for loading (132). Small charges break large tonnages from benches and backs (breaking in breast stopes is more costly); aver powder consumption moderate. Chief disadvantage is large amount of narrow work in preliminary development, cost of which increases with hardness of ore. This cost is obviously greatest in narrow orebodies. Large pieces may require blockholing in chutes.

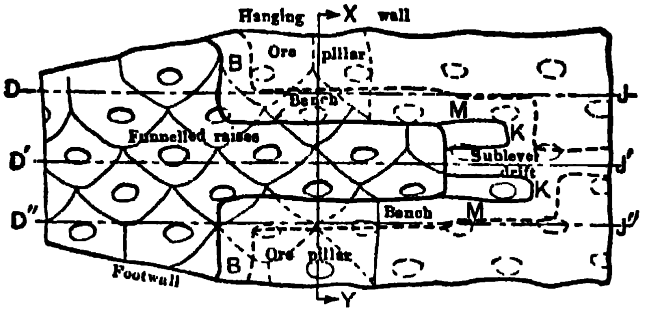

Fig 263. Plan of Sub-level Stope in Wide Orebody*

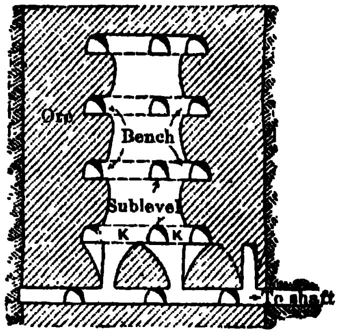

Fig 264. Vert Sec (Fig 263)

Roan Antelope mine, Luanshya, Nor Rhodesia. Data from material generously furnished in 1938 by W. J. MacKenzie, Mine Supt, through courtesy of Frank Ayer, Gen Mgr. Fig 266, 267, 268, and 269 were prepared by Mr. Bert Cole of the Co's staff. Sub-level stoping, introduced by R. M. Peterson, has proved highly satisfactory.

Geological features. Disseminated copper sulphides occur throughout a 10 to 45-ft band of well bedded argillaceous sandstone and shale; aver, 3.44% Cu. The mineralized beds forming the orebody are in an asymmetrical plunging syncline; hence the outcrop is hair-pin shaped; dips vary from flat to 90°. Plan of early underground workings, Fig 265 (501), indicates general shape of orebody. Hanging wall shades into lean and barren shales, quartzites, sandstones, and dolomites. A band of calcareous biotite schist on footwall, about 3 ft thick, sometimes has high copper content. Below the schists are feldspathic quartzites and conglomerates, or, in some parts, shales.

Development is by several inclined shafts in ore and a main vert shaft starting 180 ft back of footwall of one limb of orebody (Fig 265). In the steeper portions of orebody, haulage drifts above 420-level were at 100-ft vert intervals; below, 200 ft apart. In the flat section at the "nose" of orebody, intermediate haulageways were driven in footwall on the 220-, 280-, and 350-levels, ore from which dropped through ore passes to the 420-level. In steeper parts of orebody above the 820-level, haulage drifts were in ore along footwall. Below 820-level, haulageways will be driven in footwall rock as permanent openings for ventilation and service for stoping.

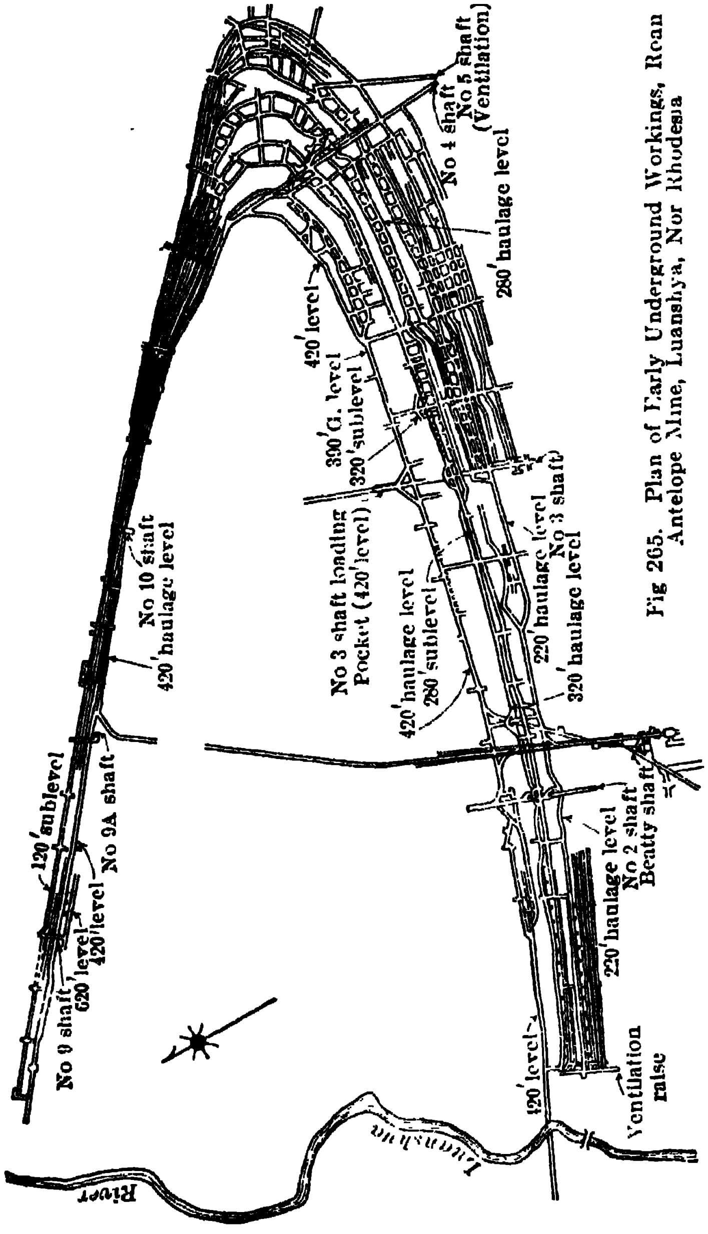

Fig 265. Plan of Early Underground Workings, Roan Antelope Mine, Luanshya, Nor Rhodesia

Stoping. There are 3 modes of procedure, depending on the dip. Fig 266 applies to "FLAT ORE," or to dips of 12°-30°. Haulage drifts *K*, 9 by 12-ft section, are driven in footwall, usually at 75-ft vert intervals. For each stope, an inclined chute raise *R* (min dip 55°) is driven from haulage drift to orebody. A grizzly is placed over the raise at the elev of the economic footwall. Grizzlies are 10 by 7.5 ft, with 16-in openings, and made of 6-in I beams covered with mild-steel wearing plates. A sub-level drift *A* gives access to grizzly. From the grizzly chamber, an 8 by 6-ft raise *B* is driven along footwall to the grizzly level of completed stope above. At 10 ft up the dip from the grizzly, a raise *C*, normal to dip, is driven to locate the economic hanging wall. Raise *D* is then driven along hanging-wall side of the ore, directly over the footwall raise. Two sets of sub-level drifts are driven 50 ft apart; one set, *E*, 2 ft below the hanging wall; the other, *F*, 4 ft above the footwall. Stoping up the dip is done in "sections," each extending from one pair of sub-drifts (hanging-wall drift and footwall drift beneath it) to the next above. Starting at raise *C*, the first operation is the cutting of a "slice" *G* (Sec *BB*) between the foot- and hanging-wall raises, advancing up the dip to the first pair of sub-drifts. This is done by drilling uppers in the back of footwall raise and down holes in the floor of hanging-wall raise. Cutting the slice is followed by "trailing." A hanging-wall "trail," *H*, is a slot, 6–10 ft wide and 6–8 ft high, cut out at top of stope face and extending up the dip. Similarly, a footwall trail, *I*, is cut. When a section of stope has been "sliced" and "trailed," the resulting bench is drilled and blasted. Broken ore is scraped to the grizzly with a 48-in hoe-type scraper, operated by a 30-hp elec, double-drum hoist. "Trailing" and breaking of benches proceeds laterally to stope widths averaging 40–50 ft. These operations, always preceded by "slicing," continue up the dip to the level above. If the stope above has caved, the lateral pillar or sill *S* is left; otherwise the sill is mined. Rib pillars separating the stopes strikewise are 10–15 ft thick. For stoping, drills are 3-in stopers and 2 $^5/_8$-in jackhammers. Production rate of such a stope is 250–300 tons per day with 8-hr mining shift and approx 16 hr of scraping.

Fig 266. Sub-level Stoping on Flat Dips, Roan Antelope Mine, Nor Rhodesia

Fig 267 shows method used in "semi-steep" ore, on dips of 30°–45°. Haulage drifts, 9 by 12 ft, are driven in footwall at vert intervals up to 150 ft. Sub-level drifts are along both foot and hanging wall, 25 ft apart vertically. A stoping "block" comprises 4–6 stopes, 40–60 ft wide (strikewise), the stopes being separated by rib pillars 12–15 ft thick. Chute raises, *A*, are driven from a haulage drift to the ore, on center lines of the rib pillars, so that each may serve 2 stopes. A few feet below the economic footwall, a

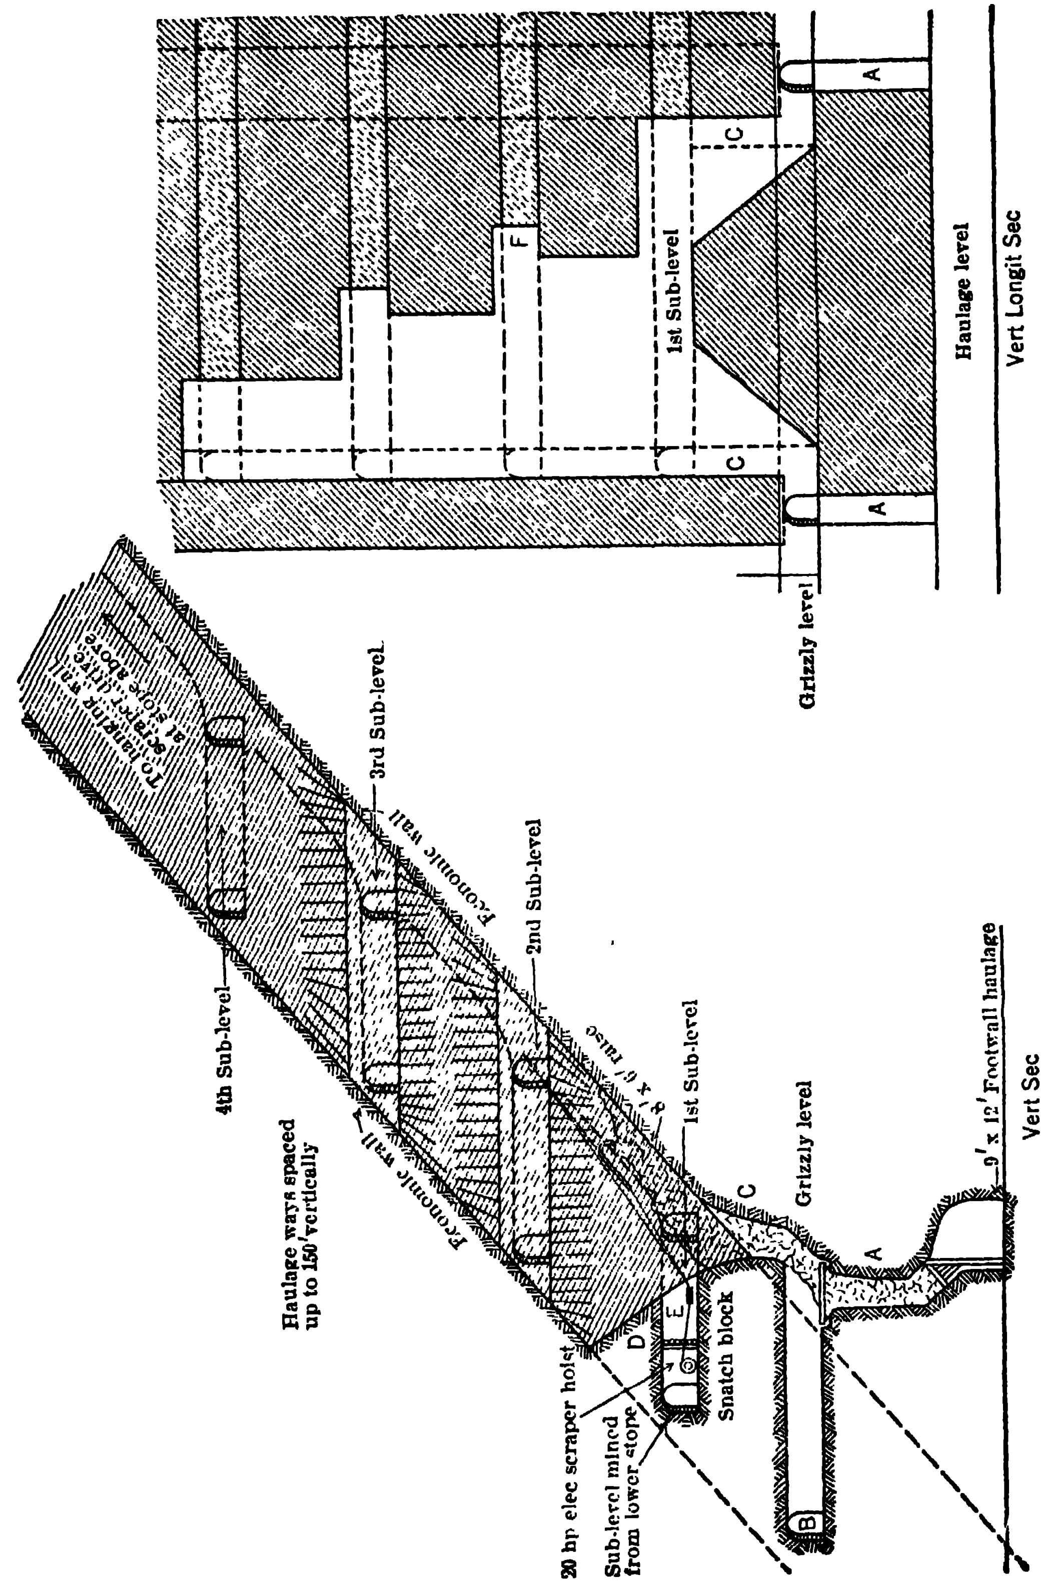

Fig 267. Sub-level Stoping on Semi-steep Dips, Roan Antelope Mine, Nor Rhodesia

grizzly is placed over each chute raise; height of grizzly above haulage level, about 30 ft. A sub-level drift *B*, at the same elev, with crosscuts to the grizzlies, serves as a travelway. A short drift runs from each grizzly to edge of the stope, from which point a raise *C* is driven along the pillar line to a footwall sub-drift (1st sub-level), about 50 ft above the haulage level. From there an 8 by 6-ft "mining" raise is driven on footwall and along the pillar line to the grizzly level of the completed stope above the next higher main level. When this raise reaches the 2nd sub-level, raises *C* are belled out and the back of the mining raise mined out to the point where a protective brow *D* is left over that portion of crosscut *E* which houses a scraper hoist. When the mining raise reaches the third sub-level, an opening on the second, 12 ft wide and 7 ft high, is cut from foot to hanging wall, connecting with the hanging-wall drift. The back and floor of this opening are drilled and blasted, breaking out the slice between first and second sub-levels. As the mining raise advances, successive slices along the pillar line and between sub-levels are similarly removed. On completing a slice below a given sub-level, a horiz "trail" *F*, or notch, is cut from foot to hanging wall, connecting the open ends of the sub-drifts at this elev. Benches thus formed are drilled and blasted into the open stope below. Movement of broken ore to "mill hole" *C* is aided by a scraper and 20-hp elec hoist; an "aerial rig" (Fig 268) permits easy movement of the headblock to any desired point across width of stope. Production from this type of stope is 300-400 tons per day, with 8 hr mining and 16 hr scraping.

Fig 269 and 269*a* show method in "STEEP ORE," on dips of 45°-90°. A haulage drift is driven in footwall. As it advances, chute raises *A* are driven 110 ft apart, to cut the orebody just below the grizzly level, 55 ft above haulage level. Chute raises are branched strikewise to give a c-c spacing between grizzlies of 55 ft. From each grizzly, a crosscut *B* is driven to connect with a hanging-wall sub-drift *C*, which serves as a travelway between grizzlies. Haulage- and grizzly-level development are carried on concurrently, so that the grizzly level may serve as a return air course in driving the haulage drift. From each grizzly, drifts are driven about 10 ft in both directions along footwall and from their ends, raises *D* are driven to first sub-level, 25 ft above grizzly level. These raises are later funnelled both strikewise and toward the hanging wall, and are known as "mill holes." Sub-level drifts are centrally located in the orebody, at 30 to 35-ft vert intervals. Standard length of stope is 70 ft. Rib pillars between stopes vary in width from 10 to 20 ft, depending on strength of ground. Height of stopes is 420-660 ft vert, or as much as 750 ft along the dip. "Block pillars" *E* are often required to support the 70-ft span of hanging wall between main rib pillars. Position of block pillars is determined by inspection and records of previous stopes in the block.

A stoping " block " is 800-1 000 ft in length along the strike, forming 8 or 12 stoping panels respectively. The block is developed by a central service raise *F*, 8 by 6 ft, and a muck raise, spaced either 86 ft or 45 ft apart. With the former spacing, the muck raise *G* is later used for opening the last stope of the block; with the latter spacing, about 40% of length of raise serves for establishing the "block pillars" within this stope. The service raise is advanced by a "bulkhead pent-house" (transfer chute) system, whereby muck from raise is hand-trammed on the sub-levels into the muck raise, which is driven ahead of the service raise. Ladders, comp-air line, water line, tugger hoist, track, and ventilation line are kept within 50 ft of the service-raise face. As each sub-level elev is reached, crosscuts, driven off the service and muck raises, are connected by a sub-level drift. As each sub-level is established, the drift is driven to the extremities of the block. When the first level above the grizzly level reaches the block extremity, the first mining raise *H* is started from the grizzly excavation and driven, on the economic footwall, up the side of the main rib pillar. This raise is extended as each sub-level drift above reaches the pillar. When the raise reaches the second sub-level, the stope floor is cut on first level and the raises from the grizzly properly belled. As cutting of floor and belling of mill holes is completed, stoper holes in the back of the first level are blasted. When this work has retreated 25 ft from the mining raise, floor cutting is begun on the second level, the first opening being 10 ft along the strike and from foot to hanging wall. Holes in the back and floor are drilled and blasted, making a slot between first and second levels. This operation is repeated on each upper level, but only after the level below has retreated at least 10 ft. It may be necessary to make 2 cuts in the slot with down holes, in which case the blasting of up holes on a level lags behind blasting the down holes. When the slot has been cut, regular benching begins. This consists of cutting a trail 8–10 ft wide from foot to hanging wall, drilling the back and floor, and blasting the bench into the stope.

Fig 269. Sub-level Stoping on Steep Dips, Roan Antelope Mine, Nor Rhodesia

In some parts of the mine the hanging wall will not stand up for completion of stopes 600–700 ft high. A RELAY SYSTEM is therefore used, whereby an intermediate grizzly level *I* is opened approx midway up the panel. The regular mining raise is driven from the lower grizzly level (so located with respect to the footwall and rib pillar as to allow for wear by scouring) to the intermediate grizzly level. If the nature of ore permits, this raise is enlarged from 6 by 8-ft size to an opening 30 ft along the strike by the distance from foot to hanging wall. This opening is carried up to the sub-level immediately below the intermediate grizzly level; from there a 6 by 6-ft raise *J* is driven to the grizzly level. Branch raise *K* is also driven from this level to hole into the grizzly level about 50 ft from the mining raise. Grizzlies are placed on these openings and mill-hole raises are driven to the sub-level above the grizzly. Normal stoping follows. Ore from upper part of stope passes through the grizzly into the enlarged mining raise below, lower part of which provides good "ore-pass" storage. When the upper half of stope is completed, the intermediate grizzlies are removed and the mill holes bulkheaded. The lower half is then completed and if little sloughing of waste rock has occurred above, the sill at the intermediate grizzly level is blasted out and recovered. Production in these stopes is 6 000–20 000 tons per mo, depending on width of ore, which is 9–35 ft. Break per machine-shift is 50–130 tons.

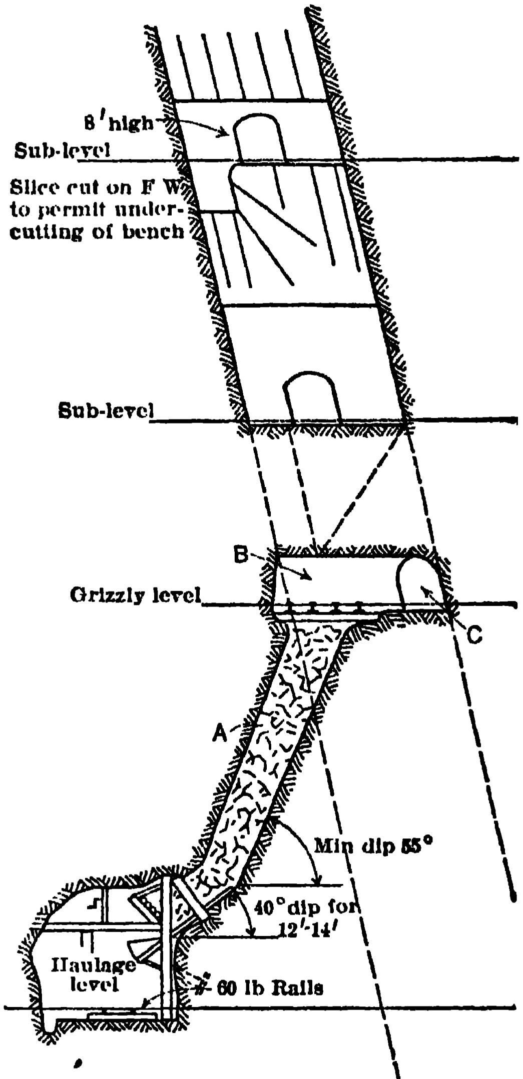

Fig 269a. Typical Sec through Chute Raise A—A of Fig 269

R. M. Peterson in 1932 (501) cites following factors favoring use of sub-level stoping at Roan Antelope: (1) a working place can always be barred and made safe, and sub-level exit is always at hand; (2) working and drilling conditions in stopes are always the same; native labor does best in repetition tasks; (3) pillar spacing can be varied as conditions demand; (4) stoping can be shut down or opened up to full capac at short notice, without affecting ore grade or causing wastage of reserves.
